The treatment of the different affections or morbid conditions with which intestinal hemorrhage is usually connected need not be here repeated. It will suffice to refer to measures having reference to the hemorrhage. These are essentially the same as in cases of gastric hemorrhage. Rest in the recumbent position and quietude of mind are important. The peristaltic movements are to be quieted by opium. Cold applications to the abdomen should be made if the arrest of the hemorrhage be urgently indicated. The most effective mode of applying cold is by means of the ice-bag. In cases in which this indication is less urgent, dry cupping, sinapisms, and warm stimulating pediluvia will suffice without the application of cold. Food and drinks should be taken cold. The diet should be restricted and bland. Purgatives are contra-indicated. The mineral acids are generally thought to be useful in cases of intestinal, as well as in gastric, hemorrhage. The sulphuric acid lemonade has the advantage of being a grateful beverage. The various hemostatic remedies given in cases of gastrorrhagia, namely, tannic acid, gallic acid, acetate of lead, ergot, the astringent preparations of iron, etc., are to be resorted to in proportion to the importance of arresting the hemorrhage.

CHAPTER VII.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINE—(CONTINUED.)

Constipation. Intestinal Colic. Enteralgia. Lead Colic.

CONTINUING to consider the functional affections of the alimentary canal, this chapter will be devoted to constipation, intestinal colic, enteralgia, and the so-called colic from lead-poisoning.

Constipation.

The terms *constipation* and *costiveness* are commonly used as synonyms, denoting insufficiency of evacuations from the bowels. The latter of the two terms is sometimes used to denote a less degree of insufficiency than the former, the number of dejections being normal, but the quantity deficient, and the act of defecation labored. The term *obstipation* has been already defined to denote a greater amount of difficulty than constipation, that is, obstruction of the bowels, either as a functional disorder or dependent on the various lesions which have been considered in a preceding chapter. Constipation exists as a functional disorder, and it is incidental to various affections. As a functional disorder it is extremely frequent, and, although not a serious affection, it claims attention on account of the inconvenience which it occa-

sions, its importance as leading to other ailments, and the difficulty often of its removel.

The affection is seated in the large intestine. The anatomical arrangements of this portion of the alimentary canal show it to be intended to serve as a temporary depot for fecal matter, thus providing against the need of frequent acts of defecation. The contents of the alimentary canal are propelled more slowly in the large than in the small intestine, *first*, because the circumference of the former is larger in proportion to its muscular power; *second*, in the ascending part of the colon and of the sigmoid flexure, the contents are propelled in opposition to gravitation; and, *third*, the liquid portion of the contents is absorbed in their passage through the small intestine. Experience shows that one free evacuation from the bowels daily is the rule in health. But this rule is not without exceptions. Some persons have, habitually, two or three evacuations daily, and, on the other hand, some have an evacuation regularly every second or third day, without any of the inconveniences of constipation; in fact, persons of the latter habit are apt to experience discomfort if, temporarily, evacuations take place daily. In determining, then, the existence of this affection, the habit in health is, of course, to be taken into account. In some cases the act of defecation is delayed for one, two, or three days after the period when it should have taken place, but the evacuation, when it occurs, is ample. In other cases the act occurs daily, but it is incomplete, and in these cases the act is usually labored and painful, the feces being dry, compact and hard. The affection may be occasional and transient, or it may be habitual.

Constipation gives rise to various local morbid effects, such as a feeling of pressure or weight in the perinæum, a sense of abdominal distension or uneasiness, flatulency, diarrhœa, and colic pains. Hæmorrhoids are often attributable to this affection. It gives rise, also, to pain in the head, dulness of the mind, flushing of the face, palpitation, and general malaise. If the act of defecation require violent straining efforts, these occasion, sometimes, hemorrhage into the brain, if the cerebral arteries be diseased, and hernial protrusions. The contractility of the muscular tunic of the large intestine may be permanently impaired by long-continued distension, so that the affection is necessarily permanent.

Occasional constipation is not generally considered of sufficient importance to require medical advice; persons resort, of their own accord, to a purgative or an enema. It is when the affection has become habitual or chronic, that cases come under the cognizance of the physician. And, in order to understand the pathological character of the effection in these cases, and its causation, certain points pertaining to the function of defecation in health are to be borne in mind. In its normal condition, the rectum is empty, as shown by the researches of O'Beirne.[1] This portion of the large intestine is endowed with a peculiar sensibility which, in health, gives notice of the presence of feces, and occasions the desire to defecate. The ability to perform the act involves a certain contractile power in the large intestine, and also in the abdominal and other muscles which co-operate in the performance of the act. In habitual constipation the contractile power of the intestine is impaired by distension. The muscular tunic is more or less paralyzed from the accumulation of the intestinal contents, in the same way as the bladder becomes paralyzed from over-distension. The accumulation giving rise to the distension may be owing to the large quantity of excrement, but it is generally a result of habitual neglect of the calls of nature. The desire to defecate is resisted, or, the mind being pre-occupied, the call is unheeded, and the act

[1] New Views of Defecation, etc. By James O'Beirne. Am. ed., 1834.

is postponed, until, at length, the sensibility no longer gives notice of fecal accumulation; hence, the accumulation goes on, the rectum and other portions of the large intestine become distended, and paresis follows. This is the manner in which constipation, as a chronic affection, is produced in a large majority of cases. The hurried performance of the act of defecation, the evacuation being, in consequence, incomplete, has measurably the same result as the neglect of the calls of nature. Instead of receiving adequate attention as important to health, it is considered an annoyance to be escaped from as quickly as possible. The uncomfortable provisions for defecation, especially in the country, contribute to constipation by rendering it disagreeable to devote to the act more time than seems absolutely necessary.

Various circumstances may contribute to this affection. The abdominal muscles play an important part in the act of defecation. These muscles become weakened by obesity, and, in females, as a result of pregnancy. The muscular tunic of the intestine, and the auxiliary voluntary muscles concerned in defecation, lose more or less of their contractile power, in common with the whole muscular system, in anæmia and other enfeebling conditions. Deficiency of bile and of the intestinal secretions may enter into the causation in some cases, but probably the importance of this source of constipation has been over-estimated; constipation is not always present when no bile enters the alimentary canal in certain cases of jaundice. The ingestion of purely nutritious food, leaving but little excrementitious residue, contributes to constipation. Sedentary habits are supposed to favor the affection, but it is probable that other causes are generally more operative, and especially inattention to the calls of nature. On the other hand, active exercise induces constipation by rendering assimilation more active, the liquid contents of the small intestine being more entirely absorbed. Loss of fluids by abundant perspiration or by diuresis is another cause. The change of habits, with, generally, an increased assimilation, incident to a sea-voyage, as is well known, induces, in most cases, constipation.

Occasional constipation, if slight, is relieved by a laxative pill repeated, if necessary, or by a small quantity of Epsom or Rochelle salts dissolved in a tumbler of simple or carbonated water, and taken upon an empty stomach. The Congress or the Kissengen water, and the stronger bitter waters, namely, the Friedrichshall, Pullna, or Hunyadi-Janos, in small doses, may be taken in lieu of the salts just named. A preferable method, which will generally suffice, is to excite the action of the large intestine by a simple enema of cold water. By means of Davidson's syringe, the patient can resort to this measure without any difficulty. If the constipation be more than slight, a few grains of blue mass or a purgative pill may be taken at bedtime, and followed, if necessary, by a saline draught or an enema in the morning. Persons are apt to have recourse, without consulting physicians, to purgatives, under an impression that they are always harmless and generally useful aside from the relief of constipation. Hence, it is common to take active purgatives for slight constipation, and, often, when nothing is required. If the constipation give rise to little or no inconvenience, it is better to wait for spontaneous relief, and a little delay will often show that medicinal interference was unnecessary.

The management of habitual constipation often requires much care and perseverance on the part of the physician and patient. The object is to secure regularity and sufficiency in the evacuations. The means which may be employed are various. They may be arranged into dietetical, medicinal, and mechanical. The dietetical means consist in using freely articles which leave, after digestion, a bulky residuum, namely, cabbage, lettuce, and the various vegetables known in this country as greens; or articles having a laxative

property, such as molasses, prunes, figs, etc.; or articles with indigestible constituents which stimulate or irritate the alimentary canal, namely, bran bread, corn meal, groats, or cracked wheat. A diet consisting, in part, of the foregoing articles, will sometimes succeed in obviating habitual constipation. But, with regard to the choice of this class of means, the following practical rule is to be adopted; they are not to be preferred if they disorder digestion or occasion more disturbance than medicines. More harm sometimes results from overloading the digestive organs with articles of diet difficult of digestion, or subjecting the canal to the irritation of unbolted flour, than the continuance of constipation would occasion. A tumbler of simple water, or of carbonated water, taken in the morning before breakfast, is not unfrequently efficacious; if not, a teaspoonful of table salt added will often render it sufficient.

The medicinal means are laxative remedies. With regard to these, a general rule is, the remedy chosen should be mild, and the quantity as small as will suffice for the object. Purgation is to be avoided. Some patients fall into the custom of allowing the constipation to continue for several days, and then resorting to a free purgative. The constipation is, of course, relieved for the time, but the constipated habit becomes more and more fixed by this course. Another general rule may be stated: If more than one *small* dose of laxative be required, the remedy is to be given in small doses repeated twice or thrice daily, rather than given in a single dose. In this way the object is effected with a less amount of medicinal impression, and there is less risk of purgation.

As regards the particular remedy, aloes is especially suited to the desired object. It may generally with advantage be combined in a pill with a tonic, either the sulphate of quinia or a preparation of iron, and a small quantity of hyoscyamus or belladonna may be added. A very small proportion of aloes, a small fraction of a grain in each pill, will often suffice. The old preparation known as the elixir proprietatis (tincture of aloes and myrrh) is well suited to the object, a drachm given at bedtime, and repeated, if necessary, once or twice during the day. This preparation loses with age its disagreeable bitterness, and is not generally repulsive given with a little water and an abundance of sugar. The extract of nux vomica combined with belladonna or hyoscyamus sometimes answers well. A small piece of rhubarb taken repeatedly during the day, effects sometimes the object satisfactorily, and this remedy to many persons is not disagreeable. I have known a few drops of the tincture of colchicum, repeated shortly after each meal, to answer admirably. The syrup of buckthorn is a good remedy. There are various modes of rendering the daily use of a laxative remedy not unpleasant to the taste. Prunes stewed in an infusion of senna answer well, and are not unpalatable. The confection of senna and medicated figs are also suited to persons who take a pill or potion with repugnance. Trousseau claimed for his favorite medicine, belladonna, that it acts as an efficient laxative in cases of habitual constipation. It has failed to have this action in my experience, and I have frequently made trial of it. Here, as in other instances, experience in individual cases is to be the guide. In the majority of cases in which medicinal means are relied upon, some form of the so-called dinner-pills, or, as they have been aptly termed, "peristaltic persuaders," will be found most convenient and satisfactory; and, for the fastidious, they may be silvered or sugar-coated. The white mustard-seed was formerly a popular remedy much in vogue, but this is objectionable on account of a liability to accumulate and become impacted within the intestine. Laxative remedies are not to be continued for a longer period than is required to secure an habitual action of the bowels. A minute

dose of strychnia or nux vomica, added to a laxative, renders the operation of the latter more successful.

The mechanical means consist in the use of enemas and suppositories. The regular use of an enema of cold water, at the same hour daily, is a simple, and sometimes an effective measure. This measure, however, is better suited to occasional than to habitual constipation. Habitually resorted to, it is apt to fail after a time; the rectum becoming accustomed, as it were, to the stimulus of distension, it ceases to excite the peristaltic movements. In some cases a suppository of soap answers the purpose of provoking a regular and sufficient evacuation. The cocoa-nut butter may be used for this purpose. Common molasses candy answers equally well, an oval mass of the size of a pigeon's egg being introduced within the rectum. This, however, is only a temporary expedient, ceasing usually to be effective after a time.

The most important part of the management in cases of habitual constipation is not embraced in the foregoing measures. It is the adoption of a rule to solicit an evacuation at the same hour daily. The importance of this rule is to be enjoined, but, of course, its success will depend on the perseverance of the patient. The time of the day most convenient for the act of defecation is to be selected, and, in general, the most favorable time is in the morning after breakfast. At the time fixed upon, the patient should devote a reasonable period to the function of defecation, but without persisting in violent fruitless efforts. This should be considered in the light of a duty, not to be omitted a single day except from necessity. It may be long before the desired object is accomplished, but, sooner or later, with the aid of some of the means which have been indicated, the desire will be felt at the appointed hour, and the ability to defecate at that time will be acquired in the great majority of cases. It is impossible to secure regularity and sufficiency of the evacuations without perseverance in this part of the management. The management also includes a rule not less important, namely, never to neglect or postpone the call to defecate, when it occurs either after or before the time for the habitual performance of the act of defecation. The importance of waiting for a certain period after the contents of the rectum have been expelled is to be enjoined. Often the expulsion of the contents of the rectum is immediately followed by the passage from the colon into the rectum of fecal matter which, remaining, blunts the sensibility of the bowel and renders it accustomed to distension. The objects in the management are to be understood and kept in view, namely, 1st, To preserve or restore the normal animal sensibility of the rectum, by which the presence of fecal matter is felt; and, 2d, To prevent paresis from distension, and to restore the muscular power which has been lost from this cause.

If this plan were early inculcated and carried out in health, habitual constipation would be as rare as it is now frequent. The prevention is not less sure than simple. This fact should be generally understood, more especially in the training of girls, most of whom become affected with habitual constipation, and suffer from it all their lives. Unfortunately the existence of the function of defecation is too often ignored from notions of false delicacy, and the affection becomes established because parents and teachers are either themselves ignorant of this simple method of prevention, or consider the subject as belonging exclusively to the physician.

Cases in which the intervals between fecal evacuations are many weeks and even many months, the accumulation of intestinal contents being tolerated, with more or less inconvenience, during these long periods, are among the curiosities of medical experience. Of the cases in medical literature, the one in which the longest interval occurred, with a single exception, was communicated for the *Am. Journ. of Med. Sciences* in 1874, and the autopsy in

1876, by Dr. Thomas D. Strong, of Westfield, N. Y. In this case eight months and sixteen days elapsed without an evacuation from the bowels.[1]

Intestinal Colic.

The term colic, in its etymology, relates to the colon, but it is often applied to paroxysmal, spasmodic pain in other parts. Thus, the phrase hepatic colic is used to denote the pain caused by the passage of gall-stones, and renal colic the pain caused by the passage of renal calculi along the ureter. A painful affection of the uterus is sometimes called uterine colic. In the present nomenclature of diseases, there is no suffix or prefix which, joined to the name of a part, expresses a painful spasmodic affection of that part. The affection of the alimentary canal known as colic may not be seated exclusively in the colon. It is probable that the small, as well as the large, intestine is affected in certain cases of intestinal colic. As applied to the intestine, colic denotes pain occurring in paroxysms or in marked exacerbations, the pain of a character supposed to indicate spasm, that is, twisting, constricting, or griping. Colic pains are symptomatic of different inflammatory affections, namely, dysentery, enteritis, peritonitis, and of the various lesions which give rise to intestinal obstruction. They enter, also, into the functional affection called sporadic cholera or cholera morbus. As constituting an individual malady, colic, of course, is independent of inflammation or structural lesions, and is disconnected from any other functional affection.

An attack of colic is characterized by paroxysms or exacerbations of pain, varying much in its severity in different cases. The pain is usually seated in the region of the umbilicus. It is frequently extremely severe; the patient bends the body forward with the thighs flexed, writhes, and tries a variety of positions, groaning or crying aloud from the intensity of suffering. This severe pain continues for a few moments, and then either ceases completely or abates, to return again with the same severity after an interval usually of brief duration. If left to continue without measures for relief, an attack may embrace a few paroxysms only, or it may last for several hours. An attack lasting for a short time, and ending in one or more free evacuations from the bowels, is so common as to be familiar to every one.

The abdomen, in attacks of colic, is frequently retracted, but, in some cases, it is more or less tympanitic. Generally, there is absence of tenderness, and firm pressure with the hands, or lying upon the belly, affords relief; but in some cases there is more or less soreness and tenderness on pressure, especially over the site of the cæcum. During the paroxysms of pain, the abdominal muscles are sometimes spasmodically affected, especially the rectus muscle, the sections of which are felt as hard bunches. Usually there is constipation. Nausea is sometimes present and occasionally vomiting. The pulse is but little, or not at all, accelerated, and absence of fever is shown by the thermometer. The skin is cool, and, during the severity of pain, frequently bathed in perspiration.

In a case presenting the characters just described, it is important to determine, as soon as practicable, the existence simply of a functional affection, that is, to differentiate colic from affections in which pains like those of colic occur. The diagnosis is to be made by excluding these affections. Dysentery and enteritis are to be excluded by the absence of diarrhœa and of symptoms denoting inflammation. The pain, in these two affections, is rarely as violent as in most cases of colic; but in cases of acute peritonitis the exacerbations of pain may equal in violence those of a severe attack of colic, and the error of confounding these two affections has been committed in not a few instances.

[1] For synopsis of this case, *vide* Clinical Medicine, 1879, p. 374.

The exclusion of peritonitis is to be based on the absence of notable tenderness over the abdomen, of increase of temperature, of frequency of the pulse, and of other general symptoms denoting a much graver affection than colic. Invagination, internal hernia, and other obstructive lesions with strangulation, cannot always be at once excluded. As a rule, the paroxysmal pain occurring in connection with these lesions at the outset, and, indeed, all along, is less violent than in colic, and, after a time, the existence of something more than colic is shown by persisting pain, tenderness, vomiting of so-called stercoraceous matter, sometimes tenesmus, frequency of the pulse, prostration, etc. The absence of these symptoms warrants the exclusion of obstructive lesions. The possibility that some obstructive lesion may exist is not to be lost sight of in cases which at first have the appearance of simple colic. The possibility of inguinal or femoral hernia is also to be borne in mind, and a careful examination with reference to this point is not to be omitted. The resemblance of labor-pains to those of colic is to be recollected. Pregnancy is sometimes concealed, and it has happened that the physician, supposing his patient to be suffering from colic, has been taken by surprise at the cry of a newly born infant under the bedclothes.

The several varieties of colic which writers have generally recognized do not require separate consideration. Some of these varieties rest on an insufficient basis. The colic has been called crapulous when it proceeds from indigestion. Every one is familiar with the attacks which are apt to follow over-indulgence at the table, ending frequently in crapulous diarrhœa. A colic is called flatulent when accompanied with tympanites, or the expulsion of gas with relief. This variety occurs especially in infancy. The term bilious colic has been used when the affection is supposed to depend on hepatic derangement. This dependence is merely conjectural, and there is no more reason for continuing to append the word bilious to this affection, than to various others in which the co-existence of disorder of the liver is equally hypothetical. Colic has been called stercoraceous when attributable to the retention of feces; but the latter is perhaps oftener an effect than a cause of colic. In another variety called verminous, the colic is supposed to depend on the presence of worms, but it may fairly be doubted whether colic ever proceeds from this source. The variety called saturnine or lead colic is properly a distinct affection, and will be considered as such.

The morbid condition in colic is supposed to be spasm. Its seat is, therefore, the muscular tunic of the intestine. That this is the pathological character of the affection is rendered probable by the kind of pain, the constipation, together with the local symptoms, and the therapeutical measures which are found to be successful. It is not improbable, as supposed by Abercrombie, that, in certain cases, the spasm may be preceded by paralysis of a section of the intestinal tube, and consequent obstruction to the passage of its contents. Like other spasmodic affections, it may be produced by causes which act either directly upon the part affected, or indirectly through its nervous communications.

Attacks of colic are frequently, if not generally, attributable to the local action of the ingesta. They may arise from indigestion caused by either excess in quantity or the indigestible quality of food. They not infrequently follow exposure to cold or fatiguing exertions, but these causes probably act by occasioning indigestion. Certain articles of diet, for example, shell-fish, in some persons, give rise to attacks of colic in consequence of an idiosyncrasy which is inexplicable. The muscular tunic of the intestine is especially susceptible to spasm in infancy, and colic occurs much oftener in early than in middle and advanced life. A susceptibility to intestinal spasm belongs to some persons, constituting a predisposition to this affection. In the practice of every physician there are those who are subject to attacks of colic more

or less frequently. This predisposition may continue for a certain number of years and then disappear. Persons with this predisposition often have an uncomfortable sensation of weight, coldness, or numbness in the abdomen, with general languor and irritability, preceding the development of colic, and by means of these premonitions they are able to predict an impending attack.

Although attended with great, and, if not efficiently treated, often protracted, suffering, colic is not a dangerous affection. It may be doubted if, alone, it ever prove fatal. It is one of those violent functional affections from which recovery takes place rapidly. It has no tendency to eventuate in inflammation or any other disease, but, in proportion to its duration, it is followed by fatigue or weakness, and more or less abdominal soreness may remain for some time.

The object of treatment is the relief of spasm as indicated by the cessation of pain. Measures are to be directed to this object without reference to the cause of attack or the existence of constipation. If, as is generally the case, an attack have been induced by the presence of irritating ingesta, measures directed to the spasm should take precedence of evacuants; and if, as is frequently the case, the bowels were constipated at the time of the attack, the removal of this condition is a secondary object. So long as pain continues, there is a resistance to the action of cathartics, and to defer measures for the relief of the pain until the bowels have been evacuated, is to prolong needlessly the sufferings of the patient.

In mild attacks, warmth to the abdomen and extremities, a little spirit not largely diluted with hot water, some aromatic stimulant, such as anise, ginger, cloves, mint, etc., or a few drops of chloroform, will suffice to procure relief. Twenty drops of chloroform, repeated, if necessary, at short intervals, will sometimes afford prompt relief in severe cases. If not, opium in some form is to be given to the extent of procuring freedom from pain. Administration *per enema* is to be preferred. A drachm of laudanum with the same quantity of the tincture of assafœtida, in a small quantity of mucilage or starch, may be injected, with injunctions to the patient to resist the desire to expel it, and, usually, in a short time, this desire passes off. If complete relief do not follow in the space of an hour, the enema may be repeated. If the suffering be extremely intense, double this quantity of laudanum, in the case of an adult, may be given in the first or second enema, or a solution of a salt of morphia may be injected hypodermically. If necessary, the enema or the hypodermic injection may be repeated a second or third time. A similar plan is to be pursued as regards the doses and repetitions, if the opiate be given by the mouth. If hypodermic injections be given, caution is to be exercised in their repetition. Fatal narcotism has been induced by want of caution in this regard. Hot fomentations or dry heat should be applied to the abdomen. Speedy success may be counted upon by pursuing this plan of treatment.

The subsequent treatment is to be determined by circumstances relating to the abdomen. If no inconvenience be felt, measures to effect a movement of the bowels need not be employed for twenty-four or even forty-eight hours. Not infrequently, if the physician be not in haste to give a cathartic, a sufficient evacuation occurs spontaneously. If measures to effect a movement be required, a large simple enema may suffice; if not, a mild saline purgative may be given in divided doses, or castor oil, if this remedy be not offensive to the patient. The diet for a day or two should be simple and restricted.

The certainty with which colic yields to an efficient opiate treatment, renders it one of the affections which exemplify very palpably the resources of medicine. Some patients, however, suffer considerably from the after-effects of the opium given, and this in a measure compromises the mutual satisfac-

tion of the physician and patient in the success of the treatment. Persons who are unfortunately affected unpleasantly by most forms of opium, are sometimes able to take certain preparations with less inconvenience than others. The experience of the patient on this point should be consulted.

Enteralgia.

The term enteralgia denotes a neuralgic affection referable to the intestine. It has, to the latter, the same relation as gastralgia to the stomach. Gastralgia and enteralgia may be associated (gastro-enteralgia). Enteralgia and colic are not infrequently confounded, nor is it always easy to distinguish, clinically, the one from the other. Enteralgia is characterized by pain within the abdomen, with intermissions or remissions, the pain having more or less intensity, but lacking the twisting or griping character of the pain in colic. It may be so severe as to lead to contortions and oral expressions of suffering. In females, enteralgia is an element of attacks of tympanites due to the secretion of gas, and is apt to be associated with hysterical phenomena.

The diagnosis involves the exclusion of the various affections from which colic is to be discriminated, and the exclusion of the latter affection. The so-called rheumatism of the abdominal walls (myalgia) is also to be excluded. Lumbo-abdominal neuralgia is to be discriminated by the existence of tenderness in front at the umbilical or hypogastric region, and also at the points in the lumbar and lateral portions of the body, whereas, in enteralgia, tenderness on pressure is generally wanting. Moreover, this affection, as well as myalgia, is generally unilateral.

The treatment involves the same principles as the treatment of gastralgia and other neuralgic affections.

Lead Colic. Enteralgia from Lead.

The affection now commonly known as saturnine or lead colic has been described by writers, at different times and places, under a variety of names. Painter's colic, plumber's colic, colic of Poitou, colica pictonum, Devonshire colic, colic of Madrid, rachialgia, dry bellyache, and other names which might be added, all relate to the same affection, which is one of the varied forms under which lead-poisoning is manifested. The affection differs from ordinary colic as regards not only its causation and clinical history, but its pathological character; it is not a spasmodic, but a neuralgic affection, that is, a variety of enteralgia.

It is developed usually in a gradual manner, and is preceded by prodromic phenomena which are the general effects of lead-poisoning, namely, pallor due to anæmia, and frequently an icterode hue of the skin, a peculiar fetor of the breath and a metallic taste in the mouth, loss of appetite, constipation, pain in the limbs, more or less emaciation, and muscular debility. Pain in the abdomen, at first comparatively slight, progressively increases, becoming at length the chief ailment. The pain is oftenest referred to the region of the umbilicus, sometimes, however, to the epigastrium or hypogastrium, and it may be limited to other situations, or it may extend over the whole abdomen, but it is usually confined within a small space. The pain frequently shoots into the back, the genital organs, and in other directions. It is sometimes dull or aching, and, at other times, acute and lancinating. It varies, in different cases, within wide limits, as regards intensity. In a mild form it merely occasions annoyance, like the pain in certain cases of gastralgia, but in a severe form the suffering is extreme, causing the patient to assume a variety of unnatural and fantastic positions, and to utter loud groans or cries, as in severe cases of gastralgia and ordinary colic. The abdomen may be more or less meteorized or tympanitic, but it is oftener depressed and resisting

to pressure. The resistance to pressure is caused by tonic contraction of the abdominal muscles, and this, in some cases, is a marked feature of the affection. Pressure on the abdomen, if made gradually and over a considerable space, is generally well borne, and often affords relief; patients are apt to lie upon the belly, with a folded pillow, or some other substance, and sometimes the closed hand, placed under them over the seat of pain. Pressure, however, with the ends of the fingers or percussion of the abdomen may not be well borne. The bowels are constipated, the exceptions to this rule being infrequent, and the dejections frequently consist of small hard lumps, or scybala. More or less nausea occurs in a majority of cases, and not infrequently vomiting. Hiccough and eructations of gas are not uncommon. The appetite is lost. The urine is scanty and micturition is sometimes difficult and painful. Circumscribed projections or tumors, changing their situation, and due, evidently, to an accumulation of gas in a portion of the intestinal tube, have been observed. The pain may be exclusively in paroxysms, the patient, in the intermissions, being entirely free from it, but much oftener more or less constant pain is experienced, with exacerbations. The paroxysms or exacerbations vary much in different cases in duration, as well as severity. They may last for a few moments only, or continue for several hours. The intermissions or remissions also vary in duration from a few moments to hours and even days.

In conjunction with the foregoing local symptoms, there is no fever unless there is some accidental complication. The pulse is abnormally slow, and frequently irregular. It is generally fuller and harder than in health.[1] The skin is cool. The mind is anxious and depressed. The strength fails in proportion to the severity of the pain and the duration of the affection. The affection may be complicated with other manifestations of lead-poisoning, namely, paralysis affecting certain of the voluntary muscles, and especially the extensors of the forearm, amaurosis, neuralgia in different situations, occasionally epileptiform convulsions, delirium, and coma. The latter have been embraced by Tanquerel and other writers under the name lead encephalopathy.

The affection has no definite duration, in this respect resembling neuralgic affections in general. When left to itself, it may end in a few days, or after the lapse of weeks, and, if the patient continue to be exposed to the cause, it may persist for an indefinite period. In itself, it involves little or no danger to life, nor is there ground to believe that it leads to any serious abdominal disease. But other effects of lead-poisoning, which may complicate or follow this affection, especially the effects embraced under the name lead encephalopathy, are liable to end fatally. The affection frequently pursues an irregular course, varying in severity much at different periods; and relapses, after all the symptoms have ceased for days or weeks, without any fresh introduction of lead, are not uncommon.

The introduction of lead into the system in sufficient quantity to give rise to its morbid effects, may take place through the lungs, the stomach, the mucous membrane in other parts, and the skin. Certain occupations involve the inhalation of lead. Persons employed in the manufacture of lead-paints are most exposed, and, of those who suffer from lead-poisoning, the largest proportion are of this occupation. Next to this class, painters are most exposed. More or less exposure, by inhalation, belongs to a great number of occupations, such as paper-staining, grinding of colors, glazing cards, manufacturing earthern pottery, plumbing, shot-making, etc. Lead-poisoning has repeatedly occurred from sleeping in newly-painted rooms. Lead may be introduced through the stomach in various articles of food and drink. The colic of Poitou was due to wine, and that of Devonshire to cider adulterated with lead in order to give it sweetness. This kind of adulteration has been prac-

[1] *Vide* Riegel, Deutsches Archiv f. klin. Med., Bd. 21, p. 175, 1878.

tised since the occurrence of the affection in the places just named, and it is perhaps still sometimes resorted to. Liquid and solid articles of diet, especially if they contain a free acid, become impregnated with lead by being in leaden vessels or earthen vessels glazed with lead. Some years ago a large number of persons within a limited district in Ohio were affected with a disease which, for some time, was regarded as a novel epidemic and received the name dry cholera. It was found to have the diagnostic characters of lead colic, and was traced to the common use of a cheap kind of earthen-ware made in that vicinity, into the glazing of which lead entered. An epidemic colic in New Orleans, was traced to lead contained in soda-water; and Prof. Doremus, some years ago, demonstrated the presence of lead in considerable quantity in soda-water drawn from fountains in this city (New York). Water distributed in lead pipes is not infrequently the vehicle of its introduction into the system.[1] Lead sometimes enters into the substances used to color confectionery, condiments, and other articles, in sufficient quantity to give rise to poisonous effects. Articles inclosed in lead foil may become contaminated. Authentic instances of poisoning by the use of tobacco thus inclosed have been reported; and in France inclosing tobacco in lead is prohibited by law. The habit of chewing shot and pieces of the lining of tea boxes has been known to give rise to various manifestations of lead-poisoning lasting for years before the cause of disease was discovered.[2] During the spring of 1866 two hundred and thirteen cases of lead-poisoning occurred in the Walkill Valley, Orange Co., New York. After considerable research it was ascertained that lead was contained in the flour and meal used in that part of the country. The source of the lead was ascertained to be the stones used for grinding the meal and flour. The stones were old, constantly needing repair, large cavities frequently occurring, which instead of being filled up with cement were filled with common lead. The attrition of the grinding detached minute particles of lead, and the lead thus becoming mixed with the flour and meal was transformed into the carbonate by the process of fermentation and baking.[3] Children may be poisoned by sucking leaden toys, glazed writing cards, painted artifical nipples, etc. These are only a few of the diverse modes in which lead finds its way into the alimentary canal. The use of lead as a remedy has given rise to colic and other morbid effects. It may be introduced through the skin, although doubtless with difficulty. Lead-poisoning is sometimes attributable to the long-continued application, to the hands and face, of a cosmetic containing lead. I have known a case in which phenomena denoting lead-poisoning were attributable to the use, for a long period, of a dressing for the hair containing the acetate of lead. Finally, instances of lead-poisoning by means of collyria and vaginal injections have been reported.

The diagnosis of lead colic, in most cases, is not difficult. If the occupation of the patient involve obvious exposure to lead, a suspicion of the nature of the affection is, of course, at once aroused; but this, and other manifestations of lead-poisoning, not infrequently occur in persons who are not aware of any such exposure, and it may require no small pains to discover the mode in which the poisoning has taken place, after the character of the affection has been ascertained. The diagnostic characters of lead colic as compared with those of ordinary colic, offer points of difference which enable the physician to discriminate it from the latter. The gradual development, the

[3] Philadelphia Medical News and Library, July, 1866.

occurrence of remissions much more frequently than intermissions, the persistency of the affection, the concurrence of pain in the back, limbs, and sometimes in the chest, the occurrence of nausea and vomiting, the obstinacy of the constipation, and frequently dysuria, characterize this affection when contrasted with ordinary colic. Co-existing paralysis in some cases, especially if limited to the extensor muscles of the forearm, confirms the diagnosis. Enteritis and peritonitis are excluded by the absence of symptoms denoting inflammation. Enteralgia, exclusive of its occurrence in connection with hysteria, is so rare, except when produced by lead, that its existence is strong presumptive evidence of this causation. A valuable sign is a blue discoloration of the gums at their junction with the teeth. The blue line on the gums may be apparent on the upper or lower jaw or both. It is wanting in sections where teeth have been lost. It is most marked in proportion as the teeth are incrusted with tartar, and in persons who neglect cleanliness in this situation. The discoloration is attributed to the formation of the sulphide of lead, sulphuretted hydrogen being evolved from the decomposition of particles of food remaining between the teeth and beneath the margin of the gums. The lead may be introduced through the mouth either with the inspired air or in food or drink, or sufficient lead may be eliminated in this situation to account for the sign. The sign is not present in all cases. Its absence, therefore, is not proof that lead colic does not exist. Clinical observation, however, shows that the sign is present in a large majority of cases. It is found frequently to precede the development of colic and other affections dependent on lead-poisoning. It is not a transient sign, but is apt to persist, not only during the continuance of the affection, but for some time afterward. In a diagnostic point of view it is highly important, and the gums should be examined with reference to it whenever lead-poisoning is suspected. A chemical analysis of the urine may show the presence of lead in this fluid. In a case in which the lead was introduced by the use of a cosmetic called "the bloom of youth," lead was obtained from the urine in sufficient quantity to form distinct particles of the metal.[1]

The treatment of lead colic embraces palliative and curative measures. The pain is to be palliated by anodynes given by the mouth or rectum, conjoined with soothing applications to the abdomen, as in cases of ordinary colic. Chloroform given by the mouth and applied over the abdomen sometimes acts promptly and efficiently in relieving the pain. If this prove ineffectual, opium in some form is required, the doses and their repetitions to be graduated by the intensity and persistence of the pain. Relief is afforded by free purgation, and, for this end, saline, or such other cathartics as the stomach will best tolerate, may be given, and their operation aided by large purgative enemata. The obstinacy of the constipation often renders it difficult to procure free evacuations from the bowels, and active cathartics may be required. The employment of cathartics may be useful in removing lead contained in the contents of the alimentary canal. Aside from this object and obviating inconvenience from constipation, cathartics are not indicated. Croton oil and other drastic cathartics, heretofore entering into the treatment of this affection, are contraindicated. The warm bath is useful as a palliative, soothing measure.

Several remedies have been supposed to have a curative efficacy in this affection. Alum is one of these. Brachet, in a prize essay on the subject of lead colic, stated that he had treated 150 patients with this remedy more successfully than by opium and purgatives. From one to two drachms of

[1] For the method of testing the urine for the presence of lead, employed by Prof. Doremus, *vide* my work on Clinical Medicine, 1879.

alum were administered during the day in a ptisan to which 40 or 50 drops of laudanum were added, a mild aperient given on the third day, and the alum continued for two or three days after the symptoms of the affection have disappeared. Other observers have not met with a similar success from the alum treatment. Sulphuric acid has been advocated on the basis of success in a large number of cases. A drachm of dilute sulphuric acid in a quart of sweetened water forms a pleasant drink resembling lemonade, and this may be taken in the twenty-four hours. Tanquerel denied the efficacy of this remedy, giving, as the basis of his denial, the results of its trial in 53 cases. The prophylactic efficacy of the sulphuric acid lemonade appears to have been satisfactorily proven in the lead works at Birmingham, England.[1] Strychnia or nux vomica has been recommended as a curative remedy.

The remedy now regarded as possessing the most efficacy is the iodide of potassium. Its use in the treatment of lead diseases, and also in those due to the presence of mercury in the system, dates from the publication, in 1849, of a paper by Melsens.[2] Assuming that the local manifestations of lead-poisoning are due to the presence of an insoluble compound of lead in the tissues of the affected parts, Melsens claims for the iodide of potassium the power of effecting the liberation of the lead and its elimination from the system. The iodine is supposed to combine with the lead in the tissues, forming the soluble iodide of lead which passes out of the body in the urine. Chemical examination of the intestine, the paralyzed voluntary muscles, and other organs, in cases of lead-poisoning, has shown the presence of lead in larger quantity than is to be accounted for on the supposition that it may exist in the body in health. The examination of the urine in cases of lead-poisoning under treatment with the iodide of potassium, has shown the presence of lead, its absence in this liquid having been ascertained prior to the treatment.[3] Finally, clinical observation appears to afford proof of the efficacy of this treatment. With reference to the therapeutics of this affection, knowledge of its natural history as regards termination when left to its own course is important. Tanquerel, in his valuable treatise, gave the results in 31 cases in which no treatment was pursued for 12 days after admission into hospital, the affection having existed for one or more days before admission. Of 8 of these cases in which the colic was violent, in 3 a spontaneous cure took place within the 12 days, namely, on the 3d, 8th, and 11th day. Of 13 cases in which the colic was of moderate severity, in 5 a spontaneous cure took place on the 4th, 7th, 8th, 9th, 11th day, and in 1 on the 13th day. Of 10 cases in which the colic was light, in 6 a spontaneous cure took place within the 12 days.

In the treatment of lead-poisoning by the iodide of potassium, Melsens enjoins to commence with moderate doses, and to increase the doses gradually. He supposes that disturbance may arise from dissolving the lead out of the tissues rapidly. Five grains may be given three times daily at first, and the quantity increased to a drachm *per diem*, if the remedy occasion no inconvenience.

The utility of the warm bath as a palliative measure has been already referred to. It may be useful in promoting the elimination of lead through the skin. It is useful by removing from the skin lead which comes into contact

[1] Appendix to Tanquerel's Treatise, by Dana.

[2] Annales de Chimie et de Physique, 1849; also, British and Foreign Medico-Chirurg. Review, 1853.

[3] For facts verifying this statement, see a report of the results of treatment with the iodide of potassium in 23 cases, in the New York Hospital, by H. S. Swift, M.D., New York Medical Times, February, 1854.

with, and adheres to, the surface in persons engaged in certain occupations. The sulphur bath may be employed for the latter object. This is made by adding four ounces of the sulphide of potassium to thirty gallons of water in a wooden bathing-vessel. The use of this bath renders the presence of lead on the skin apparent by the production of a dark discoloration which is readily removed by a brush. The blackness is marked in various parts of the body in painters and workmen employed in the manufacture of the preparations of lead used as paints, especially if they have neglected cleanliness; but it may be due to the presence of lead eliminated from the body and remaining adherent to the surface. The bath renders the lead which may be in contact with the skin inert, and it is useful as affording evidence that the surface of the body is entirely free from lead, whether derived from without or eliminated.

Prevention of the continued introduction of lead into the system is an essential part of the management. The occupation is to be suspended if it involve exposure; and if the affection be renewed or there be other manifestations of poisoning on resuming the occupation, it should be exchanged for some other. If the source of the poisoning be not apparent, it is to be sought for until found. This poison is one which gives no notice of its entrance into the body, and no manifestations of its presence until a certain amount of accumulation has taken place. The affection under consideration is but one, although the most frequent, of the forms of disease to which the poison gives rise. There is reason to think that obscure and indefinite ailments are not infrequently produced by it in cases in which suspicion of the cause is not awakened, and the liability to these, as well as the more marked effects, from the use of water conducted in lead-pipes and various other sources, some of which have been enumerated, is one of the important subjects pertaining to public health.

The protection of those necessarily exposed to an atmosphere more or less charged with lead, or to contact with it, is also an important subject. Much may be done to prevent its introduction by attention to ventilation, clothing, baths, washing the mouth, and the occasional use of purgatives. Special means of protection, such as the application of moist sponges to the mouth and nostrils, or the use of masks, under certain circumstances may be important.

After recovery from the colic, an anæmic condition, with general debility, will often claim appropriate medicinal and hygienic measures of treatment.

Colic from Copper.

Writers have described a form of colic supposed to be produced by the introduction and accumulation of copper in the system, and the term *metallic colic* has been used to embrace, not only the colic due to lead, but abdominal pains, with other symptoms, attributed to copper, mercury, and arsenic. The diagnostic features of so-called copper colic, as contrasted with lead colic, have been considered to be as follows: Limitation of pain to the abdomen, increase of pain by pressure, enlargement more frequently than retraction of the abdomen, and diarrhœa with greenish stools. These symptoms denote, not merely functional disorder, but gastro-enteric inflammation. An extended and careful examination of numerous establishments in which the workmen were exposed to emanations from, and contact with, copper in various modes, conducted by Chevallier and Boys de Loury, in Paris, led to the conclusion that such an affection as colic from copper does not exist.[1] This

[1] *Vide* Nysten's Dictionnaire de Médecine etc., 1858. Also, Valleix, *op. cit.*, tom. v.

conclusion, however, is by no means inconsistent with the fact that copper within the system exerts a deleterious effect. Arsenic and preparations of mercury, taken in quantities sufficient to produce the phenomena of a local acrid or irritant poison, give rise to pains which may resemble those of colic. Accumulating within the system, these minerals occasion certain toxical effects, but they do not, under these circumstances, lead to abdominal symptoms which may with propriety be considered as an individual affection under the name of colic.

CHAPTER VIII.

FUNCTIONAL AFFECTIONS OF THE STOMACH AND INTESTINE —(Concluded.)

Sporadic Cholera—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Cholera Infantum. Epidemic Cholera—Anatomical Characters—Clinical History — Pathological Character — Causation — Diagnosis — Prognosis — Prevention — Treatment.

OF the functional affections of the stomach and the intestine enumerated in a preceding chapter, two remain to be considered, namely, sporadic and epidemic cholera. Cholera infantum, belonging among the diseases of children, does not come within the scope of this work. I shall, however, notice it briefly, referring the reader for a fuller consideration of it to works devoted to the diseases of children.

Sporadic Cholera.

The affection called cholera, in its ordinary form, is commonly known as *cholera morbus*. Aside from the incongruity of associating these two words, the one Latin and the other of Greek derivation, there is no good reason for appending the word morbus, which expresses no more than is implied in the name of any affection, namely, the existence of disease. The etymology of the term cholera is somewhat doubtful, but it is supposed to signify a flow of bile. The term is of ancient date, and was introduced when various liquids were embraced under the name bile. Not only is the term sanctioned by long usage, but it would be difficult, with our present knowledge, to substitute a better name for the affection under consideration. The term sporadic serves to distinguish this from another affection, known as cholera, which prevails as an epidemic. To distinguish it from the latter, which emanated from India, it is sometimes called by French writers, *European*, and by British writers, *English cholera*. Writers on this side of the Atlantic might, with equal propriety, call it American cholera, since it is sufficiently common, as an indigenous affection, in America. It is called by German writers *cholera nostras*.

Clinical History.—An attack of sporadic cholera is often abrupt, but, in some cases, is preceded, for a period usually brief, rarely longer than a few hours, by a sense of weight or uneasiness referred to the epigastrium, or extending more or less over the abdomen, with nausea, occasional colic pains,

etc. The attack occurs much oftener in the night than in the daytime. It is ushered in by vomiting which is speedily followed by purging. Vomiting and purging, occurring in quick succession, and recurring either simultaneously or in close alternation, constitute the prominent, distinctive, symptomatic features of this affection.

The evacuations from the stomach and bowels are generally abundant, and, at first, consist of the alimentary and fecal contents. Afterward, liquid is vomited, sometimes in large quantity, often having the appearance and taste of bile, sometimes acid, and sometimes so acrid as to occasion a scalding sensation in the throat. In like manner, the dejections become liquid and occasion frequently a burning sensation at the anus. The acts of vomiting and purging occur suddenly with but little premonition. They are often violent, the contents of the stomach and bowels being ejected with force. The acts of purging are preceded and accompanied by colic pains, often extremely severe, which are temporarily relieved by a free evacuation. Severe pains, like those of spasm or cramp, often attend the acts of vomiting. In the interval between the acts of vomiting, the patient usually suffers from dryness of the mouth and fauces with urgent thirst. The abdomen may be at first voluminous, but after repeated acts of vomiting and purging it becomes contracted. Tenderness over the abdomen is either wanting or slight. Spasm of the abdominal muscles sometimes occurs, causing hard bunches or knots as in some cases of colic. Hiccough is an occasional symptom.

With the foregoing local symptoms are associated anxiety, restlessness, and a sense of exhaustion proportionate to the violence and duration of the attack. The pulse is more or less accelerated, small, and feeble. The skin is cool or even cold, and is frequently bathed in clammy sweat. The voice is feeble, sometimes altered in quality, and occasionally there is aphonia. In some severe cases, cramps occur in the feet, the calves of the legs, and in other situations. These add greatly to the suffering of the patient.

The affection runs a rapid course. After continuing for several hours, the acts of purging and vomiting become less severe and occur at longer intervals, the pains, etc., progressively diminish, until, at length, all the symptoms disappear, leaving an amount of fatigue proportionate to the violence and duration of the attack. The patient usually rapidly recovers. It is remarkable that an affection involving so much disorder should leave the affected organs in a condition to resume so speedily the exercise of their functions. This is the rule as regards the progress and termination of the affection, even if its course be not arrested by remedial interference. Exceptionally, the vomiting and purging continue, the evacuations from the bowels occur involuntarily, the pulse becomes more and more feeble, coldness of the surface is more and more marked, contraction of the features takes place; in short, the patient falls into a state of collapse, and dies within a few hours from the date of the attack. This unfavorable course is extremely rare. I cannot recall an example that has fallen under my observation, exclusive of cases occurring in infancy.

Pathological Character.—Sporadic cholera appears to combine morbid conditions belonging to other functional affections of the alimentary canal. In a certain proportion of the cases considered as cases of cholera, the symptoms are attributable simply to indigestion. Vomiting and purging denote, in these cases, the coincidence of acute dyspepsia and crapulous diarrhœa. These cases are usually comparatively mild, and the vomiting and purging cease as soon as the offending contents of the stomach and bowels are expelled. In other cases something more than indigestion is involved in the pathology. The evacuation of liquid, often in great abundance, shows hyper-secretion or

morbid transudation into the stomach and intestines. The affection then combines gastrorrhœa and enterorrhœa. In some cases the secretion of bile would seem to be increased, but it is difficult to estimate, from the color and the bitter taste of the vomited liquid, the relative proportion of bile. It has been common to suppose that in this, as in various other affections, disorder of the liver is in some way involved. There is no solid foundation for such a supposition; it rests on conjecture alone. It is only in a certain proportion of cases that the bile appears to be secreted in morbid quantity. The limit of our present knowledge of the pathological character of the affection is reached when the different morbid conditions into which it is resolvable are enumerated. These morbid conditions, or elements of the affection, are indigestion, irritation, spasm of the muscular coat of the stomach and intestines, enteralgia, morbid gastric and intestinal transudation, and, perhaps, in some cases, hyper-secretion of bile. By German authors the affection is considered as a variety of gastro-intestinal catarrh.

Causation.—Sporadic cholera is not peculiar to any country, but is of more frequent occurrence in warm than cold climates. In cold and temperate latitudes it occurs very rarely except during the summer and autumnal months. An elevated temperature is thus involved in its causation, either by contributing to the development of causes, or by rendering the system more prone to be affected by them. The affection occurs oftener in childhood, youth, and middle age than in advanced life, and oftener in males than females. Frequently an attack seems to be attributable to the ingestion of particular articles of food or drink. Uncooked vegetables, fruits, ices, etc., are often supposed to stand in a causative relation to it. An attack may follow the arrest of digestion from various causes. In some cases, as already stated, the affection is apparently due to indigestion alone. It is probable that, exclusive of these cases, the affection involves a special cause, the nature and source of which are unknown.

Diagnosis.—The diagnostic features of an attack of sporadic cholera are so strongly marked that little need be said under this head. Yet there is some liability to errors of diagnosis. I have known a case of acute peritonitis, accompanied by vomiting and purging, to be considered as a case of cholera, the nature of the disease not being discovered until the autopsy was made. It is extremely rare for vomiting and purging to have sufficient prominence, early in peritonitis, to lead to this error. The diagnostic marks of peritonitis, however, which will be considered in another chapter, should always be sought after in cases of apparent cholera. The chief liability to error in diagnosis relates to cases of poisoning from the ingestion of acrid or corrosive substances. It is important to discriminate these cases from cholera, with a view to antidotal treatment, prognosis, and medico-legal considerations. The following are the differential points: The acrid or corrosive poisons occasion vomiting which continues for some time before diarrhœa occurs, whereas in cholera, the purging is simultaneous with or follows quickly the vomiting. Moreover, the vomiting in cases of poisoning is out of proportion to the diarrhœa. The symptoms in cases of poisoning denote a condition of greater gravity; the pulse is more frequent and smaller, the expression is more haggard, etc., than in the majority of cases of cholera. Redness or charring of the mouth and throat distinguishes certain cases of poisoning. There is marked tenderness over the stomach in cases of poisoning, and more constant, excruciating pain in this situation, in the intervals between the acts of vomiting—in short, the symptoms of gastritis are present. The matter vomited is apt to be bloody. Finally, in cases of poisoning the symptoms

are developed soon after a meal, or the ingestion of something containing the poison.

Prognosis.—As already stated under the head of the clinical history, this affection in the vast majority of cases intrinsically tends to recovery. A fatal termination is a rare exception to the rule; yet the fact that the termination is sometimes fatal is to be borne in mind, and should enforce prompt and effective measures of treatment. Occurring in persons already affected with some important disease, the prognosis is, of course, not so favorable as when healthy subjects are attacked.

Treatment.—In the treatment of sporadic cholera, the first point is to ascertain whether the matters vomited have contained ingesta in more or less abundance. If not, and there be reason to suppose that the stomach contains undigested aliment, a mild emetic may be given. Almost invariably, however, the contents of the stomach are expelled with the first acts of vomiting, and, as an emetic is indicated for no other object, it is very rarely called for. In my own experience I have not prescribed an emetic in this affection for the last thirty or more years. The next object is to arrest the vomiting and purging, together with the pain, etc., by the employment of some form of opiate in doses sufficient to effect this object. In the vast majority of cases, this object may be speedily effected. The form of opiate should be chosen with reference to promptness of action and its being retained. Laudanum, the black drop, and an aqueous solution of opium are well suited to the management of this affection, but Magendie's solution, or a salt of morphia placed dry upon the tongue, is, in general, the best form. A full dose—a quarter or half a grain of a salt of morphia, or an equivalent dose of any other preparation, to an adult—should be given directly after an act of vomiting The first dose will perhaps be immediately rejected, if so, a second should be at once given. If a second and third dose be instantly or quickly rejected, the administration by the mouth should be abandoned, and from one to two drachms of laudanum, or an equivalent dose of some other preparation, may be given in a little thin starch or mucilage *per enema*. The enema should be given directly after an evacuation, and the patient should be instructed to resist as long as possible the inclination to expel it. If the first enema be quickly rejected, a second and a third may be given. If the attempt to administer the opiate by the mouth and rectum fail, the hypodermic injection may be resorted to. In whatever way the remedy be introduced, it is to be repeated after an interval of from half an hour to an hour, until the vomiting and purging are arrested, the effects of each dose being carefully watched, and the intervals being sufficiently long to avoid any risk of inducing narcotism.

An important part of the treatment is the withholding of liquids. The intense thirst leads the patient to drink largely between the acts of vomiting, and this tends to prolong the affection. The drink should be restricted to a tablespoonful of ice-water at short intervals, or, what is better, small pieces of ice may be taken frequently and allowed to dissolve in the mouth. Strict compliance with injunctions on the score of drink is essential to the prompt success of the treatment. If there be great prostration, a little spirit and water may be taken, if retained, at short intervals.

In my experience this method of treating sporadic cholera has proved uniformly successful, and complete relief may generally be expected within an hour. No apprehension need be entertained with respect to the sudden cessation of the vomiting and purging; the more quickly the arrest is made, the better, after a free evacuation of the stomach and bowels. Mercury is, to

say the least, superfluous. The success of treatment without it, is all that could be desired.

Care as regards diet is alone required, in most cases, after the affection is arrested.

I do not deem it necessary to consider other methods of treatment, since the success of the plan just stated is, as far as my experience goes, uniform and immediate. The only objection to the plan is, that some persons are unpleasantly affected by opium, and, after the affection is arrested, the effects of the remedy may be more or less annoying for a time. This objection has not much weight, since the after-effects of opiates, however distressing, occasion far less suffering than the continuance of cholera. But they who frequently experience annoyance after the use of opium, under certain circumstances take it without inconvenience, and I have been led to observe that the after-effects are apt to be slight or wanting when opium is given, in this affection, to patients who usually suffer from these effects.

Cholera Infantum.

The name cholora infantum, or the more popular phrase *summer complaint*, is supposed, by some, to denote an affection peculiar to this country. The morbid phenomena, however, considered by American writers as belonging to this affection, are described in European works under other names. Cruveilhier enumerates many of the symptoms as occurring in cases in which gelatiniform softening of the stomach is found after death, a form of softening already referred to, due to the post-mortem action of the gastric juice.[1] British writers on diseases of children generally describe the symptomatic phenomena under the head of diarrhœa. Weaning brash, watery gripes, and choleric fever of children, are names under which these phenomena were described by Cheyne, Armstrong, and Copland. By some French writers they have been described as belonging to colo-enteritis, follicular enteritis, choleriform diarrhœa of children, and gastro-intestinal catarrh. German authors consider the affection as gastro-intestinal catarrh.

As commonly used in this country, the term cholera infantum, or summer complaint, embraces different pathological conditions, in fact, distinct affections occurring in children under two years of age. These different conditions, however, may be developed at different periods in the same case. In certain cases the symptoms closely resemble those of the sporadic cholera of adults. A child is seized with vomiting and purging, the latter usually occurring first; the acts of vomiting and purging are violent and frequently repeated; after the contents of the stomach and bowels are expelled, the evacuations consist of secreted or transuded liquid in more or less abundance. The attack may cease or be arrested and recovery speedily ensue, as in cases of the sporadic cholera of adults; but this favorable course does not obtain so generally in children as in adults. If the course be unfavorable, the vomiting and purging continue; the child is tormented with thirst, but everything is rejected from the stomach; great prostration ensues; collapse follows, and death takes place in one, two or three days. The fatal result may be preceded by convulsions and coma. In some cases the violent symptoms of cholera cease, and the attack eventuates in a chronic affection accompanied by diarrhœa and occasional vomiting.

In other cases, the affection is gastro-intestinal indigestion. These are characterized by diarrhœa, the dejections being lienteric and watery. Vomiting occurs only occasionally, and is an accidental symptom. It may not

[1] *Vide* page 458.

occur. The diarrhœa is more or less persisting, the discharges being often green in color, an appearance which Golding Bird, and, more recently, J. Lewis Smith, have shown not to depend on vitiated bile;[1] the appetite is impaired or lost; colic pains are apt to be troublesome; the child progressively wastes, and death may take place from inanition. In another class of cases, the affection is either enteritis or entero-colitis. The dejections in these cases contain gelatinous or stringy mucus, and are not infrequently tinged or streaked with blood. Febrile movement, with remissions, occurs in these cases. There is more or less abdominal tenderness and pain. Vomiting may be prominent as a symptom, or it occurs only occasionally. Progressive emaciation and debility mark the unfavorable progress of this affection. Head symptoms are often developed in its course. The child becomes dull and somnolent, lies with the eyelids partially closed, and frequently rolling the head from side to side. Convulsions and coma may occur before death. After death, an examination reveals the evidences of inflammation of the mucous membrane of the small, and, perhaps, also, of the large intestine, the follicles being especially involved. Enteritis or entero-colitis is liable to become developed in the cases which, at first, appear to be cases of diarrhœa dependent merely on indigestion. In still another class of cases the symptoms and the appearance after death denote the existence and limitation of inflammation to the large intestine.

Under the name cholera infantum, then, are commonly embraced cases of sporadic cholera, diarrhœa from indigestion, enteritis, colo-enteritis, and dysentery. The head symptoms which are apt to be developed in unfavorable cases of each of these affections in the young child, were formerly incorrectly attributed to inflammation of the meninges of the brain. They constitute the hydrencephaloid affection of Marshall Hall.

The affections embraced under the name cholera infantum are not, as already stated, peculiar to America, but they doubtless prevail to a much greater extent in certain parts of this country than in Europe, owing, probably, in a great measure, to the greater heat in the summer months. The causation has relation to a high temperature; the affections prevail almost exclusively during the months of June, July, August, and September. Something more than temperature, however, is concerned in their production, for they are almost limited to cities and large towns, and are more prevalent in the Northern and Middle than in the Southern States. Children of the poorer classes, in insalubrious situations, living in crowded dwellings, are more liable to be affected, but the children of those in easy circumstances and of the wealthy by no means escape. The irritation of dentition and the change of diet after weaning, doubtless, render the system more vulnerable. Infants brought up by hand are especially subject to these affections. The diet of the child, after weaning, has much to do, if not with the causation of these affections, at least with the ability of the system to resist and overcome them. Restriction to insufficient articles of nourishment, such as arrowroot and gelatin, is one source of innutrition in infancy, but there is reason to believe that infant mortality in cities is attributable, in no small measure, to the use of diluted, sophisticated, and artificial milk. The importance of undiluted milk from a pure source to the welfare of children is far from being generally appreciated. The quality of milk is comparatively of little consequence after childhood, because it then usually enters but little into the diet, but, as the chief reliance is upon milk in infancy, its purity is then of the utmost importance.

The general principles which should govern the management of the same

[1] *Vide* Smith on the Diseases of Children.

affections after the period of early childhood, are applicable to the different forms of disease embraced under the name cholera infantum, with certain modifications which will be here referred to very briefly. The treatment, in the first place, has reference to the form of cholera infantum which is presented. In the acute form, resembling the cholera of adults, in which there is a liability to a rapidly fatal termination by exhaustion from loss of fluids, the patient falling into a state of collapse, the indications are to arrest the vomiting and purging, to restore warmth to the surface by the application of dry heat, mustard-water and the warm bath, and to sustain the powers of the system by stimulants and nourishment. For the arrest of the vomiting and purging, opiates are to be relied upon, as in the cholera of adults, but they are to be given with much circumspection, in order to avoid risk of narcotism. Exclusive of this form, the affections do not occur with a sudden and violent attack, but, as a rule, they are developed gradually and tend to become chronic. Measures for the relief of vomiting are a sinapism to the epigastrium, creasote, which, in doses of a sixth or an eighth of a drop in mucilage, repeated after each act of vomiting, sometimes acts like a charm; the subcarbonate of bismuth in doses of from 10 to 30 grains; small doses of calomel with chalk, chloroform, and hydrocyanic acid. With reference to this symptom, a careful regulation of the ingesta is requisite, and milk with lime-water, given in small quantity at a time, will often be retained when other articles of nutriment are rejected.

With reference to the diarrhœa, occasionally a laxative is useful, and a few grains of calomel or blue mass, followed by the syrup of rhubarb, are well adapted for this purpose. There are no indications for mercury except as a remedy for vomiting, and an occasional laxative remedy, the convenience of its administration being perhaps its chief recommendation in cases of young children. Opium in some form, with due circumspection, is to be employed. It is most efficient when given by enema, provided it be administered with proper care and retained. If given by the mouth, the Dover's powder is an eligible preparation. Hypodermic injections of morphia should not be given. If the dejections denote acidity, chalk, in powder or mixture, or lime-water, is indicated. The mineral and vegetable astringents are highly important. Of the mineral astringents, the most efficient are bismuth, lead, and the persulphate or pernitrate of iron. The nitrate of silver is highly recommended by some authors. Of the vegetable astringents, krameria, tannic acid, kino, catechu, hæmatoxylon, geranium, and rubus villosus are articles from which a selection may be made, or which may be tried in succession.

Attention to diet and regimen is of prime importance. Many children, there is reason to believe, die with these affections from an insufficiency of nutriment. Pure milk is the most appropriate article of food. It may be rendered more nutritious by the addition of boiled flour, powdered biscuit, or other farinaceous preparations. Gelatin and arrowroot, or other amylaceous substances, alone are inadequately nutritious. The essence of meat and strong broths are often taken with avidity by very young children, and the desire for them should be indulged and encouraged. This remark is also applicable to broiled tender meats taken in a solid form. Within the past few years, the use of raw meat has been recommended as a form of diet adapted to the affections under consideration, and it is frequently taken with relish. Tender beef is to be preferred, but mutton and chicken are sometimes more acceptable to the patient. The meat is to be finely hashed, and may be given in this way, or it may be made into a kind of *purée* by being reduced to a pulp in a mortar and pressed through a fine sieve, so as to separate the vessels and areolar tissue. If the child manifest an aversion to it as thus prepared, the

hashed meat, or pulp, may be rendered palatable by the addition of salt, sugar, or some kind of preserve, or it may be added to a broth made with sago or tapioca. Cooked tender meats, however, are generally more acceptable, equally digestible, and not less nutritious. The liability to tænia, as a result of eating uncooked meat, renders its use of doubtful propriety.

As regards the administration of different kinds of food, the quantity given at a time is to be graduated by the ability of the stomach to retain and digest it; and this is the only rule of limitation. It is of vast importance for the physician not to deem it too trivial to enter into full and minute directions with respect to the details of nourishment. He should bear in mind that children often die from innutrition through the apprehensions and ignorance of nurses and mothers.

In conjunction with diet, alcoholic stimulants are highly useful. A few drops of brandy, or some kind of spirit, may be given, at shorts intervals, with advantage. The preparation known as Calisaya cordial or elixir is well suited to children, combining a tonic and stimulant in a form agreeable to the taste. The need of a stimulant is shown frequently by the avidity with which children take it in these affections.

Finally, removal from the city, either to a situation on the seaboard or to a salubrious point inland, is the most efficient of all curative means. This measure, if not deferred too long, rarely fails. If other measures be not speedily successful, this, whenever practicable, should be resorted to without delay. If it be not practicable, the child should be in the open air as much as possible, and should be carried daily as far from home as convenient, in order in this way to secure a change of air.

The head symptoms referred to in the clinical history, claim sustaining measures—stimulants and nourishment—conjoined with mild revulsives.

In these affections, hope of recovery need not be relinquished under an assemblage of symptoms which may seem to render the prognosis as unfavorable as possible. Patients sometimes recover after lingering for a long time on the verge of the grave. The reason is, the affections, when they prove fatal, do not necessarily involve incurable lesions of structure, but a fatal result is due to protracted irritation, exhaustion, and innutrition.

Epidemic Cholera.

The term epidemic cholera is selected as the one most frequently used and the most convenient to designate a disease which has received a great variety of names, such as Indian, Oriental, and Asiatic cholera, cholera asphyxia, spasmodic cholera, malignant, pestilential cholera, etc. etc. The etymology of the word cholera, it is true, is singularly inappropriate, accepting the derivation which signifies a flow of bile; but our present knowledge does not warrant a name expresssive of the pathological character of the disease. Moreover, it is to be presumed that the disease is not essentially the same as sporadic cholera; the two are not merely different varieties of one disease, but they are distinct individual affections, having certain prominent symptoms in common, but differing in essential points relating to clinical history, pathological character, causation, and prognosis.

For an account of the prevalence of this remarkable epidemic in different countries at different epochs, the reader is referred to other works. Suffice it to say that the disease appears to be indigenous in India, and to have existed there, both as a sporadic and epidemic affection, for a long period. In other parts of the world it has made brief visitations solely as an epidemic. In 1817 it commenced its march from Bengal, and during the following fifteen years it traversed nearly the whole of the known world. It prevailed in

different parts of the American Continent for the first time in 1832, and again in 1834. It began its march a second time from India in 1847, and again traversed the greater portion of the globe, prevailing in the United States in 1849, '50 '51, and '52. Commencing again its march over the globe in 1864, it reached this country in 1866 and during this and the following year it prevailed in many of the large towns in the different States of the Union. It may be proper to add that my opportunities for observing the disease in 1849 and 1852 were ample. During these years I treated, in hospital and private practice, about 200 cases, recording, at the bedside, the histories in about 90 cases. A few cases came under my observation in 1866 and 1867. The disease prevailed in different parts of this country in 1873.[1]

Anatomical Characters.—There is nothing in the pathological anatomy of Asiatic cholera which, so far as at present known, can be considered pathognomonic of the disease. The same changes may be met with in severe cases of sporadic cholera. The anatomical appearances vary according as death takes place during the algid stage, or during the stage of reaction. The changes of the algid or asphyctic stage will be first described. Post-mortem rigidity is marked; it comes on soon after death and continues for a long time. In some cases, shortly after death, visible twitchings of the muscles occur, and occasionally considerable movements of the limbs. The heat of the body is preserved for a long period after death, and there may be even a post-mortem elevation of temperature. The surface of the body has a cyanotic hue, especially in the dependent parts and in the extremities. The serous surface of the small intestine has a rosy color. The intestine is not distended with gas, but contains a large, sometimes an enormous, quantity of yellowish-white fluid, holding in suspension small white flakes, and hence presents a heavy, flabby, sodden appearance. The mucous surface of the small intestine is swollen, œdematous, moderately congested, and may contain ecchymoses. The congestion and the extravasations are most marked in the lower part of the ileum, and are not usually present in either the large intestine or the stomach. The solitary follicles and Peyer's patches are, as a rule, considerably swollen, and are grayish in color. The mesenteric glands are moderately enlarged. The surface of the mucous membrane is coated with tenacious mucus. According to Kelsch and Renaut, there are marked inflammatory changes in the intestinal coats. These observers found an increased number of lymphoid cells in the mucous and submucous coats. They also found many wandering cells in the subserous tissue. The upper part of the glands of Lieberkühn was devoid of epithelium, and filled with mucus. After death the epithelial cells lining the mucous membrane are extensively desquamated, and may be found in the intestinal contents. The view has prevailed that this desquamation occurs during life, and constitutes a lesion characteristic of cholera. Competent observers have failed to find intestinal epithelium in any considerable quantity in the discharges during life. There is no ground for assuming that during life an extensive desquamation of the

[1] For an account of the cholera epidemic of 1873, *vide* "Reports prepared under the direction of the Surgeon-General of the Army," 1875, published by the Government of the United States. The volume embraces an article on "The Introduction of the Epidemic Cholera into the United States through the agency of the Mercantile Marine, with suggestions of measures of prevention," by John M. Woodworth, Supervising Surgeon of the United States Marine Hospital Service; a "History of the Cholera Epidemic of 1873 in the United States," by Ely McClellan, M.D., Assistant Surgeon U. S. A.; a learned and comprehensive "History of the Travels of Asiatic Cholera," by John C. Peters, M.D., and an extensive "Bibliography of Cholera," by John S. Billings, M.D., Surgeon U. S. A.

epithelium takes place. Excepting the presence of desquamated epithelium, the intestinal contents found after death are essentially the same as the rice-water discharges which will be described afterwards.

Changes in other parts of the body are in great part explicable by the enormous transudation of fluid from the blood into the intestines. The blood is dark, and, from loss of water, so thick and viscid that it circulates with difficulty during life. It is accumulated chiefly in the large veins and in the right cavities of the heart, where it may be fluid, or it may contain soft, dark, or in some cases decolorized, clots. The heart, especially its left ventricle, is generally firmly contracted. By way of compensation for its loss of serum, the blood absorbs fluid from the tissues, and hence, these are found abnormally dry. The muscles are firm, dry, and dark-red in color. In consequence of the concentration of the fluid in the serous cavities, the pleura, pericardium, and peritoneum are often covered with a thin layer of sticky substance which has been sometimes mistaken for an inflammatory exudation. The meningeal vessels of the brain and cord are often congested. The cerebro-spinal fluid is diminished, and the substance of the brain and cord is firm and dry. The lungs collapse to an unusual degree in consequence of the empty and dry state of the bronchi. The upper portion of the lungs is usually dry and light colored; the lower portion frequently engorged with blood. There are sometimes hemorrhages in the lungs. Small ecchymoses are usually present in the tissue of the pleural and of the pericardial membrane. The spleen is usually small, flabby, and dark-red. There is nothing noticeable in the liver. The kidneys, in this stage, are not usually swollen. The veins may be somewhat distended, and ecchymoses are often found. Yellowish-white patches in the cortex, indicating fatty degeneration of the epithelium, appear in the asphyctic stage, but are more numerous later. The mucous membrane of the pelvis and calyces is hyperæmic and ecchymosed. The bladder is contracted, and nearly or quite empty.

The composition of the blood in cholera patients has been studied with great care by C. Schmidt. He found that the degree of concentration of the blood generally reached its maximum in thirty-six hours after the onset of the choleraic discharges, at which time the relative proportion of solid constituents may be nearly one and a half times greater than normal. This increase pertains mainly to the organic matters in the blood. As chiefly the chloride of sodium escapes in the transudation, the relative quantity of phosphates and of potash salts in the blood is, therefore, increased. The functions of the kidneys being suspended, there is an accumulation of urea and of extractive matters in the blood. The percentage of red and white corpuscles in a given quantity of blood is increased. The red corpuscles are shrunken; the white are often found in clumps in the blood after death.

In the stage of reaction, or typhoid stage, the morbid changes are notably different. The tissues no longer are abnormally dry. The intestinal contents do not present the rice-water character, but are stained with bile and sometimes with blood. They usually have a pasty consistence. The solitary follicles and Peyer's patches may be pigmented. The congestion may have disappeared, or, in its place, may have developed a more intense inflammation than was present in the first stage. Follicular ulcers are not infrequent. Changes similar to those in dysentery, with diphtheritic inflammation and necrosis, occasionally make their appearance in this stage in the large intestine. In the brain and cord there are often congestion and increase of the cerebro-spinal fluid. The lungs not infrequently are œdematous and hyperæmic. Pneumonia may develop in this stage. The spleen may be normal in size or swollen. The most important changes relate to the kidneys. Following the anæmia of the first stage, parenchymatous and fatty degenera-

tion of the renal epithelium ensues. Sometimes, but not usually, an acute nephritis develops. The kidneys are congested and swollen, especially in the cortical portion. Yellowish streaks, indicating fatty degeneration, appear in the swollen cortex, in which the normal markings are obscured. The dark red color of the pyramids contrasts with the yellowish-white aspect of the cortex. The epithelium of the tubes in many places is desquamated, and has undergone parenchymatous and fatty degeneration. Hyaline, granular, and fatty casts are found in the tubes. Parenchymatous degeneration of the liver and other organs may be present in this stage.

Of the numerous low vegetable organisms which have been found in the stools of cholera patients, not one has been shown to be characteristic of the disease or to bear any causative relation to it.

Clinical History.—In the great majority of cases, the disease is preceded by simple diarrhœa, the dejections being greater or less in number, copious, and painless. The duration of this preliminary diarrhœa varies in different cases from a few hours to several days. With this diarrhœa in some cases occasional vomiting occurs. Aside from these symptoms, nothing denotes a tendency to the disease. The system otherwise is but little, or not at all, disturbed, and it is difficult to persuade the patient, often, that the intestinal disorder is of any special importance. Of 45 cases in which the existence, or otherwise, of premonitory diarrhœa was noted in the histories which I have recorded, it existed in 34 cases and was wanting in 11. Statistics on a larger scale show a much smaller proportion of cases in which the premonitory diarrhœa is wanting. Thus, the report of the General Board of Health of London for 1848–49, contains the statement by Dr. MacLoughlin, one of the sanitary inspectors, that of 3902 cases the premonitory diarrhœa was not wanting in a single case. Of 142 cases treated in hospital, in Paris, by Michel Levy, the premonitory diarrhœa was wanting in only 6. Of 274 cholera cases treated in the different Parisian hospitals in 1853, the existence of premonitory diarrhœa was ascertained in 140, in the remainder of the cases it being absent or its existence not ascertained. By some the period during which the premonitory diarrhœa exists is reckoned as a stage of the disease. This is obviously improper, as there is nothing then distinctive of epidemic cholera, and during the prevalence of the epidemic very many have the same kind of diarrhœa without the development of cholera. The simple diarrhœa which prevails extensively during the prevalence of cholera, is called, in France, *cholerine*, a term adopted, to a considerable extent, in other countries. By German writers, however, this term is used to designate a mild form of cholera. In a practical view, the importance of taking cognizance of the premonitory diarrhœa is very great, as will presently appear.

The development of cholera is generally first denoted by characters relating to the intestinal evacuations. If diarrhœa have existed, the discharges are suddenly increased in quantity, or sudden and copious liquid discharges, without previous diarrhœa, mark the onset of the disease. This constitutes the attack, and in the majority of cases it occurs during the night. The characteristic stools consist of a thin liquid generally known as the rice-water or choleraic discharges. The liquid is generally yellowish-white and slightly opalescent. It contains, in more or less abundance, small, white, solid particles, like grains of rice in rice-water or flakes of curd in whey. It is devoid of bile, but may be somewhat bloodstained. There is no distinctive odor. The reaction of the fluid is neutral or slightly alkaline. It contains a remarkably small quantity of solid constituents. These do not usually exceed one to two per cent. The specific gravity varies between 1006 and 1013.

The chief solid ingredient is chloride of sodium. There is also present some carbonate of ammonium, which gives the alkaline reaction, and a very small quantity of albumen. The particles resembling rice grains are composed of mucus with granular matter and some pus-cells. Occasionally a few cylindrical epithelial cells may be found, but they are not abundant. Various low vegetable organisms are present in large number, as sarcinæ, round and rod-shaped bacteria, spores. The same forms may occur in ordinary diarrhœa. The quantity expelled at each act, or in the aggregate, is very variable. A large quantity, enough to nearly fill an ordinary chamber-pot, sometimes escapes at a single dejection, or the quantity with each act may be small. The quantity is not always in proportion to other symptoms denoting gravity. The dejections are not accompanied by pain, but by a sensation of relief. There is no smarting at the anus. The patient is suddenly impelled by a sense of distension to evacuate the bowels, and when the quantity is large it escapes very rapidly. In some cases the evacuations, after several have occurred, cease ; in other cases, after a time the liquid flows away constantly, the patient being unable to prevent it. The characteristic dejections are sometimes wanting. The disease has been called *cholera sicca* when death takes place without choleraic discharges. The name, however, is inappropriate. In the so-called cholera sicca, the rice-water-like liquid is present in the alimentary canal, and the quantity found after death may be unusually large. It is conjectured that in these cases the peristaltic movements of the intestine are paralyzed, so that the intestinal contents are not expelled. These cases terminate with great rapidity.

Vomiting usually occurs. In a diagnostic and pathological view it is less important, as a symptom, than the characteristic diarrhœal discharges. In some cases it is a prominent and persistent symptom, everything taken into the stomach being rejected ; in other cases it occurs occasionally, and sometimes it occurs at the onset and ceases. The matter vomited is a watery liquid, frequently consisting chiefly of water which has been drank, but sometimes evidently a transuded liquid. The quantity may exceed that of the liquids ingested. The vomited liquid is usually neutral, but it is sometimes acid. The vomiting is not preceded nor accompanied by much nausea. The act of vomiting occurs suddenly, and appears to arise simply from distension of the stomach.

These symptoms, conjoined with a sense of prostration, more or less feebleness and, generally, frequency of the pulse, coolness of the skin or perspiration, with, in some cases, cramps of the muscles of the limbs, may constitute the clinical history of the disease. In other words, the disease may either end spontaneously or be arrested, without other symptoms than those just described. The vomiting and purging cease, improvement as regards the other symptoms follows, convalescence is at once declared, and recovery is rapid. The duration, in these cases, of the disease is brief—a few hours only. But in a large proportion of cases the disease does not pursue such a favorable course. A group of striking symptoms becomes developed, and the disease passes into what has been called the algid or cyanosed stage, or, more commonly, the stage of collapse. It remains to sketch the further clinical history in these cases.

Important symptoms pertain to the circulation. The pulse is usually frequent and proportionately feeble, beating 120, 130, or 140 per minute, but in some cases it becomes more and more feeble without acceleration. I have observed it to fall below the normal frequency. When the state of collapse is fully developed, the pulse at the wrist is extinct. Feebleness or absence of the apex-beat of the heart and of the heart-sounds also shows greatly diminished power of this organ. The blood stagnates in the veins, giving

rise to lividity at the roots of the nails, and a dusky hue of the prolabia, face, and surface of the body generally. Hence, the significance of *cholera cyanosis* and *cholera asphyxia* as names of this stage of the disease. If venesection be practised, the blood trickles from the aperture, not flowing in a projected or continuous stream. Leech-bites do not bleed as usual. The blood is manifestly thicker than in health.

The respiratory system presents striking symptoms. The number of respirations is usually increased, but sometimes diminished. Dyspnœa is occasionally complained of, and sometimes exists in a distressing degree, owing to the feeble circulation from the thickened state of the blood. The respiration is frequently suspirious or sighing, and irregular in rhythm. The expired atmosphere, when the collapse is complete, is low in temperature as compared with health (76° or 80° Fahr.), giving to the hand a sensation of coolness. It contains more oxygen and less carbonic acid than in health, showing a notable deficiency of the changes incident to the function of respiration. The voice undergoes a marked change, becoming feeble, raised in pitch, husky, and, not infrequently, extinct, attributable in part to muscular debility, but chiefly to dryness and stiffness of the vocal cords. In the moribund state the tracheal râles, which so often precede death from other diseases, are wanting.

Very little pain is experienced except from muscular contractions or cramps. As regards the nervous system, the disease is characterized by mental indifference or apathy. The patient has no apprehensions, although prior to the attack there may have been intense dread of the disease. In some cases there is great restlessness and jactitation, and in other cases the patient lies quietly, save when disturbed by evacuations and cramps. The latter give rise to most of the suffering. Cramps are usually, but not invariably, present. They are seated especially in the feet, calves, and abdominal walls, the muscles of the upper extremities and even of the face being somewhat affected. The prominence of this symptom renders the name *spasmodic cholera* significant. The muscular strength, in some cases, is retained in an extraordinary degree. Patients, if not prevented, will sometimes get up and walk about even a few moments before death.

The functions of most of the secretory organs are nearly or quite suspended. No bile is contained in the matter vomited nor in the dejections; the urine is suppressed. Patients do not weep. It is a remarkable fact, however, that in nursing women the lacteal secretion may continue. The disease, also, does not prevent the occurrence of menstruation, but the menstrual discharge is diminished. The skin, in addition to its cyanosed appearance, is cold and often covered with a copious, viscid perspiration; in other cases it is cold and dry. The coldness of the surface is like that of a cadaver. Of this, however, the patient is not conscious; on the contrary, there is generally a sense of heat and a desire to be uncovered. The heat of the body is diminished, as shown by the thermometer in the rectum or vagina; the axilla, in this disease, does not give a fair representation of the internal temperature. The diminution ranges generally from two to four degrees below 98°; but it may fall to 90°, and even considerably lower; it has been known to fall to 73°. The skin is frequently shrivelled and wrinkled like the arms of washerwomen. Its elasticity is diminished, as shown by its subsiding very slowly after being pinched up. The tongue gives to the touch a sensation of coldness. Thirst is a prominent symptom; the patient craves constantly cold drinks, and iced-water or ice is taken with great avidity.

The general aspect in the collapsed state is highly characteristic. The features are contracted, the eyes sunken, the whole body is diminished in bulk, the patient appears to have suddenly grown old, and the countenance

is often so much changed that the person is scarcely recognizable by familiar friends.

Of the foregoing symptoms, most are present in all cases in which the disease is not speedily arrested. Differences relate chiefly to the degree of severity of the disease. In stating the condition of patients, it is customary to say *before* or *after* collapse, and to express different degrees of the collapsed state by saying *semi-collapsed* or *completely collapsed.* Collapse is complete when the pulse at the wrist is extinct, the surface cold, etc. The collapse may ensue with more or less rapidity—from an hour to six or eight hours after choleraic dejections occur. It occurs almost invariably in fatal cases, the mode of dying being, of course, by asthenia; but I have known cases to end fatally without the stage of collapse, the patient becoming comatose and dying by apnœa.

The patient after emerging from the state of collapse, does not, in general, pass at once into convalescence, but there follows a period of the disease commonly called the *stage of reaction.* In this stage there is more or less febrile movement, the temperature rising more or less above the maximum of health. Diarrhœa not infrequently continues, the dejections becoming green and gelatinous. Dysentery is sometimes a sequel. In other cases, constipation, more or less obstinate, follows. Vomiting, in some cases, is a troublesome symptom in this stage, the vomited matter being either green or yellow. Capillary congestion of the surface, especially of the face, is frequently marked, as in cases of typhus. The renal secretion returns, and the urine is albuminous, brownish-red in color, and contains epithelial, fatty, and hyaline casts, together with degenerated renal cells, and usually, also, red and white blood-corpuscles. This stage is not devoid of much danger. The patient may be worn out with continued vomiting or diarrhœa; somnolency and coma become developed in a certain proportion of cases, dependent, probably, on uræmia; delirium, of a passive kind, is not uncommon, together with subsultus, sordes, and other symptoms of the typhoid state. Pneumonia is sometimes developed. A fatal termination occurs in a pretty large proportion of the cases in which the stage of reaction takes place; and, in the cases which recover, the powers of the system are generally impaired for a long period. Exceptionally, patients emerge from the collapsed state and pass, either gradually or quickly, into convalescence without febrile movement or other symptoms belonging to the stage of reaction.

Pathological Character.—Most of the striking phenomena of the disease are plainly attributable to the blood-lesions resulting from the loss of the constituents found in the choleraic dejections. The blood circulates with difficulty, and the changes incident to respiration take place imperfectly; hence, the feebleness and extinction of the pulse, the cyanosis, loss of temperature, thirst, mental apathy, spasm, unchanged expired air, defective secretion, etc. etc. The retention in the blood of excrementitious principles, doubtless, plays an important part in the production of morbid phenomena. The coma which occurs in some cases may be due to uræmia. Cholesteræmia may occur, since the function of the liver is suspended.

The transudation, however, which is first in the catenation of appreciable events, involves an underlying, and at present inappreciable, pathological condition. It is fair to infer that the primary change is not in the solid structures of the alimentary canal, from the rapidity with which recovery takes place when the disease is promptly arrested. This fact shows that the essential pathological condition is transient and admits of speedy readjustment, provided the immediate effect of this condition, namely, the transudation, be prevented.

Causation.—A special cause is undoubtedly essential to the production of epidemic cholera; ordinary causes of disease, alone, are incapable of producing it. This is a logical inference from the epidemic character of the disease, its remarkably distinctive features, and its great uniformity, as regards symptomatic phenomena, in all places and periods, although the nature and source of the special cause are unknown. Is the special cause a contagium? To account for the diffusion of the disease on the supposition of its communicability, was the easiest mode, and certain facts favor this supposition. The epidemic, in its migrations, follows routes most travelled; it prevails in thoroughfares and cities; frequently the first case in a new place is an imported case; different members of a household are successively attacked, etc. It is easy to gather isolated facts to support the doctrine of communicability. But, surveying the facts on all sides, the conclusion is to my mind irresistible that the spread of the disease is not due to its being directly communicated from those affected to others; in other words, the bodies of those affected do not furnish a contagium capable of producing at once the disease in others. The following are the considerations on which the conclusion just stated rests:—

1. Of those who are brought into contact with, or close proximity to, cholera patients, the proportion who become affected is not larger than that of those who are not thus exposed. This is true as a general statement. In the Report on Cholera in Paris, in 1831, published by order of the French government, it is stated that, of over fifty-five thousand persons affected and over eighteen thousand deaths, only one hundred and sixty-four were persons whose duties or profession called them to nurse or prescribe for the sick. These 164 cases were from over two thousand persons employed in the *hospices* or civil hospital either constantly or temporarily.[1] Hospitals are not foci of infection. At St. Petersburg, of 58 persons employed in hospitals, only one had the disease. At Moscow, of 123 persons attached to one hospital, 2 only; and of 253 persons connected with another hospital, only 4 were attacked. In the London Hospital, during the epidemic of 1866, of 100 persons employed in the cholera wards, 5 had the disease. Three of these were nurses who slept outside the hospital. Of 11 laundry women, one had the disease. "No case occurred in the general wards of the hospital, although during the whole period of the epidemic they contained their full number of cases, most of whom came from cholera localities."[2] Facts like these could be multiplied to any extent. Contrast with these the facts with respect to the diffusion of typhus in hospitals!

2. Imported cases in situations where the disease had not previously existed, do not lead to its diffusion. Some striking exceptions to this statement might be cited, but in general it is true that the disease does not spread from isolated cases.

3. The epidemic breaks out in a place almost simultaneously in different situations, without any communication of the cases with each other.[3]

4. It is diffused too rapidly to be propagated by contagion. If contagious, it must be most highly so to account for the rapidity with which it extends, and the latter is not consistent with other facts.

5. It runs its career in places too soon, and leaves too suddenly and com-

[3] *Vide* Report, by the author, of the Epidemic at Buffalo in 1849, in Buffalo Medical Journal, vol. v., 1850; also, Report of the New York Metropolitan Board of Health for 1866, page 166; also, Facts relative to the Rise and Spread of the Disease in London and other towns in England during 1848–49 and 1865–66, in Brit. and For. Medico-Chir. Rev., Oct. 1870, p. 483.

pletely, for a contagious disease. Compare its course as an epidemic, in this respect, with typhus, smallpox, or scarlet fever!

6. Efforts to produce the disease, experimentally, by the greatest amount of exposure, by inoculation, tasting the excretions, etc., have failed.

There can be little or no doubt that the special cause may be transported in clothing and other substances after the manner of fomites. Facts might be cited in proof of this opinion; in other words, the disease is *portable*, without being contagious.

Since the preceding remarks on the causation of cholera were written (1866), the repeated visitations of the disease in Europe and in this country, have given rise to renewed inquiries and speculations respecting the source of the special cause and the manner in which it is diffused. The theory advocated by the late Dr. Snow, of London, has obtained considerable currency. According to this theory, cholera is a disease of the alimentary canal, and is always attributable to the introduction of a specific virus within the canal. The disease being thus produced, the excreta from the alimentary canal, that is, the matters vomited, and discharged from the bowels, contain a virus, and it is exclusively by means of this virus that the disease is propagated. Snow accounted for the diffusion of the disease by supposing that the virus existing in the excreta of cholera patients is especially liable to be contained in water which is drank, and that it may be contained in the air and thus get into the mouth or nostrils, and thence into the stomach. He supposed that the virus in a dried state may adhere to clothing, and that the disease is in this way portable.[1] The theory of Dr. Snow has been accepted by many with certain modifications. Thus, it is supposed by Thiersch and others, that the excreta do not contain a virus, but that a special poison is produced by a fermentation or decomposition of the excreta, the process requiring several days and being favored by a high temperature. Again, a doctrine advocated especially by Pettenkofer, is that the choleraic excreta furnish germs which are developed into activity in the soil, various conditions pertaining to the moisture of the soil, the temperature, etc., being favorable, or otherwise, to the production of the poison. It is supposed that these germs are produced within the alimentary canal, not only in the cases of fully developed or well-marked cholera, but in cases of so-called cholerine, the latter, as well as the former, affection being caused thereby. This supposition, of course, involves the conclusion that the diarrhœa which prevails during the prevalence of epidemic cholera, that is, cholerine, is essentially choleraic.

The statements in the foregoing paragraph were contained in the fourth edition of this work (1873). At the present time (1880), the doctrine stated in the latter part of the paragraph is, perhaps, generally received in all countries. According to this doctrine, the intestinal excreta, in cases of cholera and cholerine, contain something which is essential for the diffusion of the disease. Some hold to the opinion that this something is capable at once of causing the disease; that is, the disease is directly communicable. This opinion, in view of the facts which have been stated, is untenable. The more prevalent opinion is that, for the efficiency of this factor contained in the excreta, certain changes after it leaves the body are necessary. When these have taken place, and the efficient cause has gained entrance into the body, either by means of the atmosphere or in drinking water, the disease is produced. The disease is thus indirectly communicable; it belongs among

[1] *Vide* Reports on the epidemic Cholera, by Baly & Gull, London, 1854. Exposition of Dr. Snow's Theory, by Dr. B. W. Richardson, in London Med. Times and Gaz., Oct. 1865; and in Am. Journ. of Med. Sciences, April, 1866.

the miasmatic contagious diseases (*vide* page 89). This theory is reconcilable with facts which disprove the doctrine of direct communicability, and, in the present state of our knowledge, is rationally probable.

If the germ theory be adopted, as affording the most rational explanation of the causation of other infectious diseases, this disease certainly comes within the range of its application. Adopting this theory, the disease requires for its production a specific germ or organism. Adopting the theory of indirect communicability, as just stated, germs are contained in choleraic excreta, but they require development under favorable conditions without the body in order to acquire infective power. Before reaching the required development, they are incapable of producing the disease. When the cholera germ has undergone the requisite development, it may be transported in the atmosphere or carried from place to place, attached to clothing, merchandise, etc. It is also intelligible that undeveloped germs may in like manner be transported, and find, in situations more or less distant from the places in which they were produced, the conditions favorable for their development. To inquire into the supposed conditions favorable for the development of cholera germs is to open up a field of discussion which cannot be entered upon in this work. The following remarks on auxiliary causes are not less pertinent now than when they appeared in the first edition of this work:—

Auxiliary causes appear to give efficiency to the special cause. Epidemics are chiefly confined to large towns, rarely extending into rural districts. It is not probable that the special cause is limited to cities, but the various local causes of disease peculiar to cities contribute to the production of epidemics either by acting in conjunction with the special cause, or as localized conditions which promote the development of the special cause. This view of the causation has an important practical bearing. If the special cause of cholera be not destroyed, it may be rendered to a great extent inoperative by means of sanitary regulations which remove auxiliary causes. The epidemic prevails mostly in districts in which the hygienic conditions are most unfavorable, in filthy streets, and among the poorer classes, in overcrowded dwellings. Statistical researches by the Registrar-General of Great Britain show the mortality in London from this disease to be in an inverse ratio to elevation.[1] Deprivations, intemperance, depressing emotions, over-exertion, fear of the disease, etc., are auxiliary causes in certain cases, aside from the causes which affect the inhabitants of a place or district in mass. The disease has prevailed in all climates and seasons. Feeble persons are more apt to be attacked than the robust. As regards age, no period of life is exempt, but the largest proportion of fatal cases is among persons advanced in life. Excluding old persons, the mortality is largest after adult age, next in early infancy, and last in childhood and youth. This statement is based on an analysis of 18,400 cases.[2]

Diagnosis.—During the prevalence of cholora, there is no difficulty in recognizing it when fully developed, that is, when symptoms denoting existing or impending collapse are present. There is scarcely any other disease in which the diagnostic features are so strongly marked. But it is vastly important to recognize it before it has advanced sufficiently to manifest its most obvious, striking characters. The diagnosis is then to be based mainly on the characteristic intestinal evacuations. As soon as the so-called rice-water or choleraic stools are apparent, the patient is to be considered as

[1] British and Foreign Med.-Chirurg. Review, July, 1852.
[2] Valleix, *op. cit.*, tome i.

attacked with cholera. In a very small proportion of cases these evacuations do not occur at all, or not until other symptoms characteristic of the disease become developed. The diagnosis in these cases must be based upon the latter.

Cholera is to be discriminated from the simple diarrhœa which generally precedes it, and which, during the continuance of an epidemic, affects a large number of persons without eventuating in cholera. It is probable that this premonitory diarrhœa proceeds from the epidemic cause, but cases are not to be considered as cases of cholera when neither the choleraic discharges nor other characteristic symptoms occur. This discrimination is important with reference to determining the rate of mortality and the value of therapeutical measures. The apparent success attending the practice of some physicians, or the employment of certain methods of treatment, may depend on cases of simple diarrhœa being reckoned as cases of cholera.

This disease is one of the most insidious in its approaches. Aside from a mild diarrhœa, it gives no warning of the attack. So little are patients conscious of danger, that they often apologize for giving the physician the trouble of visiting them, when a glance suffices to show that they are on the verge of collapse. It behooves the physician, in all cases of simple diarrhœa during an epidemic of cholera, to watch carefully the evacuations with reference to the diagnosis. On the other hand, during an epidemic, physicians are not infrequently called to see persons who, under nervous excitement, imagine that they are about to be attacked, when no symptoms whatever of the disease are present. These have been aptly called cases of *choleraphobia*.

Prognosis.—Of those attacked with cholera, a large proportion die. The average mortality in hospitals varies from one-half to one-third. When developed in hospital wards among patients admitted for other diseases, it proves fatal in the great majority of cases. In private practice, especially among the better classes of society, the mortality is considerably less. In individual cases the prognosis is widely different according to the period of the disease at which the patient is first seen. If seen immediately after the attack, before serious blood-lesions have occurred, the prospect of an arrest of the disease is good. But if the disease have advanced to the stage of collapse, the prognosis is always exceedingly unfavorable. After reaction from the collapsed state occurs, the danger is still great, but the cases in which recovery takes place preponderate. The statistical researches of Duchesne show the rate of mortality at different periods of life in the epidemic at Paris in 1849.[1] The proportion in 1000, in subjects under 5 years, was 148; from 5 to 15 years, 50; from 15 to 30 years, 177; from 30 to 45 years, 254; from 45 to 60 years, 206; and from 60 to 85 years, 162. The mode of dying is, in general, typical of asthenia. Accumulation of liquid in the air-tubes very rarely takes place.

Prevention of Cholera.—The prophylaxis of cholera claims consideration under a distinct heading, and I give it precedence over the therapeutical management, in view of its greater relative importance. In addition to the removal, as far as possible, of all the auxiliary causes of disease which contribute to render the special cause of cholera efficient, the prevention involves prompt attention to the diarrhœa which, in the great majority of cases, precedes the attack. This premonitory diarrhœa is amenable to simple measures of treatment, and, if effectually treated, there is reason to believe the supervention of cholera is prevented. All physicians who have had much practical

[1] Valleix, *op. cit.*

acquaintance with this disease will bear testimony, *first*, to the fact that an attack of cholera is generally preceded by diarrhœa, and, *second*, to the fact that an attack very rarely occurs when this diarrhœa receives appropriate attention. Giving results of my own experience with respect to the facts just stated, in 1849, for the space of three months, I prescribed for as many private patients with the premonitory diarrhœa, as my physical endurance would permit, my practice being chiefly among the prudent classes, and I had, during that epidemic, but 10 cases of cholera in private practice. In only one of these 10 cases did I prescribe for any premonitions, and, in the single case, the prescription was for a slight nausea only. In each of the 10 cases, either the premonitory diarrhœa did not exist, or it was neglected. During another epidemic in 1852, I had about the same number of cases of cholera in private practice; in not a single case had I been called upon to prescribe for premonitory diarrhœa, and I prescribed for hundreds of persons with simple diarrhœa, not one of whom had an attack of cholera. The experience of others would doubtless furnish, in like manner, evidence of the above stated facts, and from these facts the following conclusion may be drawn: Excepting the very small proportion of cases in which cholera is not preceded by diarrhœa, it may with almost absolute certainty be prevented. It needs but a little reflection to see the immense practical importance of this conclusion.

The treatment of diarrhœa during a cholera epidemic is very simple. An anodyne, astringent remedy, with regulated diet, rest and recumbency, suffice. A few drops of laudanum, with camphor, or the camphorated tincture of opium in conjunction with the tincture of kino, catechu, or krameria, a salt of morphia or opium with either tannic acid, or the acetate of lead, or bismuth and capsicum, may be given in doses sufficient to arrest at once, and repeated often enough to prevent recurrence of, the diarrhœa. Cathartics are on no account to be given. If there be sufficient constipation to occasion inconvenience, the bowels should be relieved by simple enemas.

The great difficulty, as regards the prophylaxis, is in the prompt application of simple but effectual treatment in all cases of diarrhœa during the epidemic. Very many pay no attention to the premonitory diarrhœa, through ignorance, and not a few of those better informed neglect it, either from recklessness or because they cannot appreciate the fact that a disorder so slight and ordinary can be a precursor of a malady of such gravity as cholera. Public announcements by handbills, articles in newspapers, etc., of the importance of promptly resorting to treatment for diarrhœa, fail in accomplishing the object. The only effectual plan is to organize a sanitary police, and provide for one or two domiciliary visits daily at every house within the limits of the epidemic, the purpose of the visits being to inquire if any one be affected with diarrhœa, to impress the importance of immediate attention to it, and, when circumstances render it necessary, to supply at once appropriate remedies. This plan, faithfully carried out, would, I believe, demonstrate that cholera is in a great measure preventable. The prevention is affected by arresting at once diarrhœa, as often and as soon as it occurs. Abundant proof of the successful operation of the system of the house-to-house visitation was furnished by its practical results in London and other towns in Great Britain during the epidemic of 1849.

Another mode of escaping the disease is to remove without the range of its prevalence. Persons not compelled to remain by necessity, or by a sense of duty, should go beyond the limits of the epidemic; and the removal of persons in districts, where, owing to the activity of auxiliary causes, the disease is especially rife, should be enforced as a sanitary measure, by municipal authority.

The foregoing remarks relate to the prevention of cases of cholera during an epidemic. To prevent the epidemic is an object of still greater importance.

This is to be done by thorough sanitary measures in regard to the removal of filth, attention to sewers, cesspools, and privies, also to wells or other sources of water-supply, together with proper protection against causes of disease from waste-pipes in houses; providing against overcrowding of tenements, etc., and by efficient quarantine regulations. Ships, merchandise, baggage, etc., coming by sea or land from a cholera region, should be effectually disinfected. The clothing of persons from an infected place should be disinfected, but only those need be detained in quarantine who are suffering from cholera or diarrhœa. By these means the introduction of cholera germs may be prevented. If these means do not prove protective, it is because they are not, and, perhaps, cannot be, employed with sufficient completeness; for, with our present views of the causation of the disease, it may be affirmed that, if germs can be completely excluded, cases of cholera cannot occur.

When the introduction of the disease is not prevented, the prevention of its diffusion is practicable by the prompt and effective disinfection of every house in which it occurs. In this way an epidemic is "stamped out." That this is practicable was demonstrated in the city of New York in 1866. A thousand cases occurred in that year in different situations widely separated from each other. Cases occurred in 362 houses, all of which were instantly disinfected, and all local appreciable causes of disease removed. In no instance did the disease extend beyond the house in which a case occurred. These facts are of momentous importance.[1]

Treatment.—To consider the host of remedies and therapeutical measures which have been advocated as more or less efficacious in the treatment of this disease, would require not a little space. There are but few articles in the materia medica which have not been tried, even including antimony and drastic purgatives. Much injury has doubtless been done by over-medication under the idea that the treatment, as regards activity, must be proportionate to the amount of danger from a disease. On the other hand, many of the remedies which have been employed, exert little or no effect either for good or harm. It would be unprofitable to devote space to the consideration of the great variety of practice which the literature of cholera affords. There is no known remedy which is to be considered as a specific, yet there is reason to believe that the disease is frequently controlled by efficient treatment, and, when not arrested, the recovery may depend on the judicious employment of measures for that end. I shall limit myself to a brief statement of the principles of treatment which my own experience and reflections have led me to regard as most consistent with our present knowledge.

The treatment is to be considered as applicable to the different stages, namely, before collapse, during the collapsed stage, and after reaction. Prior to collapse, the paramount object is the arrest of the intestinal effusion. This effusion is the first appreciable link in the chain of morbid sequences, and, if promptly arrested before it has proceeded so far as to affect seriously the blood and circulation, the patient is usually safe. The remedy on which most dependence is to be placed in effecting this object is opium. Some form of opiate is to be given promptly in doses sufficient to effect the object. The form of opiate is to be chosen with reference to promptness of action and the

[1] For further details and the processes of disinfection, which were contained in the preceding edition of this work, *vide* Report of the Metropolitan Board of Health, New York, 1867.

probability of its being retained. Opium in substance is unsuitable from the comparative slowness with which it is absorbed. Laudanum, or the acetated tincture, or an aqueous preparation, is to be preferred. But the article which I have been led to regard as the most eligible is a salt of morphia, administered by placing it dry upon the tongue. In the endeavor to effect the object of treatment in this stage, moments are precious, for there is always danger that, if the object be not promptly effected, the patient will fall into the collapsed state. The opiate should, therefore, be given at once in a full dose. A grain of a salt of morphia is rarely, if ever, too large a dose for an adult. A physician should, if possible, remain with the patient. If the first dose be quickly rejected, a second should be instantly given. The remedy is to be repeated at intervals of from half to three-fourths of an hour, until the dejections cease. If, owing to the occurrence of vomiting, the administration by the mouth be ineffectual, it should be given by the rectum; and, in cases in which the symptoms are urgent, both modes of administration should be resorted to. The system, even in this stage of the disease, is not readily affected by opiates thus given. In view of the importance of the object, if it be necessary in order to effect it, some risk of inducing narcotism is justifiable; but if the administration be in the hands of the physician, and the effects of the doses watched with care, danger from this source may be avoided. The practical point is to employ the remedy promptly so as to effect the object, bearing in mind that the delay of half an hour or an hour is often fatal. Relying upon the opiate, it is best not to add other remedies, lest by increasing the bulk of the doses they will be more likely to be rejected. A full dose is preferable to small doses frequently repeated, because the effect within a short space of time is greater, and the remedy is more likely to be retained. Aside from the rejection of the remedy, vomiting is, if possible, to be prevented in view of its perturbatory effects. The patient, in this stage, should be restricted to a very small quantity of water, or spirit and water, given at short intervals, or to small pieces of ice. Perfect quietude is important. He should not be permitted to get up to go to stool, and he should be urged to resist, as much as possible, the desire to evacuate the bowels. Frictions, the warm bath, sinapisms, etc., in this stage, are useless and hurtful.

I have repeatedly succeeded in arresting the disease by this plan of treatment, and when arrested before the stage of collapse, the recovery is usually speedy. Regulated diet, rest, with perhaps a tonic remedy, suffice for the cure. The bowels should be allowed to remain constipated for several days, and then, if movements do not spontaneously occur, simple enemas will probably be sufficient; if not, a little rhubarb or some other mild laxative may be given. I believe no other plan of treatment promises more than this, but it is not to be expected that it will always prove successful. It will fail, or rather it is not available, when, owing to the persistent vomiting and frequent purging, the remedy is not retained sufficiently long to exert its effect; and it is not available when, owing to the great rapidity of the transudation, the state of collapse occurs so quickly that there is not time enough to obtain a remedial effect. These difficulties are equally in the way of success from any remedies.

The foregoing remarks on the treatment prior to the phenomena of collapse were written before the hypodermic method of administering opiates and other remedies had come into vogue, and the inquiry has arisen whether, by means of this method, the opiate plan of treatment of cholera, in the first stage, may not be carried out more efficiently than by giving opiates by the mouth or rectum. Considering the vast importance of the promptness of the effect of opiates, and the uncertainty attending their administration by the mouth or rectum, owing to their rejection by vomiting or purging, and the

difficulty of absorption if they be retained in the alimentary canal, the hypodermic method seems to offer a great advantage as regards speediness and reliability of effect. The hypodermic injection of Magendie's solution of morphia was employed in a large proportion of the cases which came under my observation in 1866. The vomiting, purging, and cramps were generally arrested promptly by this measure; recovery, however, followed in a very small proportion of cases. So far as my experience goes, it affords evidence of the efficiency of the measure with regard to the immediate objects, namely, the arrest of the vomiting, purging, and cramps, but it does not afford proof of its curative efficacy. With regard to the latter, the character of the patients is to be borne in mind, nearly all who were seen in the first stage being inmates of the hospitals, and many being affected, when attacked with cholera, with some serious chronic disease such as phthisis, Bright's disease, etc. The hypodermic injection of a solution of morphia, in this disease, is to be employed with circumspection. Narcotism is sometimes induced by an amount much below that which might be given by the mouth without risk. I have known a little less than a grain, given in two injections, with an interval of two hours, to produce deep narcotism. The tolerance of opiates in large doses by the stomach or rectum is not a criterion of the quantity to be injected beneath the skin in epidemic cholera.

Rectal injections of brandy and a strong tea-infusion were used considerably, with apparent efficacy in arresting the evacuations and preventing collapse. The proportions used were half an ounce of brandy and two ounces of the tea-infusion, the injections being repeated every half hour, every hour, or after longer intervals, according to circumstances.

In the stage of collapse, the plan of treatment indicated prior to this stage may prove not only ineffectual, but hurtful. It is still an object to arrest intestinal transudation, if it continue; but to employ opiates largely for this object is not judicious with reference to the recuperative efforts of the system. The symptoms in this stage are due, mainly, to the damage which the blood has sustained in the loss of its constituents from the transudation which has already taken place. Opiates may be given, and, owing to the remarkable degree of tolerance under these circumstances, they may be given in considerable doses, but much care should be observed not to induce narcotism. They should be given by either the mouth or the rectum; never, in this stage, by the hypodermic method. Astringent remedies, if the stomach will retain them, may be added, such as tannic acid, the acetate of lead, bismuth, etc. If, however, these or other remedies provoke vomiting, they will do more harm than good. Remedies to allay vomiting may be tried, namely, the hydrocyanic acid, creasote, chloroform, etc.

In a large proportion of cases after collapse has taken place, little can be done with much hope of success. Even if the vomiting and purging cease, recovery may not follow. The blood may have been damaged irremediably. Under these circumstances it is plain that active treatment can effect nothing. Recovery, however, in a certain proportion of cases, takes place, and under a great variety of treatment. It may take place when no treatment is pursued. My first case of cholera, in 1849, illustrated the fact just stated. The patient was brought into hospital completely collapsed. I remained with him several hours, and resorted to various therapeutical measures. At length all measures were discontinued. He was allowed to drink abundantly of cold water, under the impression that the case was utterly hopeless, and, therefore, the indulgence could do no harm. Much to my surprise, after an absence of several hours, I found the vomiting and purging had ceased and reaction was coming on. He recovered rapidly. I have been led to doubt whether any active

treatment is of use in the collapsed stage, and I cannot doubt that it is often prejudicial. The object of treatment in this stage, aside from the arrest of vomiting and purging, is to excite and aid the efforts of nature in restoring the circulation, together with the functions dependent thereon. The measures to be employed for this object are external warmth, stimulating applications to the surface, diffusible and other stimulants, and alimentation.

The application of heat may be made by means of warm blankets, or bottles of hot water placed near the body. The more active modes of applying heat are of doubtful propriety. I have never seen benefit from the warm bath, or the application of steam or hot air. It is not desirable to excite perspiration, and, if perspiration occur, it should be wiped away with warm, dry cloths. Violent friction does more harm than good. The surface may be gently stimulated with sinapisms or the tincture of capsicum. Diffusible stimulants, in the form of spirits and water, should be given as freely as the stomach will bear, always recollecting the risk and the evils of inducing vomiting. They will be most apt to be retained if given in small quantities at a time, and often repeated. If vomiting be provoked by either drinks, remedies, or aliment, more or less injury is done. The ethers, stimulants such as capsicum, the essential oils, cardamom, ginger, etc., are appropriate if they be grateful to the stomach and retained. Concentrated nourishment—essence of meat, chicken-broth, and milk—is to be given in small quantities at a time, provided the stomach will retain it. It is doubtless desirable to introduce liquid into the system as far as possible. The only objection to the free ingestion of water is the risk of provoking vomiting. Small lumps of ice should be freely allowed.

If the patient emerge from the collapsed state, the indications are to support the system by the moderate use of stimulants and by alimentation; to restore the function of the kidneys by diuretic remedies and mucilaginous drinks, bearing in mind that uræmia belongs among the dangers of this stage; to restrain diarrhœa, if it occur, by anodynes and astringents; to strengthen by tonics, and to palliate, by appropriate remedies, the various symptoms which may arise.

The disinfection of the intestinal excreta, in cases of cholera, is important in view of the reasonable probability that they contain cholera germs; and, during the prevalence of an epidemic, it is desirable that this precautionary measure be resorted to in all cases of diarrhœa.

CHAPTER IX.

INTESTINAL WORMS.

Ascaris Lumbricoides. Oxyuris Vermicularis. Tricocephalus Dispar. Ascaris Mystax. Tænia. Trichina Spiralis. Anchylostoma Duodenale.

OF the various *entozoa* which dwell within the human body, the larger number are developed in the intestines. They give rise to more or less disturbance, and are properly enough considered in connection with the functional disorders of the alimentary canal. I shall treat of intestinal worms only in so far as concerns the practical duties of the physician. The study

of these and other parasites, as belonging to comparative anatomy and physiology, and as a branch of zoölogy, is highly interesting, and has led to valuable practical results, but other points than those which relate directly to them as involving morbid conditions would be here out of place.

The intestinal worms of frequent occurrence are the *ascaris lumbricoides*, lumbricoid or round worm, and the *oxyuris vermicularis*, thread or seat-worm. The worm known as *tricocephalus dispar* is probably sufficiently common, but of little or no practical importance. The different species of *tænia*, or tapeworm, are of rare occurrence in this country, but constitute an important affection. These different worms will be noticed under distinct heads. The worm called *anchylostoma duodenale* will be noticed in connection with the cylindrical worms. And, as appropriately classed among the intestinal worms, because they are received and developed within the alimentary canal, the *trichina spiralis* will be considered in this connection.

Ascaris Lumbricoides.

With this worm every young physician soon becomes familiar. It resembles the common earth-worm. It is the most common of all the intestinal worms. It is of a whitish or yellowish color; the body is round, fusiform, and marked by numerous fine transverse rings. The mouth is surrounded by three tubercles. The sexes are distinct. The males usually measure from four to six inches in length, and the females from ten to fourteen inches.

The common lumbricoid worm inhabits the small intestine. It rarely exists in early infancy, and is most common between the ages of three and ten. It is not very uncommon in adults, but is extremely rare in old age. This species of worm is not usually solitary. In different cases the number of lumbrici varies greatly. Sometimes the number is very great, and in autopsical examinations they are occasionally coiled together so as to form balls or masses of considerable size. Cruveilhier cites a case in which over a thousand were found after death. They are not infrequently brought into the stomach by acts of vomiting and ejected from the mouth. They may find their way into the nares, and they have been known to pass into the Eustachian tube, frontal sinus, and larynx. They may migrate from the intestine into the biliary ducts and gall-bladder. In a subject dead with lumbar abscess connected with caries of the vertebræ, I found a great number within the hepatic ducts, some extending along the ducts, and others coiled up. They may possibly give rise to hepatic abscess. They may penetrate into the pancreatic duct. They have been found in the peritoneal cavity and in abscesses within the abdominal walls. In these cases they escape through intestinal perforations caused by ulceration or sloughing incidental to other morbid conditions; it is not probable that the worms ever perforate the intestines, as was formerly supposed. They have been observed to escape from the body through fistulæ communicating with the intestinal canal.

The symptoms denoting the presence of these, or other worms within the intestinal canal, are obscure. A host of symptoms having little or no significance have been enumerated by writers. Nothing is more common than the passage of lumbrici from the stomach or bowels when there had been no symptoms of disorder. The morbid effects have heretofore been greatly exaggerated. These worms, it is probable, very rarely give rise to serious results except when they migrate into the biliary or pancreatic ducts, the Eustachian tube, or the larynx, and these migrations are exceedingly infrequent. There is no foundation for the belief that they give rise to a form of fever, as implied by the term *worm fever*. They are not infrequently, in cases of fever, passed from the bowels, and found in the intestine after death; but their

presence is merely a coincidence. That they may give rise to convulsions, epileptic paroxysms, chorea, and other affections of the nervous system, as is generally supposed, must be considered as by no means established.

Symptoms generally regarded as denoting these worms are colic pains, tumefaction of the abdomen, impaired appetite, excessive flow of saliva, diarrhœa, itching of the nose, swelling of the face, offensive odor of the breath, disturbed, dreamy sleep, and grinding of the teeth during sleep. It is never prudent for a physician to declare positively that a child between three and ten years of age has not worms, for he is liable to be convicted of error by the operation of a vermifuge given without his sanction; but the only readily available diagnostic proof is the presence of one or more in the stools. When more or less of the above-named symptoms are present, a brisk purgative may be given, and the stools examined, with reference to diagnosis. If one or more worms be passed, it is proper to act as if there were others remaining. According to Davaine,[1] a microscopical examination of the feces will show the characteristic ova, if lumbrici be present. He states that their ova are readily recognized, and hence the diagnosis may be made positive in this way. Practitioners in general, however, will be satisfied to base the diagnosis upon other facts.

The lumbricoid worm is propagated by ova. The body of a female lumbricus contains a vast number of eggs, estimated by Eschricht to be sixty-four millions. These ova are discharged with the feces. The observations of Davaine and others show that their vitality is retained for many months. Their ingress into the alimentary canal is probably by means of water containing them; and, finding in the small intestines favorable conditions, the production of the worms takes place. That special conditions are required may be inferred from the fact that these worms are so common in certain periods of life, and so infrequent at other periods. As regards the nature of the conditions, we have no positive knowledge; mucus in abundance is supposed to be a favorable nidus for their production.

The expulsion of lumbricoid worms is generally effected without difficulty. Premising a brisk purgative, which is sometimes alone sufficient, an anthelmintic remedy is to be given for several successive days. Of the various anthelmintics, those best suited for the destruction of these worms are chenopodium or wormseed, santonin, and spigelia or pinkroot. Santonin is most easily administered, and perhaps as effective as the other articles. The dose is from 3 to 6 grains, repeated three or four times daily, given either mixed with sugar, or made into *dragées* or troches. Wormseed is taken most conveniently in the form of the oil. From 5 to 10 drops may be given three times daily mixed with sugar or in an emulsion. The pinkroot has long been relied upon as an efficacious remedy. The infusion may be used, but the fluid extract of spigelia and senna is the most eligible form, the dose being from 1 to 4 drachms three times daily. Tanacetum or tansy, and absinthium or wormwood, are doubtless efficacious remedies. All these remedies act toxically, that is, by poisoning the worms. After two or three days, a brisk purgative should be given. If with this treatment no worms be discharged, their non-existence may be inferred. If worms be brought away by this treatment, it need not be continued or repeated unless, from the continuance or recurrence of symptoms denoting disorder, it be inferred that

[1] Traité des Entozoaires et des Maladies Vermineuses de l'Homme et des Animaux Domestiques, 1860. The reader is referred to this work as treating of entozoa minutely and comprehensively. Also, Heller, in Ziemssen's Cyclopædia, vol. vii., Am. ed.; Leuckart, Die menschlichen Parasiten, Leipzic, 1863–1876; and Cobbold's Treatise on Parasites, London, 1879.

their expulsion is not complete. The absence of the ova in the stools, according to Davaine, may be relied upon as proof positive of the absence of the worms.

With a view to prevent the ingestion of the ova of lumbrici, attention should be directed to the purity of the water used as drink. Water from shallow wells in the neighborhood of dwellings and small rivulets should be avoided. Filtration would probably prove effectual in the way of prophylaxis. Davaine states that it is not common in Paris for children and others to be affected with this worm, a fact which he attributes to the custom of using filtered water.

Oxyuris Vermicularis.

This worm, called also *ascaris vermicularis* and commonly known as the thread, pin, seat or maw-worm, inhabits the large intestine, and especially the rectum. The size is small, as indicated by certain of the names in common use, and the length varies from two to five lines. The vermicular oxyurides frequently exist in immense numbers, and they are sometimes voided in large masses or balls agglomerated by mucus. They occur especially in young children, but they are not extremely uncommon at any period of life. I have met with several examples of their occurrence in aged persons.

These worms occasion pain in the rectum, tenesmus, and, more especially, pruritus at the anus. The latter symptom, which is often due to an herpetic eruption in this situation, should always excite suspicion of the presence of these parasites. The itching is apt to occur in paroxysms, and is particularly troublesome at night. Excitation of the sexual organs is apt to occur, with seminal emissions, and it is stated that the habit of masturbation, in either sex, may originate from this source. In girls the worms sometimes migrate into the vagina and occasion pruritus with leucorrhœa. The diagnosis is made without difficulty. On examination of the stools, the worms are seen, in greater or less number, adhering to the feces; and on an ocular inspection of the anus they may generally be discovered. It is doubtful if they ever lead to any serious disorders, but, owing to the irritation which they occasion, and the loss of sleep, the general health may become more or less impaired.

The treatment is simple and efficacious, but it may require a certain amount of perseverance. The same anthelmintics may be employed as for the destruction of the lumbricoid worms, and given in the same way. Purgative remedies are to be given from time to time. In addition, enemas of either cold water, salt and water, or soap and water, are to be administered once or twice daily. These are to be continued for a fortnight, or longer, until all the local symptoms disappear. The treatment by enemas will frequently alone prove effectual. Various remedies in enemas have been advised, such as wormwood, vinegar, empyreumatic oil, assafœtida, camphor, sulphide of potassium, etc. Injections containing a small percentage of carbolic acid are efficacious. Infusion of quassia and decoction of aloes are also useful in enemas. The irritation or slight inflammation about the anus, which is sometimes caused by the presence of these worms, may be relieved by the application of a soothing unguent, or the daily injection of a little almond or olive oil. Extreme cleanliness is essential in the treatment. Zenker and Heller have found the eggs of this parasite beneath the nails. The danger of autoinfection from this source should be guarded against.

Tricocephalus Dispar.

This worm, as the name tricocephalus denotes, is characterized by the hair-like appearance of the cephalic extremity. It is from an inch and a half to two inches in length. The filiform cephalic portion forms about two-thirds of its length. As in the ascaris lumbricoides and the oxyuris vermicularis, the two sexes are distinct. The tail of the male is curved, that of the female is straight and bluntly pointed. It inhabits the cæcum especially, but is sometimes found in the colon, and, very rarely, in the small intestine. The propagation is by ova which, according to Davaine, are readily recognized by means of the microscope in the dejections. The parasite is found frequently, when sought after, in the bodies of subjects of all ages dead with different diseases. Some years ago, when engaged in examining bodies dead with typhoid fever, I was led to examine the cæcum for it, and I rarely failed to find one or more. It is not positively known that its presence gives rise to disorder. Barth, of Paris, reported a case in which death took place with the symptoms of meningitis, and after death no lesions were found within the head, but the intestines contained an enormous quantity of worms of this species.

The foregoing species of intestinal worms belong in the class styled by helminthologists *nematoda*, or cylindrical worms (see Part I. p. 95). Another worm belonging to this class was described by Bellingham under the name *ascaris alata*. It is the same parasite as the ascaris mystax which infests the dog and cat. According to Cobbold, about seven instances of its occurrence in man have been noted. This parasite, as regards its practical importance, is in the same category with the tricocephalus dispar.

Tæniæ or Tapeworms.

On the natural history of tæniæ, constituting the class *cestoda* in helminthology, and commonly known as tapeworms, much light has been shed by the researches of Küchenmeister, Von Siebold, Leuckart, and others. Referring the reader to other works for a full account of these researches, suffice it to say that different varieties of tænia have been shown to be the cystic entozoa known as *cysticerci* and *echinococci*, in a state of maturity or complete development. A cysticercus is an immature or undeveloped tapeworm. Different varieties of cysticerci are found in the solid parts of different animals, and each variety, received into the alimentary canal of another animal, and finding there favorable conditions, becomes a perfect worm or tænia, each kind of cysticercus becoming a particular kind of tænia. A cysticercus, on the other hand, is the product of the ovum of a tænia. The eggs of the tænia, passing out of the body, finding their way into the bodies of men and other animals, and probably entering into the circulation, are transported to, and fixed in, solid parts, where they become cysticerci. The latter, as long as they remain in solid parts, reach only a certain stage of development; if, however, the parts containing the cysticerci are eaten by another animal, they attain to their complete development in the alimentary canal of the latter. Thus a particular cysticercus found within the liver of the rat, if eaten by the cat, is developed into the kind of tapeworm frequently found in the intestine of the latter; and the ova from this tapeworm received into the body of the rat give rise to the kind of cysticercus found in the liver of this animal. The ovum from the tænia of the dog, received into the body of the sheep, becomes the cystic entozoon, called *cœnurus cerebralis*, found in the brain of the latter, which, if eaten by the dog, becomes the tænia found in the intestine of this animal. These highly interesting, and, in a practical view, important, facts have been substantiated by observation and experiment.

The tænia or tapeworm is distinguished, as these names import, by its ribbon-like form. It is composed of numerous segments or joints, called proglottides, each one of which, after it attains to its full maturity, is provided with male and female generative organs. Several varieties have been found in man, but, as regards medical practice, the discrimination is not of much importance, the same measures of treatment being alike applicable to all. In the vast majority of cases, the tænia developed in the human intestine is one of three kinds; it will suffice to notice these. In this country, of the three kinds of tænia, the one which has been supposed to be most common is the *tænia solium*, or solitary tænia, so called because it is supposed always to exist singly. This is true as a rule, with some exceptions; two or more tænia have been observed together, but instances are rare. The tænia solium varies in length from four or five to thirty-five feet, the number of segments or joints varying from 800 to 1000. Towards the head it becomes attenuated, forming a thread-like neck of considerable length, and in this portion there are transverse markings or rugæ, but no visible joints. The joints succeeding the neck are about as long as they are broad, but lower the length is twice or thrice the breadth. From the resemblance of these joints to the seeds of a gourd, the worm has been called *vermis cucurbitinus*, or gourd worm. The generative foramina are placed near the middle of one of the margins of each joint, and are generally alternate. The head is about the size of a pin-head, hemispherical or triangular in form, and, under the microscope with a low power, it is found to present four projections or suckers, and a coronet of 26 alternating short and long hooklets surmounting a projection called the rostellum. The joints of the inferior part are constantly thrown off, and are passed almost daily by stool. These exfoliated joints contain an immense number of ova. Bennett quotes an estimate of the number of ova in the tapeworm of a cat to be 12,500,000. It is fortunate that worms are not developed from the ova within the alimentary canal!

The second variety, called *tænia mediocanellata* (*tænia saginata*), has not until within late years been generally recognized as distinct from the tænia solium; and the relative frequency of its occurrence in this country has not as yet been ascertained. It is probable that here, as in England and Germany, it is more common than the tænia solium. The generative foramina are situated alike in both varieties; but the joints are longer and thicker, and the head has four suckers without hooklets or rostellum.

The third variety is known as the *tænia lata*, or broad tapeworm, reckoned by some helminthologists as a species distinct from the true tænia, and named *Bothriocephalus latus*. This worm is distinguished from the tænia solium by the breadth of the joints, which are broader than long, by the situation of the genital orifices, which are in the middle of the joints, and by the different conformation of the head. The head is unprovided with hooklets, and hence this and the second variety are distinguished as the unarmed tænia, while the tænia solium is said to be armed. The form of the head is elongated, and, instead of suckers, it has two lateral longitudinal depressions or fossæ; hence the name *bothriocephalus*, from βοθριον, a small pit. This worm may attain to even a greater length than the tænia solium. Like the latter, it is usually solitary. A tænia called *Bothriocephalus cordatus*, distinguished by the form of the head, is only known to infest the inhabitants of North Greenland.

Of these varieties of tapeworm, tænia mediocanellata and tænia solium are the ones commonly met with not only in this country but in most countries. As already remarked, tænia mediocanellata seems to be the most common. Bothriocephalus latus has been observed chiefly in Russia, Switzerland, and Ireland. It is observed that this variety is apt to affect inhabitants living on the coasts of seas, lakes, and rivers, whence it has been inferred that it

proceeds from a cystic entozoon existing in fish. The opinion, however, is also entertained that the embryos of this worm may be taken into the system in drinking water and developed in the intestine without the intermediate stage of cystic development in the solid parts. The tænia solium is attributable to the ingestion of the *cysticercus cellulosæ* which is common in the flesh of swine. It is the presence of this entozoon in large numbers which renders pork "measly." Pork, eaten raw or partially cooked, is the source of this form of tapeworm. Thorough cooking destroys the cysticercus, and the development into the tapeworm does not then take place. It is a matter of observation that butchers and cooks are prone to tapeworm, and it is stated that in Abyssinia, where the custom of eating uncooked meat prevails, nearly all persons, of different ages, become affected with tænia. The production of tænia in children by the use of raw meat as food, in cases of so-called cholera infantum, has been already adverted to. The tænia mediocanellata is derived from a cysticercus found in beef. Tænia solium is the pork tapeworm, and tænia mediocanellata is the beef tapeworm. The frequency of one or of the other of these species in a given district bears a strict relation to the amount of underdone measly pork, or beef consumed by the inhabitants.

The habitat of a tapeworm is the small intestine. When it attains to a great length, it extends into the large intestine, and has been found to reach nearly to the anus. No age is exempt from the liability to its occurrence, but, in the majority of cases, the ages are between twenty and forty years. It occurs oftener in females than in males. Professor Armor has reported a case in which an infant five days old passed segments of tænia. Two months after the birth of the child the mother was treated for tænia.[1] The frequency of its occurrence varies much in different countries and in different sections of the same country. The report of the military surgeons of the French army from 1840 to 1848 showed only seven cases among 250,000 soldiers. During a practice of forty years I have not met with more than from thirty to forty cases.

The existence of a tapeworm is not denoted by well-marked diagnostic symptoms. The symptoms attributed to it are vertigo, tinnitus aurium, disturbance of vision sometimes amounting to temporary amaurosis, pruritus at the nose and anus, salivation, disordered appetite and digestion, colic or neuralgic pains in the abdomen, and emaciation. These are symptoms which may be due to other morbid conditions, nor are these symptoms uniformly, if generally, marked in cases of tapeworm. The existence of the worm is often discovered accidentally, and in persons who, prior to the discovery, considered themselves perfectly well. In the case of a young female affected with sciatic neuralgia, I was led to prescribe a full dose of turpentine, and the result was the expulsion of a large quantity of tapeworm, the existence of which had not been suspected. After the existence of the worm is known, disorders of all kinds are apt to be referred to it, and often the imagination creates various morbid sensations. Convulsions, epilepsy, and chorea are supposed to be occasional effects, but clinical observation supplies but little data for this supposition. The pathological effects of the presence of this worm have doubtless been greatly exaggerated. Tapeworms are almost invariably found in the intestines of dogs destroyed for experimental purposes apparently in perfect health.

The diagnosis must rest on the discovery of detached joints or segments of the worm in the evacuations. This mode of diagnosis is always available. Segments are generally passed at short intervals, and hence it is usually not long before its existence is ascertained. If there be reason to suspect its

[1] Detroit Review of Medicine, Jan. 1872.

existence before segments have been seen, a brisk purgative may be given, and this will be likely to be followed by the expulsion of a greater or less quantity. If an examination of the stools for some time, and especially after the administration of purgatives, fail to discover any portions of the worm, the physician may be satisfied of its non-existence. Persons not infrequently fancy they have a tapeworm. This is one of the notions likely to be seized upon by hypochondriacs, and in some cases the notion becomes a fixed belief, of which the mind cannot be dispossessed, becoming, in fact, an insane delusion. Several instances of this kind have fallen under my observation. A few instances are on record in which portions of the worm have been vomited.

With reference to treatment, a point of importance is the natural duration of the life of this parasite. It is undoubtedly long-lived. It is not uncommon for fragments to be passed at short intervals for many years. Cases have been reported in which this was observed for twelve, twenty-five, and even thirty-five years. If an interval of several months elapse without any segments having been discharged, and subsequently they make their appearance, it is probable that a second worm has become developed. Sooner or later, the worm dies a natural death, and a cure takes place spontaneously. If successive remedies have been used in such a case, the last remedy, of course, gets the credit of having effected a cure. For a cure to be effected with certainty, the head must be expelled. The frequent exfoliation of segments is natural, and if, as an effect of a remedy, or from any cause, a large portion, or even all the body be expelled, reproduction by growth may take place as long as the head remains; it is, however, a matter of observation that the parasite is apt to die when the separation takes place near the head. As positive evidence of a cure, the head is to be sought for, but it is not found in the larger proportion of the cases in which a cure is effected.

Of the remedies to be employed for the destruction of the tapeworm, one of the oldest, and, certainly, in many cases an effective remedy, is the oil of turpentine. It is most likely to be effective if given in large doses. A half ounce may be given in emulsion, with the addition of some aromatic tincture to prevent nausea, this dose being repeated every half hour until two or three ounces are taken, or, sometimes, the whole amount taken at once is well borne. Strangury is an occasional result, but is less likely to occur than when the remedy is given in small doses. After a large dose, the patient feels as if slightly inebriated. This remedy, thus given, may be repeated, if necessary, after intervals of several days. Given in the quantity just stated, it generally acts as a purgative. Chabert's empyreumatic oil, which has been much in vogue as a remedy for tænia, is probably efficacious chiefly from the turpentine which enters into its composition, and is much more disagreeable than the turpentine alone. It is stated by Bellingham and others that turpentine, given in moderate doses, and repeated for several successive days, is frequently successful.

The male fern (*filix mas*) is a tænifuge, the efficacy of which rests upon the testimony of many observers of large experience. In my own experience it has proved promptly efficacious. It may be administered in powder, from half a drachm to a drachm being given in divided doses in the course of a few hours; but the oil and ethereal extract are more eligible preparations. The oil may be given in doses of a drachm in mucilage, or in gelatine capsules; the dose of the extract is from 20 to 30 grains. Dr. Alexander Fleming advises a drachm of the oil, with mucilage, to be given in an ounce and a half of sweet milk, at bedtime, the dinner and evening meal of the day having been omitted. This mode of administration is advised on the supposition that milk being a favorite food of the worm, it is more effectually poisoned by imbibing the remedy in this vehicle.

Another effective tænifuge is the kousso (*brayera anthelmintica*), the dried flowers of a tree in Abyssinia where tapeworm is exceedingly common. This remedy is said to be relied upon in that country. Within the past few years it has been used with much success in Europe and in this country. Half an ounce of the powdered flowers mixed with water may be given in a dose, both the liquid and sediment being taken.

Another remedy is an emulsion of pumpkin-seeds (*cucurbita pepo*). The emulsion is prepared by pounding a couple of ounces of the seeds in a mortar with half a pint of water and straining through cloth. This quantity will constitute a dose which may be repeated for several days. This remedy has proved successful in the hands of a number of physicians in this country. It has the advantage of producing no unpleasant effects, being, aside from its action as a vermifuge, innocuous..

The bark of the pomegranate root (*punica granatum*) is another anthelmintic remedy which has been found destructive to the tapeworm. A decoction made by boiling two and a half ounces of fresh bark in a pint and a half of water until this quantity is reduced one-half, is the form in which this remedy is to be administered. The whole of the quantity just named may be given in the course of a few hours. It generally produces purging and not infrequently vomiting. Kameela, the powder and hairs from the capsules of Rottlera tinctoria, is a powerful anthelmintic which has been found promptly efficacious in cases of tænia. The dose is from one to two drachms given in honey or thick gruel. It acts efficiently as a purgative. This remedy has been given with great success in combination with the ethereal extract of the male fern. Carbolic acid in doses of half a grain or a grain given hourly, if well tolerated, throughout the day, followed by a cathartic, has been found efficacious.

These are the most valuable of the anthelmintics which experience has shown to be capable of destroying the tapeworm toxically. The powder of tin (*pulvis stanni*) given in doses of a scruple or more, mixed with honey, has, in some cases, proved efficacious, destroying, probably, the worm by its mechanical action. It is far less reliable than the toxical remedies. Active cathartics, such as calomel and jalap, scammony, gamboge, and croton oil occasionally succeed, their action, probably, being mechanical. They will generally bring away greater or less portions of the worm, but, alone, they are not to be relied upon for effecting a cure, that is, for destroying the worm. In conjunction with the toxical anthelmintics, they are generally useful.

The success of the treatment will depend much upon accessory measures. The worm is nourished, not by nutriment sucked from the intestinal walls, but from the alimentary contents of the intestine, which enter the body of the parasite by endosmosis. An important part of the treatment, therefore, is to weaken the parasite by starvation. The patient, by way of preparation for the administration of the tænifuge, should abstain from those articles of food which are digested in the small intestine, for at least a day or two. Beef-tea or chicken-soup may be allowed freely. The treatment should commence with a mild purgative, and the administration of the anthelmintic remedy should be followed, after a few hours, by a pretty active purgative. If the treatment prove unsuccessful, the strength of the patient should be restored by a return to a full diet and tonic remedies, and the same plan again repeated, employing the same remedy or selecting another. The treatment is to be repeated, allowing sufficient intervals for recruiting the strength, until a cure is effected. It is to be borne in mind that, if the greater part of the worm be expelled, although the head may not be found, the death of the worm is apt to follow, and the treatment, therefore, need not be repeated, until the discharge of fragments is again observed.

The prophylaxis involves care never to eat meat not thoroughly cooked. In meat much underdone, the cysticerci which may be contained in it are, perhaps, not destroyed. Purity of the water used as a drink may be an important measure of prevention. The use of filtered water is to be recommended. The meat contained in the Bologna sausages is liable to contain living cysticerci. In view of the danger of acquiring a tapeworm, it is doubtful if it be ever judicious to advise raw beef or pork as an article of diet.

Trichina Spiralis.

From the discovery of the *trichina spiralis* by Paget and its description by Owen, in 1835, up to a recent date, this parasite had been observed occasionally in the muscles of subjects in the dissecting-room, but, in a pathological view, it was not considered to have any importance. Facts, however, accumulated within the past few years, have shown that the introduction and multiplication of *trichinæ* within the body of man may give rise to morbid effects of great gravity, which often prove fatal. Much information has been obtained respecting the natural history of the parasite, the circumstances under which the human body becomes infested by it, and the morbid phenomena which characterize the disease. This information has added to the nosological catalogue a new and highly important affection known as the *trichinal* or *trichinatous* disease, *trichinosis* or *trichiniasis*.

The trichina spiralis belongs in the class *nematoda*. As found in the muscles, it is coiled up in a cyst containing a granular substance at first, and afterward, calcareous matter. When expelled from the cyst, the parasites are seen to be round worms, $\frac{1}{25}$ of an inch long, and $\frac{1}{625}$ of an inch in thickness. So long as they remain in the muscular tissue, the worms are quiescent. When, however, they are taken into the stomach, and set free by the action of the gastric liquids upon the muscular tissue and the cyst, they pass from the stomach into the intestinal canal, and immediately begin to grow rapidly, attaining to three or four times their former size; they acquire fully developed generative organs, copulate, and, at the end of a week, the female parasites contain living young in great abundance. According to Virchow, each trichina gives birth to 200 young; Gerlach says 400, and Leuckart 1000. The young trichinæ, shortly after birth, penetrate the mucous membrane, and find their way rapidly to the different muscles throughout the body. They appear to select the voluntary muscles for their permanent dwelling-place. It is stated that they have not been found in the muscular walls of the heart. In other than muscular organs they are rarely found.

Trichinæ are found especially in the muscles of swine; but they have been found in the muscles of various other animals, namely, eels, cats, rats and mice, dogs, badgers, hedgehogs, and moles. They get into the bodies of swine from their feeding upon the flesh and excrement of other animals infested with these parasites, especially rats and mice. Hence, to prevent trichiniasis in swine, and in other animals which serve as food for man, it is highly important to cut off all the sources of the disease in the diet of these animals. They find their way into the alimentary canal of man chiefly from eating trichinous pork not subjected to processes of cooking sufficient to destroy the parasites. They are not destroyed by salting or smoking, and they may retain their vitality in roasted or broiled meat much underdone. To secure effectually their destruction, every portion of meat which is eaten should have been subjected to thorough cooking. The custom which prevails among the Germans of eating sausages and smoked hams uncooked, involves a liability to the disease. It has been traced to eating pork chops which were under-

done in the centre, although sufficiently cooked on the outside. Meat abounding in trichinæ may present no evidence of the fact as regards the gross appearance, especially if a calcareous deposit have not taken place in the cysts which contain them; hence, trichinous meat may be sold and bought without any suspicion of its being unwholesome. The only reliable evidence of the presence of trichinæ in the meat procured for food, is afforded by microscopical examination. The trouble, however, of such an examination precludes its being generally resorted to as a means of protection. Moreover, a microscopical examination of a few specimens is not adequate to determine that trichinæ are not present. They may not be found in the few specimens examined, although present in other portions. Hence, this test is only reliable in a positive, not a negative, point of view.

After becoming encysted in the muscles the trichinæ retain their vitality for an indefinite time. In one case trichinæ were found encysted and alive in portions of muscle attached to a cancerous tumor removed from a patient. The previous history of this case showed conclusively that the patient was affected with trichiniasis twenty-four years before the operation.[1] The flesh of animals, therefore, which have been affected with trichiniasis, ever afterward will be likely to contain living trichinæ. Moreover, the flesh of a single trichinous animal may produce trichiniasis in a very large number of persons, so that the disease in its prevalence may present the character of an epidemic. Muscular trichinæ, however, may after a time become completely calcified, in which case they are innocuous.

The clinical history of the disease caused by trichinæ is highly important with reference to an early diagnosis. The primary symptoms relate to the alimentary canal, and are due chiefly to the perforation of the mucous membrane by the newly-produced worms. Abdominal pains, vomiting and diarrhœa characterize the first stage of the disease. These symptoms occur within ten days after the ingestion of trichinous meat, that is, as soon as the young worms have been produced and become developed so as to begin to migrate toward the muscles. It is not difficult to understand that the aggregated punctures of the mucous membrane by these parasites should occasion notable disturbance, when it is considered that the trichinæ which have been found to be contained in a half pound of meat may be sufficient to give birth, in a few days, to a brood numbering 30,000,000. It is stated that peritonitis may be produced by the passage of worms into the peritoneal cavity.

The secondary symptoms relate to the muscles. Pains resembling those of myalgia are occasioned by the entrance of the trichinæ in the muscles. Certain of the muscles become contracted, in some cases, and their extension occasions great suffering. Constitutional disturbance, more or less marked, accompanies both the primary and secondary symptoms. The general symptoms are not unlike those of typhoid fever, for which the disease is likely to be mistaken. The temperature in the axilla varies from 101° to 106°. Œdema of the face or lower extremities is apt to occur, and sometimes anasarca. Sweating is generally prominent as a symptom. Death takes place in a certain proportion of cases, after a protracted period of suffering and exhaustion, being often preceded by coma. It is stated that life in some cases is destroyed by the impairment of the respiratory muscles from the presence of the parasites. Aphonia is a symptom which exists in some cases, attributable to the presence of trichinæ in the muscles of phonation. Deafness may be caused by trichinæ in the stapedius muscle. The danger, *cæteris paribus*, is proportionate to the abundance of trichinæ generated

[1] Medical News and Library, Philadelphia, May, 1866.

within the alimentary canal. If the number be not sufficient to cause death from the amount of local and constitutional disturbance which they occasion, recovery takes place very slowly, the illness lasting for several weeks or even months. The trichinæ become encapsulated in the muscles, thereafter remaining quiescent.

Diarrhœa and abdominal pains, followed by muscular pains, together with more or less constitutional disturbance, should excite suspicion of this disease. Inquiries respecting food should be instituted, and, if any portion of the suspected meat remain, it should be examined microscopically. The diagnosis may be made still more complete by harpooning some one or more of the painful muscles and obtaining portions sufficient for examination with the microscope. Davaine suggests that the presence of trichinæ in the stools may be ascertained, and the diagnosis in this way rendered positive. If clinical observation should establish the availability of the latter method of arriving at a diagnosis, it would have this advantage, namely, the existence of the disease may be positively ascertained before the trichinæ migrate from the alimentary canal. The practical importance of making the diagnosis thus early, is sufficiently obvious.

It is evident that the treatment of this disease, to be effective, must be employed while the worms are in the alimentary canal. Hence, the importance of an early diagnosis. It remains to be ascertained whether treatment can be effectively employed in this stage, and to determine the measures most likely to prove effective. The object is either the destruction of the worms or their expulsion from the intestines. Cathartics are indicated for the latter object, but clinical experience has yet to ascertain what toxical anthelmintics are best suited to destroy this parasite. Benzine has been found by Mosler, to destroy the trichinæ in the intestinal canal when given in doses which are well borne by the patient. Mosler's method of treatment with this remedy is to have a mixture consisting of two drachms of benzine, an ounce of liquorice-juice and mucilage of gum-arabic, and four ounces of peppermint water. Of this mixture a tablespoonful is to be given every one or two hours. This remedy, however, has not proved efficacious; but it is to be considered that the diagnosis is rarely made prior to the emigration of the parasites from the alimentary canal. The carbolic acid is a remedy which should be tried with a view to the destruction of the worms in the intestinal canal. After the trichinæ have left the intestines, the opportunity of destroying or expelling them has passed. Recovery now depends on the ability of the system to endure them until they become encysted. Measures to palliate pain, to restore disordered functions, and to support the powers of life, are indicated, and the success of the treatment will depend on the judicious employment of measures for these ends.

The prevention of this disease is the great practical benefit to be derived from its discovery. The mode of prevention is sufficiently simple, namely, abstaining from meat, more especially the flesh of swine, not thoroughly cooked. The process of smoking, pickling, or salting, cannot be relied upon for the destruction of this worm. Uncooked sausages cannot be eaten without danger. Heller states that the parasite is destroyed by a temperature of 155° Fahr.

Anchylostoma Duodenale.

This worm was discovered by Dubini in Milan, in 1838. Its relation to a severe form of anæmia which prevails in Egypt, Brazil, and some other tropical countries, was first made known by Griesinger in 1851. Subsequent observations, in confirmation of Griesinger's view, have been made by Bilharz,

Kerangel, and Wucherer. The disease to which this parasite is believed to bear a causative relation, has received various names, of which the following are the most important: Egyptian chlorosis, anchylostoma-disease, tropical chlorosis, tropical hypoæmia (Brazil), intestinal anæmia, *cachexie aqueuse*, and geophagia. Anchylostoma duodenale belongs to the family strongylidæ of the order of nematoid worms (Part I. p. 96). It is also called strongylus or dochmius duodenalis. It is found only in the upper part of the small intestine in man. The worm is from six to eight lines in length and has a round thread-like body. It resembles superficially the small thread-worm or oxyuris vermicularis, but can be distinguished from it by examination with a *loupe* and by the situation in which it is found. The conical-pointed head is bent backward, and presents a mouth surrounded by a horny capsule and possessing four claw-like hooks. The intestine is usually found filled with blood. A characteristic feature is the presence of a bursa or sac on the caudal extremity of the male, inclosing the genital opening. This parasite has been found in enormous numbers by Bilharz, in Egypt, in the upper part of the small intestine. It is probably prevalent in many other tropical countries, as it has been found already in widely separated districts. It has been observed in Italy, but not in Europe north of the Alps. It prevails in South America, but no cases of its occurrence have been reported in this country. The anchylostoma duodenale bites with its claw-like hooks or teeth the intestinal mucous membrane, and sucks the blood from the intestinal vessels. Sometimes the living worm is found rolled up in the substance of the mucous membrane in a little cavity filled with blood. It leaves behind an ecchymosis of the size of a pea, with a white spot in the centre presenting a little hole through which blood can ooze. This parasite when present in large numbers proves dangerous by means of the hemorrhages which it causes. The parasite has also been found in cases of severe tropical anæmia in which intestinal hemorrhages have not occurred. Here, also, it seems to produce deleterious effects, although there is some uncertainty as to whether it is the cause of the profound anæmia or not. It is believed by Leuckart that the embryos of anchylostoma live in muddy water, and are introduced into the system chiefly by the drinking-water.

The symptoms of tropical anæmia due to the presence of this parasite are so similar to those of pernicious anæmia, that the reader is referred to the clinical history of the latter disease. There are certain symptoms, however, which deserve especial mention. Tympanites and pain in the upper part of the abdomen are frequent when the disease is fully developed. Colliquative diarrhœa and intestinal hemorrhages are observed especially in the later stages. The parasite has never been found in the discharges from the bowels. A morbid desire to eat innutritious and disgusting substances, such as chalk, coal, wool, clay, etc., is sometimes developed. Some writers identify this disease with that called geophagia or dirt-eating. They consider the dirt-eating more as a symptom than a cause of the anæmia. It remains to be established how far the conditions embraced under the name tropical chlorosis or anæmia are identical, or referable to similar pathological states. The disease under consideration attacks mostly those living in the country, and surrounded by unfavorable hygienic conditions. The duration of tropical anæmia varies from a few months to years.

The prognosis depends upon the degree of the anæmia and the obstinacy of the diarrhœa. The disease is said sometimes to cease spontaneously. The treatment consists in the administration of anthelmintics and of iron. An anthelmintic of great repute in Brazil against this parasite, is the juice of a

tree called ficus doliaria which grows there in abundance. An alcoholic extract called doliarina is prepared.[1]

Animals not entozoötic, such as snakes, slugs, and lizards, are not infrequently exhibited to physicians as having passed from the alimentary canal. It is a popular notion that they may live and grow indefinitely within the stomach and intestine, and give rise to a variety of morbid symptoms. In the great majority of cases the statements with respect to the passage of these animals are simply falsehoods proceeding generally from a morbid exaggeration of that craving to become objects of curiosity and interest, which enters largely into the mental constitution of many persons. In some cases, however, the statements are honestly made, persons being deceived. Prof. Dalton performed a series of experiments to ascertain the duration of life of the common garden slug (*Limax agrestis*) and the water-lizard (*Triton millepunctatus*) after having been introduced within the stomach of a dog. The former were found completely dead at the end of nine and a half minutes, and no traces of them were discoverable when the dog was killed an hour after their introduction. The lizards were found perfectly dead, and about to undergo the digestive process, at the end of fifteen minutes.[2] It is safe to set down most of the cases referred to as cases of either self-deception or imposition. Maggots, however, have been known to be discharged from the nasal cavity, the mouth, and the rectum. They may be developed in the nasal cavity from ova inhaled.

CHAPTER X.

DISEASES OF THE PERITONEUM.

Acute Diffuse Peritonitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Circumscribed Peritonitis. Chronic Peritonitis. Hydro-Peritoneum.

THE peritoneal cavity, like other serous cavities, is a large lymph-sac lined with a single layer of flat, polygonal cells, called endothelium. It communicates by means of minute openings, called stomata, between the endothelial cells, with the lymph-spaces in the subserous connective tissue. Liquids and small particles are readily absorbed from the peritoneal sac by the adjoining lymphatic canals. By this free communication with the lymphatic system, the peritoneum readily receives infectious and otherwise deleterious substances which may be present in adjoining organs. This disposition favors the propagation of inflammation from these organs to the peritoneum. Peritonitis may be acute or chronic, diffuse or circumscribed. It will be convenient to consider separately acute diffuse or general peritonitis, circumscribed or partial peritonitis, and chronic peritonitis. Some writers divide the disease into several varieties, according to its different causes, or to the

[1] An account of the anchylostoma disease in Brazil is given by Wucherer, Ueber die Anchylostomenkrankheit, tropische Chlorose oder tropische Hypoämie. Deutsches Arch. f. klin. Med., Sept. 27, 1872.

[2] American Journal of Medical Sciences, April, 1865.

circumstances under which it is developed. It will suffice to notice these diversities under the head of causation. Puerperal peritonitis is an important variety, presenting certain peculiarities; but it does not fall within the scope of this work to consider this form fully or separately. It is treated of at length in works on obstetrics and on the diseases of women.

Acute Diffuse Peritonitis.

Anatomical Characters.—The pathological changes are essentially the same as in inflammation of other serous membranes. The intestine, as a rule, is distended with gas. The inflammation usually begins at one spot and extends with more or less rapidity over the entire membrane. The inflammatory changes are usually most marked at the starting-point, and are elsewhere more intense in certain places than in others. At first, there is redness due to congestion and ecchymoses. The serous surface loses its normal lustre, and soon is coated with a thin grayish layer of fibrillated fibrin which at first contains few cells, but afterward becomes richly infiltrated with pus-cells, and then assumes a greenish-yellow color. The exuded fibrin causes the coils of intestine to become agglutinated to each other, to neighboring viscera, and to the abdominal walls. Together with the exudation of fibrin, there is an effusion into the peritoneal cavity of more or less serum containing flocculi of fibrin and some pus-cells. The subserous tissue is swollen and œdematous, and contains pus-cells usually in swarms about the veins. The other coats of the intestine may be somewhat altered. The muscularis is usually œdematous, and, especially in cases of puerperal peritonitis, there may be inflammation of the mucous membrane. While the chief source of pus-cells is from the blood, there is sufficient evidence that the endothelial cells lining the peritoneum likewise take an active part in the inflammatory process. They become swollen, granular, multinucleated, and, by their proliferation, produce young cells.

Different cases of peritonitis vary greatly as to the quantity and character of the inflammatory products. These products are fibrin, serum, and pus-cells, mixed with a certain number of red blood-corpuscles. According to differences in causation and in individuals, sometimes one and sometimes another of these products preponderates. In some cases the exudation is chiefly fibrinous, in others chiefly serous, and in others purulent. Again, the exudation may be described as sero-fibrinous, sero-purulent, fibrino-purulent, etc. Peritonitis with fibrinous exudation, and with but little fluid, is sometimes called dry or adhesive. In some cases the peritoneal cavity is distended by a large quantity of serum. Such cases are generally secondary to ascites. In the majority of cases the exudation may be described as sero-fibrinous; that is, the peritoneal surfaces are coated with fibrin, and the cavity contains a moderate amount of serum rendered somewhat turbid by admixture with fibrin and pus-cells. Purulent effusions are also frequently met with. All grades of transition occur between the moderately turbid serum just described, and thick creamy pus. Peritonitis due to perforation, to traumatism, and to puerperal fever and other infectious processes, is generally purulent. In septic peritonitis the exudation may be foul-smelling and ichorous. In very rare cases it has a colloid consistence. Not infrequently it has a reddish or brownish tint, from admixture with blood, but a truly hemorrhagic exudation belongs to certain forms of chronic rather than to acute peritonitis. It is not rare to find collections of serum or of pus encapsulated in different parts of the peritoneal cavity by means of fibrinous or of old organized adhesions. In connection with these collections of pus there have been observed suppuration and ulceration of portions of intestine with which the

pus is in contact, and even perforation from without inwards (ulcerative peritonitis).

If peritonitis terminate in recovery, the serum is absorbed, and the fibrin, having undergone molecular disintegration, is likewise absorbed. Large collections of pus cannot be absorbed, but the pus may lose its watery constituents, become inspissated, and be converted into a kind of cheesy mass, in which lime-salts may be deposited. New connective tissue in the form of adhesions and of thickening of the serous membrane is a result of peritonitis. The method of formation of this new tissue resembles that already described for inflammation of the pleura (page 125). There may be adhesions of the coils of intestine to each other, to the solid viscera, and of the opposing parietal and visceral layers of the membrane. These adhesions may be innocuous, but they may also be the cause of serious and even fatal consequences. In the spaces or loops formed by bridles of newly formed tissue, portions of intestine are liable to become strangulated. The contraction of the new fibrous tissue may lead to constriction of the intestine. Coils of intestine may be so bound together by adhesions that their peristalsis is greatly impaired. In cases in which the cause of the peritonitis is not evident, it is always necessary to search carefully for some lesion to which the inflammation can be referred. The presumption is, in any given case, against a primary peritonitis. A causative lesion will be found in most cases in some organ or part within the abdominal cavity, such as perforation of a hollow viscus, hernia, typhlitis, perityphlitis, and inflammation of other parts adjoining the peritoneum, especially of the female generative organs.

Clinical History.—Acute peritonitis is sometimes developed gradually. Abdominal pain and soreness, progressively increasing, may be felt one, two, or three days before the local and general symptoms are sufficient to show the existence of the disease. But in most cases the attack is abrupt, and the disease quickly declared. The disease is often, in these cases, ushered in by a chill. Pain is usually a marked symptom. Commencing at a particular point, it extends over the whole abdomen. It is burning or lancinating in character. It is increased at times so as to constitute marked exacerbations, and, not infrequently, in these exacerbations, the character of the pain is that of spasm or colic. Acute pain is produced by a deep inspiration. The respirations are usually shortened, and, by way of compensation, increased in frequency. The movements of the diaphragm are restrained, and those of the ribs proportionately increased; the breathing, in other words, is costal. Acts of coughing and sneezing occasion intense pain. Movements of the body are painful. The degree of suffering from pain varies in different cases. It is generally great, often extreme, occasionally moderate or slight, and this symptom may be wanting. Tenderness on pressure over the abdomen is usually marked. This symptom is very rarely wanting. The tenderness is often such that the slightest pressure is painful, but the degree of tenderness varies considerably in different cases. The pain and tenderness are frequently most marked in a particular circumscribed portion of the abdomen. These symptoms continue during the course of the disease. Owing to these symptoms the patient is apt to lie upon the back with the knees and thighs raised, in order to lessen the tension of the abdominal muscles and to relieve the abdomen of the weight of the bedclothes. This decubitus, however, is by no means constant. The patient may lie on the side with the knees and thighs flexed, or even on the back with the lower limbs extended. More or less tympanites is generally present, due to paralysis of the muscular coat of the intestine. The abdomen is often greatly distended and tense, and this condition persists during the course of the disease. The abdominal distension

offers a mechanical obstacle to the descent of the diaphragm, and thus increases the dyspnœa which, if great, is accompanied by cyanosis. The distension may be sufficient to displace the heart, and to push the liver upward. If the tympanites be not great, the abdominal muscles, especially the rectus muscle on either side, is usually notably rigid and resisting. The bowels, as a rule, are constipated, but the exceptions to this rule are not very infrequent. Constipation sometimes exists at first, diarrhœa subsequently occurring, and occasionally diarrhœa exists at the outset. The latter symptom is most frequent in cases of puerperal peritonitis, in consequence of the co-existence of inflammation of the intestinal mucous membrane. Vomiting is a frequent, and in some cases a prominent, symptom. The vomited matter consists of mucus and the contents of the stomach, and afterward of bile which often has a notably green color. This grass-green or spinach color is, however, not characteristic of peritonitis. The acts of vomiting occasion great pain. In the latter part of the course of the disease, the contents of the stomach are ejected by regurgitation rather than by vomiting. Thirst is usually urgent. Obstinate and painful singultus is a not infrequent symptom.

The temperature of the body is more or less raised, but there is much variation in different cases as regards the degree of pyrexia. In some cases there is but a moderate increase of temperature; in other cases there is hyperpyrexia. There may be considerable variation in the same case during the course of the disease. The temperature sometimes falls to nearly the normal shortly before death. The pulse is more or less accelerated. It often becomes quite frequent, numbering 120 or 130 per minute; but in some cases the acceleration is moderate. It is generally small and sometimes hard or wiry. The sense of prostration is considerable or great. Perspiration is apt to occur. The countenance denotes gravity of disease; the expression is haggard, pinched and anxious. In some cases the upper lip is elevated and drawn tightly over the teeth. This appearance is characteristic, and, when present, points to the disease, but it is by no means uniformly present.

Difficulty in micturition is a frequent symptom, due, in part, to paralysis of the muscular tunic of the bladder, in consequence of inflammation of its investing membrane, and partly to loss of power over the abdominal muscles in consequence of the abdominal distension. Moreover, the pain occasioned by the effort to micturate, leads the patient to postpone it as long as possible. Retention of urine, requiring the use of the catheter, is not uncommon. The urine is high-colored, and throws down a lateritious deposit of urates. Pain in the penis is a symptom in certain cases of peritonitis. This pain is sometimes extremely intense. In some cases there is priapism with intense venereal desire.

The intellect, in cases of acute peritonitis, is generally not disordered. Slight delirium sometimes occurs, especially in fatal cases, toward the close of the disease.

Pathological Character.—Acute peritonitis, as regards pathological character, does not differ essentially from other acute serous inflammations.

Causation.—Acute diffuse inflammation of the peritoneum, exclusive of puerperal peritonitis, is not a frequent disease. The liability of the peritoneum to become inflamed is vastly less than that of the pleura or the pericardium, a fact not easily explained. In the great majority of cases, peritonitis is incidental to some other affection of the abdominal viscera. The most frequent cause, exclusive of its occurrence in childbed, and of the cases in which it is caused by traumatism, is perforation of the alimentary canal. Perforation of the ileum is incidental to the intestinal lesions of typhoid fever,

and peritonitis thus produced is one of the occasional events pertaining to the clinical history of that form of fever. The intestinal ulcerations which occur in certain cases of phthisis, sometimes, although very rarely, lead to perforation, and, also, other ulcers situated in either the small or large intestine. Perforation from ulceration or sphacelation of the extremity of the appendix vermiformis of the cæcum is not of very rare occurrence (*vide* page 429). Perforation of the stomach and of the duodenum is an occasional event in cases of gastric and duodenal ulcer. Whatever be the seat of the perforation, the gaseous and other contents of the alimentary canal escaping into the peritoneal sac, peritonitis becomes at once developed. The escape of bile from rupture of the gall-bladder, or of the cystic, hepatic, or common duct, gives rise to peritonitis. Other causes are the discharge of pus into the peritoneal cavity from hepatic, ovarian, or other abscesses, rupture of the urinary bladder or ureter, and the evacuation of hydatid cysts. Inflammation, at first local, may become general, as in certain cases of intussusception and strangulation of intestine, of typhlitis and perityphlitis without perforation. Injections into the cavity of the uterus have been known to give rise to the disease, the liquid injected passing into the peritoneal cavity through the Fallopian tubes. In certain cases of puerperal peritonitis, the inflammation commences in the uterus and is propagated to the peritoneum. The disease may be produced traumatically by accidental wounds of the abdominal walls, and violent contusions. It may be caused by surgical operations which involve opening of the peritoneal cavity in cases of ovariotomy, of laparotomy in cases of obstruction, etc. It follows sometimes paracentesis, very rarely, however, except in cases in which the kidneys are diseased. It occurs in intra-uterine life, a fact which Sir James Simpson was the first to observe. The extension of inflammation from the umbilical vessels to the perineum explains the occurrence, in some instances, of infantile peritonitis.

Acute peritonitis is one of the local affections incidental to the morbid conditions of the kidneys collectively called Bright's disease. In two cases under my observation, it was developed in connection with acute articular rheumatism, the patient recovering in each case after a short duration of the disease. Exposure to cold may give rise to it. I have known its occurrence to be attributable to this cause. It has been observed to occur not infrequently in the Northern States, among laborers employed in the winter and spring to repair water-wheels damaged by ice, this occupation requiring them to work standing in water.

Occurring as an epidemic affection, in childbed, it doubtless proceeds from a special cause. During the prevalence of puerperal peritonitis, epidemic erysipelas has been observed to prevail, showing some pathological relationship between the two affections.

Diagnosis.—The diagnosis of acute diffuse peritonitis is not difficult in cases in which its characteristic features are well marked, as they are in the majority of cases. These features are sometimes obscure or wanting, and it is then liable to be overlooked or confounded with other affections. From acute enteritis it is distinguished, generally, by a greater degree of pain, greater frequency of the pulse, more tenderness on pressure over the abdomen, more tympanites, rigidity of the abdominal muscles, and the evidence, on all sides, of a graver malady.

It is sometimes mistaken for functional colic. The pains, in some cases of peritonitis, are like those of colic. But colic lacks the continuous pain, the abdominal tenderness, the muscular rigidity, the tympanites, the pyrexia, the frequency of the pulse, prostration, etc., of acute peritonitis. These symptoms, however, may not be immediately developed in peritonitis, and a

little delay may, therefore, sometimes be necessary in arriving at a positive diagnosis.

Myalgia (muscular rheumatism), affecting the abdominal muscles, may give rise to certain of the local symptoms of acute peritonitis. Instances, however, of myalgia limited to these muscles are rare. The diagnostic points are as follows: In peritonitis, movements of the body occasion pain over the whole abdomen, whereas, in myalgia, the pain is limited to certain muscles, and, perhaps, confined to one side of the abdomen. The same is true of tenderness on pressure. Moreover, in peritonitis, the pain from pressure is proportionate to its amount, but, in myalgia, deep, firm pressure may be made without augmenting the pain. These are diagnostic points pertaining to the local symptoms, but the general symptoms present in acute peritonitis are wanting in the so-called muscular rheumatism.

Lumbo-abdominal neuralgia, with hyperæsthesia of the abdominal walls or integument, sometimes simulates closely peritonitis as regards certain local symptoms. The pain may be severe, the tenderness great, the decubitus on the back with the thighs and knees flexed, and, not infrequently, there is more or less tympanites. Cases presenting these symptoms are not uncommon. The patients are generally women, and manifest more or less of hysterical phenomena. The general symptoms of acute peritonitis, frequency of pulse, prostration, etc., are wanting in these cases; but attention to certain points connected with the local symptoms will suffice for the differential diagnosis. The tenderness in the neuralgic affection is more superficial; the patient shrinks from the slightest touch, but firm, prolonged pressure with the open palm is often well borne, and may even afford relief, whereas, in peritonitis, the pain is always proportionate to the amount of pressure. The muscular rigidity of peritonitis is wanting.

I have known acute peritonitis to be mistaken for sporadic cholera in a case in which vomiting and purging occurred early, and were prominent symptoms. In the exceptional cases in which these symptoms are sufficiently prominent to suggest that affection, the error of diagnosis is to be avoided by finding, associated with the vomiting and purging, the local symptoms of peritonitis, namely, pain, tenderness, tympanites, and muscular rigidity, together with general symptoms denoting an inflammatory affection, symptoms not belonging to the history of sporadic cholera.

Acute peritonitis is sometimes remarkably latent, the local symptoms, usually so strongly marked, being obscure or wanting. Pain and tenderness may be slight or even absent. Muscular rigidity in such cases may be a very valuable diagnostic symptom. As regards occasional latency, this disease resembles other serous inflammations, namely, pleuritis and pericarditis. Pain and tenderness may be obscure in consequence of the co-existence of other affections which occasion delirium or blunt the perceptions of the patient, and, from the absence of these local symptoms, peritonitis may be overlooked. In some cases of peritonitis produced by perforation, in the course of typhoid fever, for example, the manifestations of pain and tenderness may not be sufficient to direct attention to the abdomen. In such cases, other local, in conjunction with general, symptoms must be relied upon in the diagnosis. Certain physical signs may enter into the diagnosis of peritonitis. There is, not infrequently, liquid effusion sufficient to be recognized by percussion and palpation. (*Vide* Diagnosis of Hydroperitoneum.) A peritoneal friction sound is sometimes heard by auscultation over the liver.

It is desirable, in cases of peritonitis, to determine whether the disease is idiopathic, or dependent on some one of the various local circumstances which in the majority of cases stand in a causative relation to it. In consequence of the relative infrequency of idiopathic peritonitis, the probabilities, in any

case, are in favor of the existence of some one of these causative circumstances. Developed in the course of typhoid fever, it generally, but not invariably, proceeds from perforation of the ileum. If developed in a case of pulmonary tuberculosis accompanied by diarrhœa, chronic peritonitis not preceding its development, perforation, connected with intestinal ulceration, is the probable cause. Perforation of the stomach is probable if the peritonitis occur suddenly in a case presenting the symptoms of gastric ulcer. Perforation of the intestine, connected with latent ulceration, is to be very strongly suspected whenever the affection is developed suddenly, without any appreciable cause, in a person apparently in health; and if the pain and tenderness first occur in the neighborhood of the cæcum, and continue most marked in this region, the seat of the perforation is probably the appendix vermiformis. In cases of perforation, gas usually escapes into the peritoneal cavity. Its presence here gives rise to intense tympanitic resonance on percussion, extending over the liver, and taking the place of hepatic flatness. The physical signs are to be taken into account. Perforation of the ureter may be strongly suspected if the sudden development of the disease have been preceded by symptoms denoting obstruction from calculus or some other cause. In like manner, perforation of the ductus communis choledochus is the probable cause if symptoms denoting the impaction of gall-stone in this duct have preceded. The disease is attributable to intussusception or internal strangulation of the intestine when preceded and accompanied by symptoms denoting these causes of obstruction of the bowels. Its connection with renal disease is to be determined by an examination of the urine for albumen and tubular casts. Finally, if evidence of the existence of any of the causative circumstances referred to be wanting, and the disease be fairly astributable to exposure to cold, it is to be considered as idiopathic.

Prognosis.—Acute general peritonitis is always a grave disease, involving more or less danger to life. In the majority of cases the danger is greatly enhanced, either by the circumstances on which the development of the disease depends, for example, intestinal perforation, or by co-existing affections, for example, renal disease. We have no data for determining the amount of intrinsic tendency to death belonging to simple idiopathic peritonitis. There is reason to believe that the rate of fatality in all cases depends much on the mode of management. Judiciously treated, in uncomplicated cases, the prospect of recovery is good. In complicated cases, including under this head cases in which the disease is connected with gastric or intestinal ulceration, Bright's disease, etc., the prognosis is always very unfavorable. Under certain circumstances, the disease runs rapidly to a fatal issue. It may destroy life within a few hours, if developed as a result of perforation. Recovery, however, is not impossible in cases of perforation, provided the opening be not large and closure be quickly effected by adhesions around it. The average duration in fatal cases is from five to six days.

The mode of dying is by either rapid or slow asthenia. An unfavorable progress of the disease is denoted by a progressive increase of the feebleness and frequency of the pulse, progressively increasing prostration, coldness of the extremities, cyanosis, hiccough, regurgitation, etc. On the other hand, a favorable progress may be inferred from improvement as regards the general symptoms just referred to, together with diminution of the tympanites and muscular rigidity of the abdomen. Convalescence is apt to be slow, more or less tenderness and colic pains persisting during the progress toward recovery.

Treatment.—The treatment of this disease, as inculcated and generally adopted of late years in this country, is in striking contrast with that formerly

pursued. The change consists, *first*, in the disuse of bloodletting and cathartics; and, *second*, in relying mainly on the use of opium. Governed by the general principles which should regulate the employment of bloodletting in acute inflammations, the indications for this measure are not present in peritonitis, a disease which tends to destroy life, and sometimes very quickly, by asthenia. Bloodletting has been much employed in the treatment of this disease, and certainly, clinical observation has abundantly shown that it is not, to say the least, a curative measure. It is a measure which must do either good or harm in a disease, like this, involving always not a little danger to life; and if it do harm instead of good, the amount of harm, even if not large, may bear heavily on the result. Cathartics, also, have been much employed in the treatment of this disease. Not only are they devoid of curative efficacy, but they are pernicious. An important point in the treatment of an acute inflammation of any part, is to secure for the part as complete rest as possible. The friction incident to the peristaltic movements tends to prolong and increase the inflammation in peritonitis. An object of treatment is the arrest of these movements, thus securing rest for the inflamed membrane. Cathartics not only conflict with the means for effecting this object, but they aggravate the inflammation by increasing the peristaltic movements. Moreover, they are objectionable on the same score as bloodletting and other depletory and depressing measures. Clinical observation certainly furnishes no evidence of the usefulness of cathartics in the treatment of acute peritonitis. On the other hand, it has occurred to me, as to others, to see the intensity of the inflammation reproduced by the too early administration of a cathartic when the disease appeared to be progressing favorably, and the patient's life apparently lost in consequence. Cathartics, then, should not enter into the treatment of this disease. The bowels should be allowed to remain constipated, if evacuations do not spontaneously occur, during the career of the disease, even if this period be a week or more. In pursuing this course, the physician must expect, in some cases, to encounter the importunities of the patient or friends for medicine to open the bowels. If the patient suffer from an accumulation of feces within the rectum, its contents may be cautiously removed by repeated simple injections.

An important object affected by the use of opiates is the arrest of the peristaltic movements; this is a special object in this disease, but opiates are also useful, as in other inflammations, by rendering the system more tolerant of the local affection. The latter is also an object in the treatment. With reference to both these objects, opiates are to be given in doses sufficient to produce certain effects. Relief of abdominal pain is evidence that the first object is effected. The doses, therefore, should be sufficient to produce this effect. The pain is to be relieved as quickly as possible, and the return of pain prevented by repeating the required doses at proper intervals. The success of the treatment will depend much on its being commenced early in the disease. Time should not be wasted by delay for any preliminary measures. A full dose should commence the treatment, the amount being regulated by the intensity of the pain. For an adult, a quarter or a half of a grain of a salt of morphia, or an equivalent dose of some other form of opiate, may be given at once. In two or three hours the effect of the first dose can be appreciated. If the patient be not then free from pain, another dose is to be given, the dose being increased or diminished according to the degree of pain. And, during the course of the disease, the opiate is to be repeated, if required, at intervals, in doses sufficient to prevent return of pain. Narcotism is to be avoided. In order to avoid this, the physician is to observe the effects of the doses as regard somnolency, contraction of the pupil, and diminished number of respirations. Judgment and careful watching are important, lest

narcotism be produced. The somnolency from the opiates should never become so great that the patient cannot be easily aroused. The respirations should not be reduced below twelve per minute. If, as not infrequently happens, they are found below this number, or irregular, the intervals between the doses are to be lengthened or the doses diminished. In carrying out this method of treatment, it is desirable that the physician should see the patient frequently. If this be impracticable, as it often is in country practice, the administration of the doses must be intrusted, with minute instructions, to an intelligent and faithful assistant or nurse. The doses are to be gradually diminished in proportion as the local and general symptoms denote improvement.

The extent to which opiates are to be given in order to secure the objects of the treatment, will vary much in different cases. Other things being equal, the doses required will depend on the degree of pain. But the susceptibility of different persons to opium varies greatly, and in peritonitis, as in some other diseases, there is sometimes an extraordinary tolerance of this remedy. Thus, in one of the cases treated successfully by Prof. Alonzo Clark, the patient took within the first 26 hours, of opium and the sulphate or morphia, a quantity equivalent to 106 grains of opium; in the second 24 hours, she took 472 grains; on the third day, 236 grains; on the fourth day, 120 grains; on the fifth day, 54 grains; on the sixth day, 22 grains; on the seventh day, 8 grains, after which the treatment was suspended. This patient Prof. C. had reason to believe was not accustomed to the use of opium in health, and was not intemperate. As regards the amount of opium required, this case is exceptional, the patient having an enormously increased tolerance of this drug. Rarely is more than half a grain of a salt of morphia every two, three, or four hours, needed. Often the requisite effects are produced by smaller doses. If there be irritability of the stomach, the opiate should be given by hypodermic injections. Vomiting conflicts with the great object for which opiates are given, namely, rest of the inflamed part, and, therefore, everything is to be avoided which will be likely to excite it.

In the treatment of this disease the main reliance is upon opiates. But other measures are important. Quietude of the body is to be enjoined; the bladder is to be relieved by the timely use of the catheter, if there be retention of urine. Rubefacients, sinapisms, or turpentine stupes may be applied over the abdomen; blisters are contra-indicated. All the good to be done in the way of revulsion will be effected by rubefacients, and counter-irritation beyond this does harm by increasing constitutional disturbance and contributing to depress the powers of life. Warm fomentations to the abdomen, if grateful to the patient, are useful; poultices are uncomfortable from their weight; the water-dressing or the spongio-piline is to be preferred. I cannot speak of the utility of cold applications from much observation, but it is safe to trust to the feelings of the patient in deciding between cold or warm applications. Cold may be applied by means of compresses dipped in ice-water and renewed at intervals of a few minutes, or of the ice-bag. Sustaining measures are indicated in proportion as the symptoms denote failure of the vital powers. Alcoholic stimulants, and concentrated nourishment constitute the supporting measures which are not less appropriate to this disease than to other diseases tending to destroy life by asthenia. I have seen cases in which life apparently was saved by the free and persevering use of alcoholic stimulants, in conjunction with the use of opiates. The employment of cathartics in convalescence calls for great circumspection; they may not be required, the bowels acting spontaneously. The free use of opiates continued throughout the disease does not appear to conduce to constipation, and does not prevent the occur-

rence of diarrhœa in a certain proportion of cases. Quinia in full doses, as an antipyretic remedy, is indicated if there be hyperpyrexia.

As an addendum to the treatment of this disease, may be offered a suggestion relating to measures which doubtless are too bold to commend themselves without having been carefully considered. These measures are, making an opening through the abdominal wall, washing out the peritoneal cavity by injecting a tepid, disinfecting liquid, and maintaining the opening so as to secure effectual drainage. These measures, of course, are applicable only to cases in which the presence of septic, infective morbid products may be inferred. In many instances these products probably constitute the chief source of danger. Modern experience in ovariotomy, and in the operation of laparotomy in cases of intestinal obstruction, has shown the admirable results which follow cleansing of the peritoneal surfaces, and the absence of the great danger formerly attributed to laying open the abdominal cavity. The time may come when paracentesis abdominalis, for the purposes just stated, will have been proved to be as applicable to certain cases of peritonitis, as are thoracentesis, injections into the pleural cavity, and a permanent opening in the chest, in cases of suppurative pleurisy.

Circumscribed Peritonitis.

Inflammation limited to a circumscribed portion of the peritoneum is almost invariably a complication of a prior affection of the parts covered by the inflamed portion of the membrane. Circumscribed peritonitis may be acute or chronic, but these varieties cannot be sharply separated from each other. When inflammation reaches the surface of an organ covered by peritoneum, the latter always becomes inflamed. Hence, a local peritonitis is frequent in various lesions of the stomach, intestine, liver, gall-bladder, spleen, urinary bladder, uterus and its appendages. Ulceration of the stomach leads to a peritonitis limited to the site of the ulcer. Cirrhosis of the liver in the great majority of cases is accompanied by inflammation of the serous investment of this organ. This inflammation is called perihepatitis. It leads to thickening of the hepatic capsule and to the formation of adhesions with the diaphragm and other adjoining parts. A similar perihepatitis often accompanies abscess, cancer, and some other affections of the liver. Perisplenitis signifies a local peritonitis about the spleen, and is not infrequently found at post-mortem examinations. Among the most frequent and important forms of circumscribed peritonitis is inflammation of the pelvic peritoneum in females—pelvic peritonitis, perimetritis, perioöphoritis. Intestinal ulcers and typhlitis often lead to circumscribed peritonitis. In consequence of adhesions, a perforation of the intestinal canal may give rise to only partial peritonitis. Encapsulated collections of pus may be present in the peritoneal cavity without diffuse peritonitis. Diaphragmatic pleuritis may be accompanied by inflammation of the adjacent peritoneum.

The inflammatory products in circumscribed peritonitis are the same as in the diffuse form. The exudation in many instances is chiefly fibrinous. In some chronic cases resulting in formation of new connective tissue, it is probable that from the onset there is simply a new growth of connective tissue without any free exudation. The perihepatitis accompanying cirrhosis of the liver, is usually of this simple proliferative form. The peritoneal thickening and fibrous adhesions which result from circumscribed peritonitis, may cause displacements and deformities of the viscera. Displacements of the uterus and of the ovaries thus induced, are frequently met with in gynecological

practice. Circumscribed hemorrhagic peritonitis will be considered in the following article.

The symptoms of circumscribed peritonitis are pain and tenderness within a space corresponding to the extent of the inflammation, accompanied, perhaps, by more or less febrile movement. These symptoms are marked in proportion to the acuteness of the inflammation; but circumscribed peritonitis is oftener subacute and chronic than acute. Physical exploration, in some cases, furnishes diagnostic evidence. The presence of fibrin may occasion a friction sound or a tactile sensation of rubbing due to the attrition of opposed surfaces with the diaphragmatic respiratory movements. This sign is most apt to be obtained when the peritonitis is situated over the liver and spleen. It is obtained in cases of circumscribed oftener than of diffuse peritonitis, and is of comparatively less importance in the latter, because the symptoms generally suffice for the diagnosis if the inflammation be diffuse.

It must be difficult, if not impossible, to determine the existence of circumscribed peritonitis not connected with an affection of the parts covered by the inflamed portion of peritoneum. Cases, however, are so rare that, the existence of circumscribed peritonitis being ascertained, an affection of the parts covered by the inflamed membrane is to be inferred.

The prognosis in cases of circumscribed peritonitis will depend on the nature and extent of the affection of which the peritonitis is a complication. The adhesions resulting from the inflammation may be either conservative or deleterious.

So far as the peritonitis is concerned, palliative treatment is alone called for.

Chronic Peritonitis.

Chronic peritonitis may be of the following varieties: 1, with exudation of serum, fibrin, and pus, as in acute peritonitis; 2, chronic serous peritonitis; 3, with predominant production of connective tissue; 4, hemorrhagic; 5, tuberculous; 6, cancerous.

Chronic peritonitis with exudation of serum, fibrin, and pus, may follow an acute peritonitis, or may develop slowly and insidiously. It is more frequent as the sequel of an acute peritonitis, than in a latent form; but it is, in either case, a rare variety of the disease. There is sometimes, but not always, coincident disease of some of the abdominal viscera. In consequence of the formation of membranous adhesions, the fluid part of the exudation often becomes sacculated. Sometimes the exudation consists almost wholly of fibrin, by which the intestine and other viscera may be agglutinated to each other and to the parietal peritoneum. The intestinal walls are softened and easily torn. Chronic peritonitis with an exudation almost wholly purulent, sometimes develops insidiously. When acute peritonitis passes into a chronic state, the pain, tenderness, and tympanites diminish, but do not wholly disappear. There are usually recurring febrile paroxysms with intervals of apyrexia. Gastric and intestinal disorders are present. The patient is troubled more or less by vomiting. The bowels are irregular, constipation alternating with diarrhœa. The patient emaciates and becomes anæmic. Sometimes irregularities due to encysted collections of fluid in the peritoneal cavity may be made out by inspection, palpation, and percussion. When the disease begins insidiously, it is usually not susceptible of diagnosis. The prognosis is unfavorable, but recovery may take place by absorption and by the formation of adhesions. Collections of pus may ulcerate and escape into the bowels or externally.

Chronic serous peritonitis is usually secondary to ascites. Together with

the accumulation of a large amount of serous fluid in the peritoneal cavity, there are evidences of inflammation. The serous fluid may be rendered somewhat turbid by the admixture of pus-cells. In some cases there is fibrinous exudation upon the peritoneal surface, in others the chronic inflammation is manifested by fibrous thickening of the peritoneum, either diffuse or in the form of nodules. The nodules may resemble tubercles in gross appearance. These various appearances may be combined. Peritonitis is not a frequent complication of ascites. It is more apt to develop after repeated tappings than when paracentesis has not been performed. In very rare instances chronic serous peritonitis is an idiopathic affection. Cases of this nature were formerly described as idiopathic dropsy of the peritoneum, but it is probably more correct to regard them as inflammatory in origin. A serous fluid accumulates as in ascites, but none of the recognized causes of ascites are present, such as obstruction of the circulation in the liver, in the lungs, or in the heart, or as Bright's disease, hydræmia, tuberculosis, or cancer. In most cases there is either a free inflammatory exudation, or a formation of new connective tissue in the peritoneum; but there is sometimes no more sign of inflammation than in an ordinary case of ascites.[1] Peritonitis complicating ascites may be suspected when the symptoms of the former disease, which have been described, develop; but it rarely happens that these symptoms are manifested with sufficient intensity to be diagnostic. It is very difficult to diagnosticate idiopathic chronic serous peritonitis, on the one hand, from ascites, and, on the other hand, from tuberculous peritonitis. This difficulty is increased by the rarity of the disease, which, in a given case, raises a strong presumption against its existence. A probable diagnosis can only be reached by excluding the symptoms and causes of the two diseases in question. In ascites due to that large group of causes occasioning obstruction to the circulation, the spleen is almost invariably enlarged, while by the disease under consideration this organ is not affected. Serous peritonitis may occur in chronic alcoholism, as pointed out by Leudet.[2]

Peritonitis with predominant production of connective tissue, may be called *proliferative peritonitis*. The new connective tissue is in the form either of adhesions or of thickening of the peritoneum. The two alterations may be combined. This form of chronic peritonitis may develop without any production of fibrin or of pus, or a moderate amount of these products may be present. Proliferative peritonitis with adhesions as the chief lesion, is generally circumscribed, and has been mentioned in the preceding article. Peritonitis with fibrous thickening of the peritoneum, is sometimes observed in connection with cirrhosis of the stomach. The serous covering of the stomach and intestine, the omentum, the mesentery, and the mesocolon are sometimes enormously thickened by the production of fibrous connective tissue. The peritoneum in other situations may also be thickened. The omentum, mesentery, and mesocolon are usually retracted. The coils of intestine may be inextricably united to each other by the new growth of tissue. Not only is the cavity of the stomach encroached upon, but the lumen of the intestine may also be diminished. There is usually serous or sero-purulent liquid in the peritoneal cavity, and there may be fibrin upon the thickened peritoneum. Chronic inflammation of the gastro-intestinal mucous membrane is generally present. This form of peritonitis is comparable to the chronic interstitial inflammation of parenchymatous organs. The symptoms point to

[1] In ascites the peritoneum is often thickened, and, even when no changes are visible to the naked eye, is not perfectly normal. The endothelial cells are changed in size and in shape, and present evidences of proliferation (Delafield). Similar changes exist in the pleura in hydrothorax, and in the tunica vaginalis testis in hydrocele.

[2] Leudet, Des lésions du péritoine chez les alcoolisés. Gaz. hebdom., No. 49, 1879.

some severe abdominal trouble. The symptoms of chronic gastro-enteric inflammation are often present. Vomiting, diarrhœa, dull pain, emaciation, may be mentioned as frequent symptoms. The diagnosis often cannot be made from tuberculous peritonitis or from cancer of some of the abdominal organs. The same induration of the peritoneum and abdominal organs, which may be felt through the abdominal walls, is often present in tuberculous peritonitis.

Hemorrhagic peritonitis may be either diffuse or circumscribed. Reference is not had in this connection to a simple staining of the inflammatory products with blood, such as occurs especially in cancerous and tuberculous peritonitis, but to a special form of inflammation characterized by the development upon the peritoneum of successive thin layers of connective tissue, rich in wide capillaries with thin walls which readily rupture and give rise to large and small hemorrhages. The new membrane is reddish or brown in color, from infiltration with blood. Extensive extravasations of blood form hematomata. This peculiar form of peritonitis is analogous to chronic hemorrhagic pachymeningitis, which will be described in the next section of this work. Friedrich has observed two cases of diffuse hemorrhagic peritonitis in patients with ascites, who had been repeatedly tapped. The circumscribed form was first described by Virchow. It is met with especially in the recto-uterine fossa, where it causes bloody tumors known as retro-uterine or pelvic hematoceles. A similar hematoma may occur in the recto-vesical fossa in males. The prognosis in pelvic hæmatocele is good, the blood being often absorbed with astonishing rapidity. The consideration of this form of disease belongs to works on gynecology. There are no symptoms diagnostic of diffuse hemorrhagic peritonitis. Cornil and Ranvier mention the occurrence both of diffuse and of circumscribed hemorrhagic peritonitis in hypertrophic cirrhosis, in articular rheumatism, in tuberculosis, and in Bright's disease. It is a rare form of inflammation.

The tuberculous, of all the forms of chronic diffuse peritonitis, is the most common and of the greatest clinical importance. In acute miliary tuberculosis the peritoneum—especially the omentum and the serous covering of the liver and of the spleen—is studded with small, gray miliary tubercles. This acute tuberculosis of the peritoneum is accompanied usually by little or no serous effusion. It is not attended by recognizable symptoms, and is not generally included under the heading of tuberculous peritonitis.[1] So, too, the eruption of miliary tubercles, combined often with local inflammation, on the peritoneum covering the site of tuberculous ulcers of the intestine, is of pathological, rather than of clinical, interest.

[1] Miliary tubercles of the omentum have long been favorite objects of study to those interested in the origin and structure of tubercle. According to most modern authors the cells in these tubercles are derived by proliferation from the endothelial cells covering the omentum. Martin (1879), however, finds that over the small fresh tubercles of the rabbit's omentum an intact endothelium can be demonstrated. He concludes that primarily these tubercles are no more than accumulations of lymphoid cells derived by emigration from the blood. Kundrat and more recently Delafield have called attention to proliferation of the endothelium and to the production of giant-cells in miliary tuberculosis of the peritoneum. Delafield, who has described and drawn admirably these changes (which he does not refer with certainty to the endothelium), says that they occur independently of peritoneal tuberculosis, and are not to be identified with the latter. He applies the name chronic cellular peritonitis to these changes, which may be present without an exudation, and which may produce little semi-transparent granulations on the peritoneum, or may be present without alterations visible to the naked eye. Delafield has observed this chronic cellular peritonitis not only in general tuberculosis, but also in pulmonary phthisis, in cirrhosis of the liver, and in organic heart disease. (*Studies in Pathological Anatomy*, by Francis Delafield, No. 8.)

That form of tuberculous peritonitis which is most frequent, is characterized by abundant production of firm connective tissue. This new tissue causes thickening of the serous membrane and intimate adhesion of coils of intestine and other abdominal organs to each other and to the abdominal walls. The intestinal coils are inextricably matted together. The omentum is drawn up into a thick, hard mass which can sometimes be felt during life as a transverse band above the umbilicus. The mesentery and mesocolon are likewise thickened and retracted. Tubercles are present everywhere in the thickened peritoneum and in the adhesions. They appear as translucent miliary granulations, as yellow caseous deposits, and as fibroid nodules. Some fibrinous exudation is present. Cases differ much as to the quantity and the character of the effused liquid. The quantity may be small. More frequently it is abundant, so that during life hydro-peritoneum is simulated. In the majority of cases the liquid consists of turbid, blood-stained serum. A hemorrhagic effusion is common in tuberculous inflammation of all serous membranes. Fresh ecchymoses and old pigment-stains are often present in the fibrous tissue, especially near the tubercles. The fluid part of the exudation is frequently shut into separate cavities by means of the extensive adhesions. Encapsulated collections of pus are found not very infrequently. These, as well as softened tubercles, may lead to ulcerations into the intestinal canal from without. The adherent coils of intestine may also ulcerate into each other. Even fecal fistulæ opening through the abdominal parietes may be formed.

In another form of tuberculous peritonitis there are few or no adhesions; there is an abundant collection of somewhat turbid, and often bloody, serum; and the peritoneum, which may be thickened, is studded with a large number of tubercles which may coalesce into the form of nodules and plaques as large as an inch in diameter. This form has been called tuberculous ascites.

Still less frequent is a third form described by Wilks and Moxon under the name latent peritoneal tubercle. The peritoneum is studded with tubercles in the midst of a soft, gelatinous, fibrinous exudation by which its surfaces adhere to each other.

Tuberculous peritonitis in extremely rare instances may be a local affection. It is usually accompanied by tubercles in other parts of the body. As a rule there is pulmonary tuberculosis, but cases are not very infrequent in which the pulmonary lesions are comparatively trifling. Tuberculous pleurisy is a very frequent accompaniment of tuberculous peritonitis. Primary tuberculosis of the genito-urinary organs—in females of the uterus and Fallopian tubes, in males of the epididymis and testicle, also of the bladder, ureters, and kidneys—has been repeatedly followed by tuberculous peritonitis. The mesenteric glands, the spleen, and the liver are apt to contain tubercles in all forms of this disease. There may be intestinal ulcers and waxy degeneration of various organs. Tuberculous peritonitis may occur at any age. It is rarer before the fourth and after the fortieth year of age than at other periods.

As regards clinical history and diagnosis, tuberculous peritonitis is an obscure disease. It may begin acutely, or may be attended by acute exacerbations; but, as a rule, it is insidious in its onset, and slowly progressive in its course. There is usually moderate fever, with more or less acceleration of the pulse. Vomiting and other digestive disturbances are more or less prominent. Diarrhœa alternates with constipation. Other general symptoms are night-sweats, hectic paroxysms, progressive emaciation, anæmia, and general debility. As regards local symptoms, abdominal pain and tenderness may be wanting, and are rarely prominent symptoms. Increasing distension of the abdomen by fluid and by meteorism may be the first symptom

to attract attention. It may be possible to make out encysted collections of fluid in the abdomen, and tumors formed by agglutinated coils of intestine. The detection of the thickened and retracted omentum is a significant sign.

The diagnosis of tuberculous peritonitis is not easy. When there is a large accumulation of fluid, the diagnosis from ascites is difficult. In this diagnosis the following points weigh in favor of tuberculous peritonitis: the presence of tubercles in the lungs and in other organs; the simultaneous occurrence of pleurisy; no notable decrease in the size of the liver; no enlargement of the spleen; the presence of some fever and abdominal tenderness; no history of drink; no marked collateral dilatation of the abdominal veins; a large quantity of albumen in the fluid; and the recognition of some of the local signs mentioned, such as the contracted omentum. The distinction of tuberculous from simple chronic peritonitis is all the more difficult from the fact that both may occur in connection with chronic pulmonary tuberculosis.

The termination of tuberculous peritonitis is always fatal, either from the disease itself or from tuberculosis of the lungs or other organs. The duration is from one or two months to a year or more.

Of the tumors of the peritoneum, *carcinoma* is the only one which demands clinical consideration. The occasional occurrence of echinococcus cysts in the peritoneum may be simply mentioned. Carcinoma of the peritoneum is almost always secondary. Colloid cancer is probably the only form which develops primarily in the peritoneum.[1] It occurs as a diffuse growth involving the omentum and other parts of the peritoneum. Colloid cancer has its seat by preference in the peritoneum, and attains sometimes to an enormous size, a growth weighing 114 pounds having been reported. Peritoneal cancer may develop as secondary to cancer of the ovary, uterus, testicle, retroperitoneal glands, rectum and other parts of the intestine, stomach, liver, pancreas, etc. It may appear in the form of one or more large tumors seated in the serous membrane, or there may be countless little cancerous nodules studding the peritoneum. The latter distribution is called miliary carcinosis of the peritoneum. By the aid of the microscope it is readily distinguished from tuberculosis, which it resembles in gross appearance. Peritoneal carcinoma is not necessarily accompanied by inflammation. Usually, however, there is considerable accumulation of brownish serum which may contain fibrin. The brown color comes from admixture with blood. A new growth of connective tissue with agglutination of intestinal coils may accompany cancer as well as tubercle of the peritoneum. In cancerous peritonitis the local symptoms do not differ materially from those in tuberculous peritonitis. Febrile movement is less constant and marked in the former; perspiration is not so apt to occur. The age of the patient is greater than in the majority of cases of the latter. When the primary cancer is recognized, the diagnosis of cancerous peritonitis does not usually involve much difficulty. When, however, the primary growth is latent, the diagnosis is not easy. The recognition of tumors seated in the peritoneum, is of assistance in diagnosis. The examination of the fluid withdrawn by tapping may also be of assistance. It has been pointed out by Foulis and by Thornton[2] that in cancer of the peritoneum, or in cancer of the ovary with ascites, the fluid in the peri-

[1] As already mentioned in Part First (p. 46), the development and the structure of colloid cancer are imperfectly understood, and its classification occasions considerable embarrassment. Waldeyer, the author of the doctrine that all cancers are of epithelial origin, maintains that genuine carcinomata do not develop primarily in serous membranes, these being devoid of true epithelium. Some of the tumors previously described as primary cancer of the peritoneum, he calls plexiform angio-sarcomata. Wagner and his school recognize the existence of a primary endothelial cancer (endothelioma).

[2] British Med. Journ., 1878.

toneal cavity often contains large cells in groups (budding-cells, group-cells). The prognosis is fatal.

As regards the treatment of the different varieties of chronic peritonitis, the objects are, palliation of the local symptoms, and, by tonic remedies, nutritious diet, and hygienic influences, to enable the system to tolerate the disease as long as possible.

Hydro-Peritoneum. Ascites.

The term hydro-peritoneum or ascites denotes peritoneal dropsy. The fluid accumulated in the peritoneal cavity consists of clear serum with the properties described in Part First (page 34) as belonging to transudations. Like other dropsies, hydro-peritoneum is a symptom or an effect of disease, not strictly a disease in itself. It is, however, convenient and proper to give separate consideration to ascites, as the accumulation of liquid in the peritoneal cavity may be the first and chief manifestation of disease, and as it occasions inconvenience and danger, to which therapeutical measures are especially directed. Hydro-peritoneum may occur either as a local dropsy, or as part of a general dropsy, that is, in conjunction with anasarca and with dropsical accumulations in other serous sacs.

With very few exceptions ascites, occurring as a local dropsy, is the result either of disease of the peritoneum, or of obstruction in the main trunk of the portal vein or in the branches of this vessel within the liver. In most, if not all, cases in which the ascites is attributable to disease of the peritoneum, the fluid accumulation is to be regarded as an inflammatory effusion rather than as a transudation. This is proven by the presence of a certain degree of inflammation in these cases, and by the fact that the fluid, in the amount of albumen which it contains, is, as a rule, more closely allied to exudations than to transudations. The inflammation is often no more than a chronic thickening of the peritoneum, either diffuse or in the form of nodules, and may not be attended by the exudation of fibrin. This form of peritonitis has been described in the preceding article as chronic serous peritonitis. Tubercles and cancer of the peritoneum may also be causes of ascites, even when marked inflammatory changes are absent. But here, too, the serous accumulation is to be attributed to inflammatory alterations which careful examination will usually reveal. It is a rule that slight inflammatory changes in the vascular walls are attended by an effusion chiefly serous. Obstruction of the main trunk of the portal vein as a result of pyle-phlebitis, is always followed by ascites. Cirrhosis is the most important of the morbid conditions seated in the liver, which cause ascites. Syphilitic hepatitis is also a cause of ascites. Echinococcus, abscess, cancer, and other tumors of the liver may cause ascites by compressing the portal vein or its principal branches. Atrophy of the liver induced by external pressure or by growths in its substance, may likewise be a cause. Advanced amyloid degeneration of the liver is accompanied by ascites as a rule. These various diseases of the liver will be considered in the following chapters. With the possible exception of amyloid liver, they all cause ascites by interfering with the portal circulation through this organ.

The causes of hydro-peritoneum in conjunction with general dropsy, are obstruction to the circulation in the lungs and through the heart, and a hydræmic state of the blood. The most important of the pulmonary causes are emphysema, and fibroid induration and contraction of the lungs, such as may follow chronic pleurisy. Uncompensated valvular lesions and other organic diseases of the heart, are frequent causes of ascites with general

dropsy. Bright's disease is by far the most important cause of ascites referable to hydræmia; but other cachexiæ, as the tuberculous, the cancerous, the syphilitic, the malarial, may also cause hydræmic dropsy. The connection between hydræmia and dropsy has been discussed in Part First (page 65 *et seq.*). From the foregoing it is evident that dropsy of the peritoneum, as of other parts, may be divided into mechanical dropsy and cachectic dropsy (p. 34). Ascites due to mechanical causes (namely, obstructions to the circulation in the liver, lungs, or heart) reaches a higher degree than that due to hydræmia.

Ascitic fluid consists as a rule of yellowish serum. In cachectic peritoneal dropsy it is clear and watery in appearance. In cirrhosis of the liver it is darker in color. It may be stained, especially in tuberculosis and in cancer of the peritoneum, with blood. The specific gravity is rarely below 1004 and seldom exceeds 1020. The percentage of albumen is less than in exudations. In dropsical accumulations in the peritoneal cavity, the quantity of albumen is usually less than $2\frac{1}{2}$ per cent., whereas in inflammatory exudations in the same situations, the quantity generally exceeds 4 per cent. In cachectic ascites the amount of albumen rarely exceeds 1 per cent., whereas in ascites due to tuberculosis of the peritoneum, the quantity is, as a rule, greater than $2\frac{1}{2}$ per cent. Chemical examination of fluid removed by tapping may thus be of assistance in diagnosis. Ascitic fluid contains fibrinogen and, as explained on page 34, often coagulates spontaneously when withdrawn from the body. At autopsies ascitic fluid is by no means always found devoid of coagulated fibrin. Since Schmidt's investigations as to the coagulation of fibrin, it has not been found possible to draw as sharp a distinction between fluids free from fibrin and those containing this substance, as was formerly done.

The transudation may present a milky appearance from an admixture of chyle, in consequence of compression or of rupture of the thoracic duct or large chyle-vessels. This condition is called chylous ascites (Hydrops chylosus). A similar color may be due to the presence of a large number of fat granules and of cells containing molecules of fat. This constitutes hydrops adiposus. It has been observed in connection with cancer and with tubercle of the peritoneum. In one case of chylous ascites which followed residence in a tropical climate, Winckel found, in the fluid, countless parasites resembling the filaria sanguinis detected by Lewis in the blood of those suffering from chyluria.[1]

In the account of the clinical history of ascites, reference is not had to slighter tranudations such as occur in cachectic states, and which, as a rule, neither give rise to symptoms nor call for therapeutical interference.

The effusion of liquid and its accumulation take place without pain, tenderness, or any local subjective symptoms. The enlargement first directs attention to the abdomen. In the majority of cases, it goes on with rapidity, and the abdomen soon becomes considerably or greatly distended. The symptoms referable directly to the dropsy, proceed from the mechanical pressure of the liquid, and are in proportion to the quantity of the effusion. The distension of the abdominal walls by the liquid, and its weight, occasion more or less inconvenience. The functions of the abdominal organs—stomach, liver, kidneys—are impaired by compression. Pressure on the veins within the abdomen gives rise to œdema in the lower extremities. The movements of the diaphragm are restrained or arrested, breathing being carried on by the costal muscles, and, if the accumulation be very large, the capacity of the chest is diminished by the upward pressure. The appetite is usually impaired.

[1] Winckel, Deutsches Archiv für klin. Med., Bd. 17, p. 303, 1876.

A sense of fulness is frequently felt after taking food in moderate quantity. Vomiting and diarrhœa are occasional symptoms.[1]

Enlargement of the superficial veins on the anterior aspect of the trunk, is a consequence of a portion of the blood from the portal vein passing into the systemic venous system through anastomosing branches. The superficial veins of the abdomen in some cases, of the chest in other cases, and sometimes in both situations, become more or less dilated, presenting a varicose appearance. Hernial protrusions at the umbilicus and in other situations are occasionally produced.

When the fluid accumulation is considerable, œdema of the lower extremities is a pretty constant symptom, the amount of œdema varying much in different cases. The limbs, scrotum, and penis sometimes become enormously swollen. Some œdema of the lower limbs preceded an enlargement of the abdomen sufficient to attract the attention of the patient in one-half of the cases (21), among those analyzed by me, the histories of which contained information on this point. Œdema of the face and upper extremities does not belong to the clinical history of local hydro-peritoneum. If present, it usually denotes co-existing renal or cardiac disease. In the progress of the affection, emaciation and pallor become marked. The attenuation of the upper part of the body, the distended abdomen and the œdematous lower extremities, combine to render the appearance highly characteristic of the affection. Cholæmia or icterus is occasionally present; it occurred in 7 of the 46 cases which I have analyzed.

Fever does not attend the progress of this affection. The pulse may be more or less increased in frequency and proportionately feeble, or it is more or less enfeebled without acceleration. The urine is frequently scanty. The mind is usually intact, but, in a certain proportion of cases, towards the close of life, delirium, convulsions, and coma occur. These symptoms may be due to uræmia or to retention in the blood of the excrementitious principles of the bile (cholesteræmia).

The mode of dying, in the great majority of cases, is by slow asthenia. A rapid and large accumulation of liquid may destroy life by interference with respiration; and apnœa and asthenia are combined when coma precedes death.

The prognosis in most cases is unfavorable. The cases in which a permanent recovery takes place are few. The morbid conditions on which the affection is dependent are generally incurable, and lead to its return, sooner or later, in most of the cases in which the dropsy disappears or is removed. The duration of the affection is variable. In the fatal cases of those which I have analyzed, the duration varied from six weeks to seventeen months, the average duration being about five months.

The diagnosis of hydro-peritoneum is generally made without difficulty, yet there is a liability to errors which may lead to serious results. A distended bladder has been punctured, the case being supposed to be one of peritoneal dropsy. There is a tradition that John Hunter committed this mistake. On careful examination, the tumor formed by the distended bladder may generally be felt through the abdominal walls; but the introduction of the catheter is the diagnostic test. A sacculated bladder may cause a notable anterior projection of the abdomen. The contents of the saccular appendage may generally be removed by the catheter combined with suction by means of an India-rubber bag. Pregnancy, the liquor amnii being unusually abundant,

[1] *Vide* paper entitled *Clinical Report on Hydro-Peritoneum, based on an Analysis of forty-six Cases*, American Journal of Medical Sciences, April, 1863.

has been mistaken for dropsy, and the uterus punctured. Careful examination through the abdominal walls and *per vaginam*, together with auscultation of the abdomen, should prevent this error. Great corpulency has led to error and the operation of paracentesis, as in the famous case of "dry tapping" related in the lectures of Sir Astley Cooper. Finally, tympanites, large abdominal tumors, and ovarian cysts are to be discriminated from peritoneal dropsy.

The enlargement of the abdomen from dropsy commences at the lower part, and, if the abdomen be not largely distended, it is more marked below than above when the patient stands or sits. The enlargement on both sides is equal; the abdomen is symmetrical. If the patient lie upon either side, the weight of the liquid causes the depending side to sag. Percussion on one side, the open palm being placed on the opposite side, frequently causes a characteristic shock, called the sense of fluctuation. Sometimes this sensation is more appreciable when the palm is placed near the point at which the percussion is made. The former method of percussion gives rise to what is called diametrical, and the latter to peripheral, fluctuation. But a more satisfactory application of percussion is to compare the results when the patient is placed in different positions. Percussing first in the sitting or standing posture, tympanitic resonance, from intestinal gas contained in the intestine floating upon the liquid, is usually found at the upper part of the abdomen, extending below for a greater or less distance, and flatness from this point to the pubis. Placing now the patient on the back, the change in the relative situation of the liquid and the intestine is shown by the greater extension of the tympanitic resonance toward the pubis. Similar proof of the presence of liquid is obtained by percussing upon one side of the abdomen successively when the body is inclined to that, and then to the opposite, side. The exceptional cases in which this test afforded by percussion is not available, are those in which the intestinal coils are fixed by morbid adhesions. This is rare in cases of a purely dropsical affection.

The several affections simulating dropsy which have been named, may generally be excluded by the application of percussion as just described. Ovarian cysts of sufficient size to distend the whole abdomen are the most likely to be confounded with hydro-peritoneum. These are generally, however, distinguishable by the appreciation of the cyst through the abdominal walls, the existence of a tumor on one side before it extended to the whole of the abdomen, the absence of symmetry in the enlargement of the two sides, together with the want of evidence of the presence of liquid in the peritoneal sac afforded by percussion when the body is placed in different positions. The chemical and the microscropical examination of the fluid removed by puncture, often assists in this differential diagnosis. When the fluid is thick and viscid, it is ovarian. The thin ovarian fluids present more difficulty in diagnosis. The presence of a large quantity of a modified form of albumen, called paralbumen, is diagnostic of ovarian cysts. So, too, the recognition of a large number of granular corpuscles, devoid of nuclei, and in which the granules are insoluble in acetic acid and in ether, is diagnostic. These bodies are known as the ovarian corpuscles of Drysdale. The detection of a few of these corpuscles and the presence of a small quantity of paralbumen are not sufficient for the diagnosis. Ovarian fluids very rarely coagulate spontaneously. If cylindrical epithelial cells be found, the fluid comes from an ovarian cyst, but these cells are rarely discovered. The specific gravity of ovarian fluids is generally greater than that of ascitic.

The treatment of hydro-peritoneum relates, *first*, to the dropsical effusion, and, *second*, to the morbid conditions on which the effusion depends. As regards the dropsical effusion, the object is to effect its removal or diminution. For this object, medicinal and surgical measures may be employed.

The medicinal means consist of remedies to eliminate water from the blood, and thereby induce absorption of the effused liquid. The elimination of water from the blood is to be accomplished by diuretics and hydragogue cathartics. Diuretics, in most cases, effect but little. It is difficult generally to obtain much diuretic effect from any of the remedies of this class, the difficulty arising from the slowness with which the remedies enter the general circulation, owing to the fact that the morbid conditions giving rise to the dropsy usually involve obstruction to the portal circulation. Of 13 cases treated with diuretic remedies, in 8 no effect upon the dropsy was produced; in 5 more or less diminution of the dropsy followed, but in only 2 cases was the improvement marked and progressive. Little dependence, therefore, is to be placed on diuretics, but inasmuch as, if properly prescribed, they do not cause much disorder or prostration, they should be fairly tried. The saline and vegetable diuretics may be given in succession, and a diuretic effect is more apt to be produced if several are employed at the same time or in combination.

Hydragogue cathartics act more efficiently than diuretics; but clinical observation does not furnish much evidence of success from their use. Of the different hydragogues, elaterium is the most reliable. I am accustomed to prescribe this remedy in doses of a quarter of a grain repeated at short intervals until abundant liquid evacuations are produced. Afterward the doses may be repeated according to circumstances. Owing to the disturbance and prostration caused by the prolonged use of hydragogues, they are liable to do harm and should not enter largely into the treatment.

The apocynum cannabinum, or the Indian hemp indigenous in this country, is considered by some an efficient hydragogue in this form of dropsy. From some trial of this remedy in Bellevue Hospital, I have been led to think it is less reliable than the elaterium. The decoction of the root may be employed, or the extract.

It is important to bear in mind that, in order to secure the desired effect of diuretics or hydragogue cathartics upon the dropsy, the ingestion of liquids is to be restricted, the patient drinking no more than the wants of the body require.

The surgical method of effecting the removal of the liquid is tapping. With respect to this operation, the views heretofore held are, that it is to be resorted to only when the abdominal distension occasions great distress or danger, and not until the indirect means have been thoroughly tried; that the dropsy generally increases more rapidly after the operation, and that the operation involves danger if the system be much prostrated. These views are erroneous. Tapping effects promptly, without perturbation and without impairing the vital powers, the object for which diuretics and cathartics are employed, measures generally ineffectual, disturbing the digestive functions, and enfeebling the powers of life. The operation is a trivial one, involving little risk of accidents or of peritoneal inflammation. A patient under my observation had repeatedly tapped himself, using, as a trocar, a blade of a pair of scissors, and a piece of an ordinary clay pipe-stem as a canula. There is no danger from increased rapidity of effusion directly after the operation. The patient is spared, not only the inconvenience and distress, but the permanent injury, caused by the prolonged pressure of the liquid upon the abdominal and thoracic viscera, and he is in a condition more favorable for other remedies than those which have special reference to the removal or diminution of the dropsy. Clinical experience shows that, in some cases, even when the dropsy is dependent on cirrhosis, the liquid does not accumulate for weeks, months, and years afterward. In another work I have cited several instances in which, after a great number of tappings, the dropsy ceased to return, and

recovery seemed to be complete.[1] It is judicious to resort to tapping as soon as the accumulation of liquid is sufficient to occasion much inconvenience, adopting this direct method in lieu of the indirect means, provided the latter do not prove immediately efficacious, and repeating the operation whenever the abdomen becomes again distended. These views were enunciated by me in a paper published in 1863, and were based on the results of tapping in 20 cases under my observation, the operation in these cases being performed but once in 11 cases, and in the remaining 9 cases being repeated from three to thirty times. The conclusions drawn from the facts contained in the histories of these cases are as follows: 1. Tapping may be resorted to as a palliative measure, when the condition of the patient is such that only temporary relief is to be expected. 2. In a certain proportion of cases the dropsy returns more or less quickly, and it may be necessary to repeat the operation many times. The repetitions, however, are innocuous. This was illustrated in one case in which it was performed thirty times in 18 months. 3. In some cases the dropsy does not return for a considerable or even a long period, and in some cases it never returns. That it will prove a curative measure is not to be expected in the majority of cases. Since the publication of that paper, the correctness of these conclusions has been substantiated by a large number of cases under my observation.

The dropsical collection is sometimes discharged spontaneously, the walls of the abdomen becoming attenuated by distension, and rupture taking place. The perforation, in these cases, is most likely to occur at the umbilicus or at some point at the median line. In a case at Bellevue Hospital, a protrusion of a cyst-like tumor took place at the umbilicus, which, after attaining to a large size, burst, and the contents of the peritoneal sac were discharged through the opening. Four months after the spontaneous discharge took place, the dropsical effusion had not returned.

The treatment relating to the morbid conditions on which the dropsy depends, embraces, in the first place, measures to prevent an increase of the incurable lesion which exists in the majority of cases, namely, cirrhosis of the liver. It will be seen, when we come to consider this lesion, that it is caused by spirit-drinking. Change of habits, as regards the use of spirits, is, therefore, the most important of the measures coming under this head. In the second place, certain accessory or co-operative causative conditions may be removed, causes which act by impoverishing the blood and impairing the forces which carry on the circulation. This part of the treatment embraces tonic medication with nutritious diet, and other measures to strengthen and invigorate the system. Well-directed treatment for this end, although not curative, will often do much to prolong life, and to secure as much improvement of health as is compatible with existing structural lesions.

Mechanical compression of the abdomen, after tapping, by means of a swathe or a laced supporter, is a measure of importance, as not only affording comfort, but tending to prevent a renewal of the dropsical effusion.

CHAPTER XI.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN.

Suppurative Hepatitis. Chronic Interstitial Hepatitis (Cirrhosis). Acute Yellow Atrophy of the Liver. Syphilitic Hepatitis.

OF diseases affecting the solid abdominal viscera, the greater number and the more important are seated in the liver. These will be first considered, and, afterward, diseases of the spleen and pancreas. Acute diffused hepatitis, considered as a disease distinct from acute yellow atrophy of the liver, has so little practical interest, except in certain tropical climates, that it is not embraced in the present edition of this work. Suppurative hepatitis, or hepatic abscess, chronic interstitial hepatitis, acute yellow atrophy of the liver, and syphilitic hepatitis will be treated of in this chapter, and the next chapter will embrace the different structural together with functional affections.

Suppurative Hepatitis, Abscess of the Liver.

Suppurative hepatitis is always circumscribed and leads to the formation of abscess. There may be only one abscess, which may attain a very large size so as to occupy the greater portion of the liver. Such large solitary abscesses are found especially when the disease is of traumatic origin or when it occurs in tropical climates. They are sometimes called tropical abscesses. There may be multiple abscesses, varying in number from three to forty or more. When very many, the individual abscesses are usually of small size. In a case under the author's observation, five and a half quarts of pus were at once evacuated by an opening made through the thoracic walls. The patient recovered. An abscess has been found to contain, after death, eighteen pints of pus, the entire organ, except the left lobe, being transformed into a mere sac. The abscess may be situated at any part of the gland. It is oftener seated in the right than in the left lobe, and oftenest at the posterior and superior portion of the right lobe.

The early stages of development of hepatic abscesses are not perfectly understood. Their formation has been studied chiefly in pyæmic abscesses, and in those experimentally produced in animals by traumatism. According to Virchow, Klebs, and Birch-Hirschfeld, the primary appearance is that of yellowish-white spots embracing one or more hepatic lobules. These spots consist of necrotic liver-cells and bacteria. Pus-cells appear first in the interlobular connective tissue, rarely in the centre of the lobules; they increase in number, causing a gradual breaking down of the liver tissue and the formation of an abscess cavity. The pus-cells are emigrated white blood-corpuscles. The liver-cells probably take no active part in the formation of pus-cells, but undergo regressive changes leading to their destruction. Small abscess cavities so produced may coalesce and make larger cavities. As a rule, the longer the duration of the disease, the smaller the number and the larger the size of the abscesses.

The purulent matter from an hepatic abscess often does not differ in its

characters from ordinary pus; but it may contain liver-cells and shreds of hepatic tissue. It is not infrequently reddish or brownish in color from extravasated blood. It may be stained with bile when the abscess communicates with one of the bile-ducts. The walls of the abscess at first consist of the exposed hepatic tissue, but after a time a cyst-wall of connective tissue is formed, which increases in thickness and firmness with age.

The walls of an hepatic abscess may become gangrenous. This happens sometimes when air is admitted, as by a perforation into the stomach or intestine, or when the abscess is secondary to a gangrenous focus in some part of the body. An instance is reported in the author's Clinical Medicine.

If the contents of an abscess be discharged, its walls may cease to secrete pus and cicatrization may ensue. The pus in small abscesses may become thick and dry, and remain innocuous, or an abscess may become enveloped with extremely firm fibrous tissue and cease to grow. But as a rule, if life continue, the pus makes its way, as in other abscesses, in the direction in which the pressure is least, and is at length discharged into some cavity, canal, or outlet.

When the abscess reaches the surface of the liver, a circumscribed inflammation of its serous covering takes place. This, as a rule, leads to adhesion between the surface of the liver and the diaphragm, the abdominal wall or some neighboring viscus.

In the larger proportion of cases, the evacuation is through the thoracic or the abdominal parietes. When it takes this direction, a fluctuating tumor, after a time, makes its appearance, caused by the accumulation of the pus beneath the integument. The tumor, if left to itself, increases, becomes pointed, the skin becomes reddened, and finally the discharge is effected by ulceration. The most frequent situation of the tumor is below the ensiform cartilage, but it may appear at any point over the site of the liver. Sometimes the pus burrows beneath the integument, and the tumor is situated at a greater or less distance from the liver. It has been observed as high as the axilla, and below on the inner side of the thigh; in the latter case it is liable to be mistaken for lumbar abscess. Of course, partial peritonitis and adhesion over the circumscribed space occupied by the abscess, are essential in order that the pus may be discharged externally. This conservative provision does not always precede the opening of the abscess, and then the contents are discharged into the peritoneal cavity; peritonitis is at once developed, and, under these circumstances, death speedily follows. The direction next in frequency which the pus takes, is through the diaphragm into the chest. Partial peritonitis precedes the perforation of the diaphragm, and partial pleuritis ensues, frequently limited to a small space, preventing evacuation into the pleural cavity. Occasionally, however, the latter conservative provision does not take place, and the pus, discharged into the pleural cavity, at once causes general pleuritis. If this be prevented by adhesion around the opening through the diaphragm, the lung becomes perforated, and the evacuation is into the bronchial tubes, the pus being discharged by expectoration. The abscess is sometimes evacuated into the pleural cavity, and afterward perforation of the lung takes place, and the pus is expectorated. Other less frequent directions in which the pus is discharged, are the following: Into the colon, stomach, or duodenum, the pus being then discharged by vomiting or stool; into the pericardium, causing pyo-pericarditis, or, if the quantity of pus be large, speedy death; into the pelvis of the right kidney, the pus discharged with the urine; into an hepatic vein, or the vena cava, giving rise to purulent infection of the blood; into the gall-bladder or biliary ducts, and thus, if there be no obstruction, the pus finding its way into the duodenum. In a case which came under my observation, an abscess pointed externally

and was opened; subsequently perforation of the stomach took place, and liquids ingested escaped through the external opening, the patient dying from inanition.

The clinical history of hepatic abscess is obscure. The symptoms rarely point distinctly to this affection. Pain exists if the hepatitis be near the surface of the liver, and whenever partial peritonitis ensues, but, even then, pain is not always a prominent symptom, and, if the inflammation be deep-seated, there may be no pain. Pain is felt in the right shoulder in a small number of cases. Rigidity of the abdominal walls over the liver, or of the right rectus muscle, is a sign to which much importance is attached by several observers. Febrile movement is rarely marked, and may be wanting. Chills usually occur during the suppurative process. These sometimes occur regularly, simulating intermittent fever, but generally they are irregular. Jaundice is rare. The appetite and digestion may be more or less disturbed, or they may be unaffected. The nutrition may be but little, or not at all, affected. Reference is now had to symptoms prior to the discharge of the pus or its appearance beneath the integument. The affection is not infrequently completely latent. It is not uncommon, in tropical climates, to find an abscess in the liver in bodies dead with various diseases, when hepatic disease had not been suspected during life; and the first intimation of the existence of this affection during life, in certain cases, may be the discharge of pus from the stomach, bowels, or air-passages.

The clinical history, after the discharge takes place, will, of course, depend upon the direction in which the abscess is evacuated. In certain cases the phenomena of the affections caused by the presence of pus are superadded, namely, of peritonitis, pleuritis, pyæmia, etc. If the evacuation take place either externally, or into the alimentary canal, or through the bronchial tubes, symptoms are produced analogous to those connected with purulent discharges in other situations, namely, anæmia, debility, emaciation, and, in cases which pursue an unfavorable course, hectic fever, colliquative diarrhœa, exhaustion, the death taking place by asthenia.

Hepatic abscess is rare in cold or temperate climates. It is an affection belonging *par excellence* to warm climates, and, for reasons not understood, it prevails much more in some than in other countries within the tropics. In warm climates it is apt to be associated with dysentery, and a causative relation has been supposed to exist between the two affections. Budd, and others, suppose that the abscess is consecutive to, and dependent upon, the dysenteric affection, and that suppuration takes place in the liver in consequence either of phlebitis induced by intestinal ulcerations or by the absorption of septic matter which, carried to the liver in the portal blood, occasions inflammation there.[1] This view is conjectural. Hepatic abscess observed in cold or temperate climates, is rarely associated with, or preceded by, dysentery, and of a large number of cases of intestinal ulceration from tuberculosis, typhoid fever, as well as dysentery, together with cases of gastric ulcer (324 cases) analyzed by Bristowe, the cases occurring in St. Thomas's Hospital, London, abscess of the liver existed in only 4. In each of these 4 cases it was associated with dysentery, but in 3 of the cases the dysentery was secondary. Of 31 cases of hepatic abscess, analyzed by the same writer, in only 6 were intestinal ulcerations found; in 2 of these 6 cases the ulcerations followed the evacuation of the abscess into the bowel, leaving 4 cases in which dysenteric ulcerations preceded the hepatic abscess.[2] When associated with dysentery in

[1] On Diseases of the Liver. By George Budd, M.D., etc. Am. ed., 1853.

[2] *Vide* Frerichs, a Clinical Treatise on Diseases of the Liver, publications of the New Sydenham Society, London.

warm climates, the hepatic affection does not always follow, but, in a certain proportion of cases, precedes, the intestinal affection. Annesley, and some other writers on diseases in the East Indies, are of the opinion that the hepatic affection generally precedes the dysentery, and that the latter is dependent on the former. The co-existence of dysentery and hepatic abscess in the East Indies does not occur as often as appears to be generally supposed. Of 300 cases analyzed by Waring, dysentery existed in 82. On the whole, it is questionable whether there be any special causative relation between the two affections. Dysentery is a very frequent disease in warm climates, and hepatic abscess vastly less infrequent than in cold or temperate climates; hence, in the former, mere coincidence is sufficient to explain their association in a certain number of cases. Dysentery, although not so frequent a disease in cold or temperate as in warm climates, is yet not infrequent in the former, and were it capable of giving rise to hepatic abscess, this affection should be less rare. Ulceration of the gall-bladder or ducts, and the irritation caused by the presence of gall-stones, are causes existing in a small number of cases, and occurring frequently without leading to hepatic abscess. Lumbricoid worms migrating into the hepatic ducts, is another supposed cause, but this is an occurrence of extreme infrequency. Contusions or other traumatic causes rarely give rise to abscess. Of 318 cases analyzed by Morehead, only 4 were referable to mechanical violence. In the majority of cases, the causes of circumscribed hepatitis resulting in abscess are, at present, unknown. The affection in these cases, in the present state of our knowledge, must be considered as primary or idiopathic.

In the foregoing remarks on the causation, and in the subsequent remarks on diagnosis and treament, reference is had to cases of abscess not associated with pyæmia or pyle-phlebitis. In the latter cases, there are purulent collections small in size and greater or less in number (multiple, metastatic, or embolic abscesses), rarely a single abscess containing a large quantity of pus. The reason, perhaps, is that life is not sufficiently prolonged for the small collections to increase and coalesce. It is probable that in this way the so-called tropical abscess is formed, its development dependent on the absence of co-existing affections which destroy life. Pyæmic abscesses have been supposed to follow especially injuries of the skull; but according to Thierfelder and others, they occur as frequently after inflammation of bone in other situations. It is difficult in these cases to establish the embolic nature of hepatic abscesses, inasmuch as there is often no pulmonary abscess, and, yet, the emboli must have passed through the pulmonary circulation. Kleb's view, that these hepatic abscesses are caused not by embolism, but by bacteria which accumulate in the portal vessels of the liver owing to the sluggishness of the circulation therein, has considerable probability.

Idiopathic abscess of the liver does not occur in children, and it occurs in men much oftener than in women.

The diagnosis of hepatic abscess by means ot symptoms, cannot be made with any degree of positiveness prior to its discovery by manual exploration, or the discharge of pus into the alimentary canal or the bronchial tubes. The symptoms which have been named as belonging to its clinical history, should suggest its existence as possible, or perhaps probable, especially in a warm climate, but they are not sufficiently distinctive to render the diagnosis positive. Not infrequently grounds of even a suspicion of its existence are wanting. When a fluctuating enlargement or tumor is perceived over the site or in the neighborhood of the liver, it is to be discriminated from a subcutaneous, phlegmonous inflammation, carcinoma of the liver, a hydatid formation, and a distended gall-bladder. The first of these is distinguished by pain, hard-

ness and redness of the integument, preceding the sense of fluctuation. Carcinoma offers a resemblance only when the medullary variety exists. The duration of the tumor and the nodulated condition of the liver, as felt through the abdominal walls, will serve for the recognition of this affection. A hydatid cyst is of slower development, and is not attended with the pain, tenderness, chills, and febrile movement which usually accompany an abscess. A hydatid cyst, however, may be the seat of suppuration, becoming converted into an abscess, and then the discrimination is difficult, or impossible. A distended gall-bladder, which is the most likely to be confounded with an abscess, is to be distinguished by its situation, the pear-shaped form, and by the fact that, in consequence of peritoneal adhesions rarely taking place, it has a mobility which an hepatic abscess has not. The antecedent history is, of course, always to be taken into account. Enlargement of the liver frequently, but not invariably, exists in cases of hepatic abscess, and the enlargement may be found to be limited to a particular direction, not affecting the whole organ, a point of some importance in the diagnosis. Exploration by means of a fine hollow needle attached to a hypodermic syringe, is admissible whenever there is reason to suspect the existence of abscess, and, by this method, the differentiation of abscess from the other affections just named, can be made demonstratively. There is no risk of injury in resorting to this procedure, and it should, therefore, not be omitted.

If the abscess discharge through the bronchial tubes, the diagnosis is generally made without difficulty. The sudden expectoration of pus in large quantity, without evidence of antecedent and co-existing empyema or pulmonary abscess, and the expectoration coming from the bronchial tubes of the right lung, render the diagnosis altogether probable. The presence of bile or disintegrated hepatic tissue affords demonstrative proof of the source of the purulent expectoration; but these are rarely present. A reddish or brown color of the expectorated pus is of diagnostic import. If the abscess discharge into the pleural cavity, the diagnosis is established by symptoms of hepatitis and suppuration having preceded the sudden development of pyothorax.

The discharge of the abscess into the stomach, duodenum, or colon, is followed by the vomiting of pus, or its appearance in the stools. The diagnosis is to be based on these events, together with antecedent symptoms pointing to the existence of suppurative hepatitis. The discharge into the peritoneal cavity, pericardium, and vena cava, gives rise to no phenomena distinctive of hepatic abscess. Its existence may have been suspected by the symptoms preceding the discharge, but the proof can only be afforded by an autopsical examination. The discharge into the pelvis of the kidney gives rise to pyuria, but it may be difficult or impossible to determine that the pus comes from the liver and not from the kidney or some other source.

The prognosis, even in the cases in which the abscess is evacuated in the most favorable directions, is unfavorable. When it discharges into the peritoneum, pericardium, and vena cava, death speedily follows. If it discharge into the pleural cavity, the termination is usually fatal. The cases which offer a fair prospect of recovery are those in which the discharge takes place through the integument, the bronchial tubes, or into the alimentary canal.

The prospect of recovery is, of course, less when two or three abscesses exist than when there is a single abscess.

Statistics show the duration, in fatal cases, to be longest when the discharge takes place through the bronchial tubes. The average duration, in fatal cases, is between three and four months. In cases which recover, statistics show the longest duration to be when the discharge is through the integument. The average duration in cases which recover is between four and five months.

From what has been said respecting the clinical history and diagnosis, it

follows that there is seldom an opportunity to employ therapeutic measures with a view to prevent suppuration. Even if the existence of circumscribed hepatitis were early ascertained, it is doubtful if the formation of an abscess could be prevented. Cases only in which the abscess is appreciable by manual exploration, or an exploratory puncture, and those in which the contents are discharged into the bronchial tubes and alimentary canal, admit of treatment with a positive knowledge of the existence of the affection. In a case in which the abscess is ascertained to be making its way through the abdominal or thoracic parietes, an early opening should be made into it and the pus evacuated. If a free opening be made before the pus has made its way beneath the integument exterior to the abdominal or thoracic walls, there is danger of the pus escaping into the peritoneal cavity in consequence of the absence of peritoneal adhesions over the abscess. Under these circumstances, in order to avoid this danger, an incision may be made through the skin and muscles down to the peritoneum without opening the abscess, and the wound filled with lint. This procedure induces firm adhesions around the wound, and in three days the abscess may be opened with safety, if a spontaneous opening do not in the mean time occur. If, however, the walls of the abdomen or chest have been perforated by ulceration, a free opening may be made at once without hesitation.

The plan of treatment just stated is that generally recommended. A better plan, however, is to resort to aspiration as soon as the existence of an abscess is demonstrated by an exploratory puncture. The withdrawal of the pus by means of a hollow needle or trocar of small size attached to Davidson's syringe or some one of the different instruments for aspiration now in use, need not be delayed on account of any doubt respecting peritoneal adhesions. If these have not taken place, there is no risk of the escape of pus into the peritoneal cavity. By promptly aspirating, the danger of rupture of the abscess from delay is avoided; and, also, whatever harm may result from the entrance of air. The pus should be removed as soon as it is discovered. The aspiration should be repeated if there be a reaccumulation of pus. By pursuing this plan a free opening may not be required. Aside from the local treatment, tonic and supporting measures are indicated. Good diet and out-of-door life, in so far as the patient's strength will permit, are far more important than medication.

When the abscess evacuates through the bronchial tubes or the alimentary canal, palliative remedies are called for, to relieve undue irritation of the bowels and air-passages. In addition to these, measures, hygienic and medicinal, which tend to support, strengthen, and invigorate the system, are indicated, as when the discharge is through the integument.

Chronic Interstitial Hepatitis. Cirrhosis of the Liver.

Chronic interstitial hepatitis occurs as a circumscribed affection in the neighborhood of new growths, abscess, parasites, and gall-stones in the liver. This circumscribed form has no clinical importance. As a diffuse affection, it constitutes the condition usually called *cirrhosis* of the liver. The essential pathological change in this disease is an increase in the connective tissue of the liver. During the last few years there have been numerous contributions to the pathology and etiology of chronic interstitial hepatitis. These researches have shown that there is considerable variety in the gross and microscopical appearances of the liver in different cases, and an attempt has been made to distinguish several forms, differing from each other as regards pathology, causation, and symptomatology. As there is still much controversy as to the facts bearing upon this view and their interpretation, the long

recognized form of cirrhosis, the so-called cirrhosis of Laennec, will be taken as the basis of the present description; afterward, brief reference will be made to the hypertrophic form of cirrhosis as a distinct disease. Chronic interstitial hepatitis, as constituting one of the forms of syphilitic disease of the liver, will be described under the heading Syphilitic Hepatitis.

Anatomical Characters.—The name *cirrhosis*, signifying a tawny or orange color, was applied by Laennec to the affection under consideration on account of the yellowish color of the nodules which the liver usually presents in this disease. These nodules, now known to be parts of the pre-existing liver substance, were supposed by Laennec to be new growths replacing the original parenchyma. As the essential change, however, was found to consist in the development of fibrous tissue, the term cirrhosis came to be applied not only to the liver, but also to the fibroid induration of other organs, especially of the lungs and kidneys, although this application is etymologically incorrect. The term sclerosis, signifying induration, is more appropriate. The customary division of the pathological changes of cirrhosis of the liver into two stages, in one of which the liver is enlarged and smooth or slightly granular, and in the other small, firm and nodular, is wholly schematic, and not based upon pathological observation. A cirrhotic liver is usually small, but it may be of normal size, or enlarged, even in cases of long duration, and there is no proof that the large cirrhotic livers are to be regarded as early stages of the contracted form. The left lobe is often disproportionately reduced in size, so as to appear as a mere membranous appendage of the right. The surface is nodular; in exceptional cases it may be smooth. The nodules vary in size from a pin's head to a pea, and may be larger. Some livers are coarsely nodular, others finely granular, although the size of the nodules or granules varies much in the same liver. The nodules are usually of a yellowish or greenish color, and consist of one or more hepatic lobules, in which the liver-cells are bile-stained, and usually contain oil-globules. The nodules are separated from each other by grayish-white bands of newly formed connective tissue. This nodulated aspect has given rise to the term hob-nailed, as applied to some examples of cirrhosed liver. The consistence of the liver is firm, sometimes almost cartilaginous. The cut surface is dry and anæmic. The microscopic examination shows that the most important change is an increase of the connective tissue which accompanies, under the name of the capsule of Glisson, the medium-sized and small branches of the portal vein. This increase of the interlobular tissue is not uniform, but in the form of bands or masses which surround usually a number of lobules. The new growth of connective tissue is not always confined to that surrounding the ramifications of the portal vein, but often invades the lobules, and also appears around the central vein, so that the lobules may be split up into larger or smaller portions by bands of fibrous tissue. The new tissue is usually rich in lymphoid and spindle cells, and with age generally has a tendency to become fibrous. It invades the walls of the interlobular veins, so that they lose their elasticity, and many of them become obliterated. The most important symptoms are referable to this destruction of numerous branches of the portal vein. The new tissue, however, is not poor in vessels, many of which are probably newly formed and derived from the hepatic artery. The branches of the hepatic artery and the bile-ducts suffer much less from the compression of the new tissue than the thin walled portal vessels.

This development of connective tissue is attended by atrophy of hepatic lobules and destruction of a large number of liver-cells. The atrophy of the hepatic parenchyma has been usually attributed to the compression of the liver-cells by the fibrous tissue, but an equally important factor is the lack

of nutrition consequent upon the obliteration of the interlobular veins. The remaining hepatic cells usually contain oil-globules, and are stained with bile-pigment.

In many cases of cirrhosis of the liver, numerous branching narrow channels, containing a single or double row of cubical epithelial cells, and resembling the interlobular bile-ducts, are met with in the connective tissue. They are too many to consist of only pre-existing interlobular ducts, and there has been much discussion as to their origin. Three theories have been advanced, one that they are offshoots by new growth from the old bile-ducts, a second that they are intralobular bile-capillaries, which have acquired an epithelial lining, and a third, which is perhaps the most probable, that they are rows of liver-cells altered in shape and arrangement by the ingrowth of connective tissue into the lobule.

The capsule of the liver is thickened, and often beset with little villous projections of vascularized connective tissue, which develop into the fibrous adhesions so frequently connecting the liver with the diaphragm and abdominal wall.

Cirrhosis may be combined with extensive fatty infiltration and with amyloid degeneration of the liver. Especially in the latter case the liver may be of very large size.

The changes in other organs are chiefly referable to the portal obstruction and consequent damming back of blood upon the rootlets of the portal vein. The effects of this obstruction are only imperfectly relieved by the establishment of collateral channels. The spleen in the great majority of cases is enlarged and firm. This enlargement is due to congestion and sometimes also to hyperplasia of its stroma, a condition which may be referable to the same cause as the cirrhosis. The size of the organ is not usually more than twice or thrice the normal. The increase cannot always be made out during life. The mucous membrane of the stomach and intestine is usually thickened, pigmented, and coated with more or less muco-pus; in other words, in the condition of chronic inflammation. Ascites and, in the later stages, general œdema are present. Hemorrhages into the stomach and intestine, also in other parts of the body, as in the retina, may be found after death.

The small kidney, and sometimes other forms of chronic diffuse nephritis, occasionally complicate cirrhosis of the liver, and are probably effects of the same cause.

Cirrhosis is to be regarded as a chronic inflammatory affection involving the interstitial tissue of the liver.

Clinical History.—Cirrhosis as a rule gives rise to few or no symptoms which point to the liver as the seat of disease prior to the occurrence of hydro-peritoneum. Preceding this event, and afterward, pain in the region of the liver exists in only a small proportion of cases. Dropsical effusion is usually the first symptom to suggest the existence of the affection. The dropsy may occur when the patient supposes himself to be in his habitual state of health, or it may be preceded and accompanied by indefinite ailments. The dropsical accumulation increases, and, usually, with considerable or great rapidity. It is rare for the quantity of liquid to remain at a moderate amount for a considerable period. Œdema of the lower limbs, in a moderate degree, is observed in a considerable number of cases, before the patient's attention has been directed to enlargement of the abdomen. It is, however, probable that an amount of dropsical effusion not sufficient to attract attention always precedes the œdema of the lower limbs. After considerable abdominal enlargement has taken place, the œdema increases. The limbs often are largely swollen, and the genitalia may become more or less œdematous. The œdema

in these situations is attributable to pressure of the peritoneal effusion upon the iliac veins. Œdema of the face and upper extremities does not occur save in cases in which cardiac or renal disease co-exists. Œdema of the lower limbs does not occur in all cases.

Jaundice is present in a small proportion of cases and is rarely great. The lesion does not necessarily occasion obstruction of the biliary ducts, although it must diminish the secretion of bile. Pallor of the prolabia and skin exists in the majority of cases. In general, the anæmic aspect is marked in proportion as other symptoms show the condition of the patient to be unfavorable.

Febrile movement does not accompany the disease in its progress. The pulse may be not increased in frequency, or it may be more or less accelerated; it is generally soft and feeble. When frequent, the other characters denote diminution of the vital forces or asthenia.

The obstruction of the portal circulation is compensated for, in a measure, by new channels of communication between the portal and the systemic veins. The most important of these are anastomosing branches which pass to the liver between the folds of the falciform ligament and in the ligamentum teres, communicating with the veins of the abdominal parietes through the epigastric and the internal mammary veins. The course of the blood in these anastomosing branches, in cases of cirrhosis, is the reverse of that in health, being in the latter in a direction toward, and in the former from, the liver. Owing to this, the abdominal veins become dilated, and those superficially situated in some cases are seen to be more or less enlarged. A collateral circulation, in a measure, is also established through communications between the inferior mesenteric and the hypogastric veins in the hemorrhoidal plexus; by anastomosing branches between the vena portæ and the veins of the serous covering of the liver; between the coronaria ventriculi and the œsophageal veins; and by newly formed vessels in the tissue by which the liver adheres to the diaphragm. The size of the superficial abdominal veins, on either side of the median line, is sometimes enormous. The dilated network of radiating veins around the umbilicus gives rise to the appearance called the caput Medusæ. The conservative effect of compensatory development of veins communicating with the two circulations, is shown by the fact that examples of great enlargement of the vessels may be apparent upon the abdomen in those who are free from dropsy notwithstanding a notable amount of cirrhosis.

Hemorrhage from the stomach and bowels is an occasional event. Gastrorrhagia occurred in 6 of about 40 cases which I have analyzed, the histories in all the cases not being complete. It preceded the hydro-peritoneum in 3 cases. Hæmatemesis may proceed from varices at the lower end of the œsophagus. Enterorrhagia co-existed with gastrorrhagia in 2 cases, and occurred without it in 2 cases. Vomiting is occasionally a prominent symptom, and diarrhœa is prominent in a small proportion of cases.

In an advanced period of the disease, hemorrhage is apt to occur from the nostrils, sometimes from the gums, and into the retina. In these situations the hemorrhage is attributable, not to the portal congestion, but to an altered state of the blood. The appetite is usually impaired. A sense of fulness after taking food is generally complained of, if the dropsy be sufficient to distend the abdomen. Progressive emaciation attends the progress of the disease, and, in an advanced stage, the attenuation of the upper portion of the body, the distended abdomen, and the lower limbs enlarged by œdema, render the general aspect highly characteristic.

Albuminuria is rare in cases of cirrhosis. Of 28 cases in which the condition of the urine in this respect was noted, in only one case was albumen present. The urine is generally scanty, but in some cases abundant. The

coloring matter of the urine is abnormally abundant, a fact attributable to the deficient secretion of bile; the blood-pigment which serves for the production of the bilirubin, not being expended in the liver, is eliminated in the kidneys. The abundance of the coloring matter may be such as to give to the urine the appearance of being bloody. The urates are usually deposited in great quantity, and are notably red from the abundance of pigment.

In the great majority of cases there are no important symptoms pertaining to the nervous system. The mode of dying is usually by slow asthenia. If, however, the abdomen be greatly distended, or if the dropsical accumulation take place very rapidly, death may be due in part to the extent to which the respiratory function is compromised. The mental faculties are generally preserved up to the last moments of life. To this rule there are exceptions. In 3 cases I have noted the occurrence of delirium several days before death. In one case the delirium was hilarious; in one case the patient appeared bewildered; and in one case the patient lapsed from childishness into imbecility. These cases ended in coma. In three other cases the patients died comatose. In one case convulsions occurred, followed by coma.[1] The symptoms of icterus gravis may appear in the last stage.

Causation.—Cirrhosis, in the vast majority of cases, is due to spirit-drinking. Hence the significance of the term *gin* or *whiskey liver*, applied by British writers to this affection. In most cases an inquiry into the mode of drinking will show that the habit has been to take raw spirits at different periods of the day, before breakfast and at other times, on an empty stomach, a little water being generally drank after the spirits. In this mode the greatest amount of effect from a given quantity of alcohol is obtained. Occasionally patients declare that they have been accustomed to drink only wine or beer. If the use of alcohol in any form be denied, it may perhaps be said, in connection with this disease, that etiological laws are more trustworthy than human testimony. In a considerable number of cases the statements of patients in regard to the quantity of spirits taken are not reliable.

The disease is sometimes attributed to other causes than alcohol, namely, to malarial poisoning, syphilis, chronic peritonitis, chronic phosphorous poisoning, and occlusion of the common bile-duct. The efficiency of these causes is open to doubt. At all events, if the diagnosis of cirrhosis of the liver be made, the inference of spirit-drinking is always warrantable. As to the action of alcohol in producing this affection, the explanation is, that, passing readily into the portal blood from the stomach, and carried at once to the liver, it excites, by contact, inflammation of a low grade in the interlobular spaces, and hence the production of adventitious tissue. So far as my observations go, they furnish no evidence of the agency of disease of the heart in the causation of this affection.

Cirrhosis very rarely occurs under thirty years of age, and, in the majority of cases, the age exceeds fifty years. The affection is generally a result of the habitual abuse of alcohol continued for a long period. Males are affected much oftener than females, a fact readily explained by the dependence of the affection on the use of spirits in the manner stated.

Diagnosis.—The diagnosis in most cases of cirrhosis, after dropsy has occurred, is made without difficulty. Hydro-peritoneum, occurring as a

[1] This account of the symptomatology is based on an analysis of 46 cases of hydro-peritoneum, cirrhosis existing in nearly all the cases. *Vide* Clinical Report, already referred to.

local dropsy, that is, irrespective of general dropsy, in a person addicted to spirit-drinking, warrants an inference that this affection exists. Additional proof is afforded by the diminished size of the liver. This is ascertained by percussion. The upper margin of the liver is accurately determined by finding the line of hepatic flatness; the lower border is determined, not so accurately, but approximately, by the line of demarcation between hepatic flatness and the tympanitic resonance due to gas in the transverse colon. The latter is not exact, because tympanitic resonance is conducted for a certain distance above the lower margin of the liver. The vertical diameter of the liver in health, on the *linea mammillaris*, is about four inches. Directly after the operation of tapping, while the abdominal walls are relaxed, the lower border of the liver may frequently be grasped by the fingers pressed upward beneath the false ribs, and its indurated, nodulated condition appreciated by palpation.

The physician is rarely called upon to make the diagnosis prior to the occurrence of dropsy. It may be practicable, in some cases, to determine, by palpation, induration, and a nodulated condition of the lower part of the organ before dropsy has taken place, and, this information obtained, the diagnosis is highly probable if the patient be addicted to spirit-drinking. Hemorrhage from the stomach sometimes precedes the occurrence of dropsy, and, in a spirit-drinker, renders the existence of cirrhosis probable. In a case under my observation, the patient, a woman, who presented anæmia with progressive debility, and died, at length, in the first stage of pneumonia, the liver was notably cirrhosed and hobnailed, the weight being two pounds and two ounces. Habits of intemperance had not been suspected in this case. She had had gastrorrhagia. Hydro-peritoneum, it is to be borne in mind, occurs in other pathological connections than with cirrhosis of the liver (*vide* p. 596). When it occurs as a result of occlusion of the portal vein by thrombosis, the peritoneal dropsy occurs rapidly; the spleen may become greatly enlarged, and the liver is undiminished in size. A number of cases of gastrorrhagia from cirrhosis, without dropsy, have come under my observation. I have known most profuse hemorrhage, proceeding from cirrhosis, without dropsy, to be followed by the recovery of a fair condition of health. On the other hand, I have known it to cause sudden death.

Prognosis.—Cirrhosis is to be regarded as an incurable lesion. After it has led to dropsy, in the majority of cases its course is progressively onward toward a fatal termination. The duration in sixteen fatal cases, dating from the occurrence of dropsy, varied from six weeks to seventeen months, the average duration being about five months. But doubtless in all cases the disease has existed for a considerable period before dropsy occurs. In a certain proportion of cases, the dropsy being removed, the patient may regain comfortable or even good health, and remain free from any manifestations of the disease for months and years, but sooner or later, as a rule, to which there are very few exceptions, the dropsy returns, and, unless life be destroyed by some intercurrent affection, the disease ends fatally. Circumstances which preclude much expectation of improvement are, the co-existence of cardiac, renal, or any other important disease, considerable emaciation, sufficient debility to keep the patient in bed, greatly impaired appetite and digestion, speedy reaccumulation of liquid after tapping, and the occurrence of jaundice.

Treatment.—As regards treatment, in cases of cirrhosis and in the great majority of the cases of hydro-peritoneum, the indications are the same. The reader is, therefore, referred to the treatment of hydro-peritoneum considered in the preceding chapter.

Hypertrophic Cirrhosis of the Liver.

It has already been mentioned that, exceptionally, in ordinary alcoholic cirrhosis, the liver may be large throughout the whole course of the disease, presenting the same microscopical appearances and giving rise to the same symptoms as the more usual contracted liver. Recently certain French writers[1] have called attention, under the name *hypertrophic cirrhosis with severe icterus*, to a disease which they consider to possess distinctive pathological and clinical characteristics. The liver, as a rule, is considerably enlarged, its surface smooth or finely granular, its consistence firm. Its free and cut surfaces present little yellowish islands of liver parenchyma, between which are grayish bands and masses of connective tissue. The new connective tissue is more uniformly distributed than in ordinary cirrhosis. It surrounds and penetrates into the individual lobules[2] rather than surrounds groups of lobules, and is particularly rich in so-called newly-formed bile-ducts. It is maintained by Charcot and Gombault that this form of cirrhosis begins as an inflammation of the interlobular bile-ducts, and extends to the surrounding connective tissue. This opinion, however, is hypothetical.

The spleen is constantly enlarged, and usually to a greater extent than in ordinary cirrhosis. As a characteristic feature of this form of cirrhosis, marked icterus is present throughout the greater part of the disease. Ascites is less marked than in ordinary cirrhosis, and appears later, or may fail entirely. Symptoms referable to the digestive tract are present as in ordinary cirrhosis. In the later stages, marked cerebral symptoms—coma, convulsions, delirium—are frequent. Here, too, the only well-established cause is the abuse of alcoholic liquors. The duration of the disease is usually over a year, and may be five or six years. The chief points in the diagnosis are the enlargement of the liver, the presence of icterus, the enlargement of the spleen, the absence of marked ascites, and the duration of the disease. The even surface and uniform enlargement of the liver distinguish hypertrophic cirrhosis from enlargement due to echinococcus, carcinoma, and other new growths. The causation is also to be considered in making a diagnosis. In some cases of otherwise typical hypertrophic cirrhosis with icterus, the ascites has been a marked feature.

Acute Yellow Atrophy of the Liver.

This affection is characterized, as the name denotes, by a rapid reduction in size of the liver. Its anatomical characters were first recognized by Rokitansky (1842). The same disease has been known under the names *malignant* or *fatal jaundice*, *hemorrhagic icterus*, and *diffuse parenchymatous hepatitis* (Frerichs). It is a rare disease, the recorded observations not exceeding two hundred, according to Thierfelder.[3]

Anatomical Characters.—In typical cases the liver is much diminished in size in all directions, but especially as regards its thickness. The volume and likewise the weight may be reduced one-half or even two-thirds. Occasionally the size of the liver is not below the normal. This happens especially

[1] P. Olivier, Hayem, and especially Hanot, Etude sur une forme de cirrhose hypertrophique du foie, Paris, 1876, and Charcot et Gombault, Arch. de Physiologie, 1876.

[2] For this reason it is called by Charcot insular or monolobular cirrhosis, in distinction from annular or multilobular cirrhosis, which is the ordinary form.

[3] Thierfelder, Ziemssen's Handbuch d. spec. Path. u. Ther., Bd. viii. p. 215, Leipzig, 1878.

when the disease attacks a liver previously enlarged, or when the affection is of unusually short duration. The consistence is soft and flabby, so that the organ when placed on its surface is flattened, or, when supported on its edge, folds up from its own weight. The capsule is wrinkled in consequence of diminution in bulk of the liver-substance. In the living body the shrunken liver may sink back toward the vertebral column, so that coils of intestine find place over its anterior surface.

Upon its cut surface the liver appears intensely jaundiced. The color may be yellow throughout, but the prevailing yellow color is usually mingled with some reddish-brown patches. The reddish color may preponderate over the yellow. Great variety exists in the relative proportion and the distribution of the yellow and the red substance. The yellow substance is soft and friable. Its color is due to bile-staining and the presence of fat. The red substance is of lax texture, but tough consistence, and, on section, somewhat depressed below the level of the yellow. It appears homogeneous, without any trace of the hepatic lobules, or, at the most, presents the faint outlines of very small lobules. In the yellow substance the outlines of the lobules are very much obscured. If seen at all, the lobules are found to be larger than in the red substance, but, as a rule, smaller than normal. The disease is often further advanced in the left lobe than in the right. The former may be almost uniformly red, while the latter is yellow mottled with some red spots.

The microscope shows that the atrophy is due to an actual destruction of the hepatic cells by the process of fatty degeneration. Different stages of the process can usually be found in the same liver. At first the hepatic cells are swollen, cloudy, and bile-stained; later, their outlines are obscured, and their substance occupied by fat in the form either of granules or of large and small globules. There is reason to believe that the fat is formed directly from the albuminous material of the cell. Finally, there is left no trace of the liver-cells, but in their stead a mass of granular detritus, drops of fat, together with crystallized and amorphous bile-pigment. All these conditions may be observed in different parts of the yellow substance, the degree of destruction of liver-parenchyma varying much in different cases. In some instances the detritus resulting from the disintegration of the cells seems to be more albuminous than fatty.

The red substance is usually considered to represent a later stage of development of the yellow portion. Its color was formerly supposed to be due to blood-extravasations which may be present in the liver of acute yellow atrophy. Upon microscopical examination, however, the red substance is found generally to be composed chiefly of connective tissue, bloodvessels, and probably newly formed bile-ducts. Some granules and small drops of fat, together with bilirubin crystals, may still be found in the connective tissue, but the greater part of the disintegrated liver-cells has been absorbed. Cells, which can be recognized as hepatic cells, are entirely absent or present in small number. Leucocytes, sometimes in abundance, are found in the connective tissue. The increase in connective tissue is partly apparent in consequence of disappearance of the liver-cells and of their fatty detritus, and partly real by means of a new growth of the interlobular tissue. In this red substance are found often narrow branching channels filled with a single or double row of small polyhedrical cells. These epithelial canals resemble the small interlobular bile-ducts, but are too numerous to consist only of pre-existing ones. They are considered by Waldeyer, Zenker, and others as offshoots by new growth from these bile-ducts, and intended for the regeneration of the destroyed liver parenchyma. Klebs and Perls, however, regard the cells in these canals as rows of pre-existing liver-cells altered in shape. Attempts at artificial injection of the bloodvessels of the liver after death, fail in consequence of the escape of injecting material between the liver-cells.

The larger bile-ducts are usually empty. They may be inflamed and contain a secretion of muco-pus, or they may contain bile-stained fluid. The gall-bladder contains a mucous fluid either colorless or bile-stained. It may contain apparently normal bile. Leucin and tyrosin crystals often form in the substance of the liver after death. Rod-shaped bacteria and micrococci have been found by Klebs and others in the bile-ducts and in the atrophied liver tissue. Their accumulation in large numbers in the bile-ducts, has led to the belief that they have made their way there from the intestine, whether before or after death is a matter of uncertainty.

The changes in other organs are similar to those found in certain acute infectious diseases. The tissues are jaundiced. The blood is fluid or loosely coagulated, and contains leucin and tyrosin. The cardiac muscle and the renal epithelium usually show decided fatty degeneration, not approaching, however, in degree that of the liver. The stomach and intestine frequently show evidences of inflammation. The epithelial cells of the gastric tubules undergo parenchymatous degeneration. The spleen is found swollen and soft, unless its size has been reduced by hemorrhage from some of the rootlets of the portal vein. Multiple hemorrhages occur in the majority of cases. These occur especially from vessels of the portal circulation. Blood is often found in the contents of the stomach and intestine, also in the mucous membrane of the bladder, pelvis of the kidney, beneath the serous membranes, in the lungs, etc. Hemorrhages very rarely take place in the brain.

Clinical History.—The affection is either developed abruptly or preceded by a prodromic stage. The premonitions are symptoms denoting gastro-duodenitis, and are not significant of the affection. Without or with premonitions lasting from three to five days usually, but sometimes much longer, jaundice occurs. It is usually marked, but not intense, and does not differ, as regards the coloration of the skin, from ordinary jaundice. Intense cephalalgia and delirium, either simultaneously with the jaundice or after a period varying from two to twenty-one days, become prominent symptoms. The delirium is often active, patients crying out, and sometimes requiring restraint; but in some cases the delirium manifests itself only in quiet wandering. In a third of the cases convulsions occur. These in some cases are epileptiform; in some cases they consist of general tremor or rigor, and in some cases they are limited to a few muscles. Trismus has occasionally been observed. To the delirium and convulsions, stupor succeeds, eventuating in profound coma. The pupils are sometimes contracted, but usually dilated, and in some cases unaffected, responding readily to light. When the jaundice first appears, the pulse is slow, but when delirium occurs, the pulse is more or less frequent. During the progress of the disease, the pulse fluctuates remarkably as regards frequency. At one time it may rise to 120, at another time falling to 80 or 90. The pulse varies also as regards other characters than frequency. In the latter part of the disease it becomes persistingly frequent, increasing progressively in frequency and becoming more and more attenuated and feeble. There is generally a moderate rise of temperature in the early stage, but at a later period fever may be absent, except that sometimes shortly before death a considerable rise (104°, 105°) occurs. Hemorrhages take place in various situations, generally into the stomach and intestines, in females from the uterus, and occasionally hæmaturia occurs. Extravasations are not uncommon, giving rise to petechiæ and to ecchymoses found after death in various situations. Pains in the epigastrium are common, extending to the right hypochondrium. Tenderness on pressure exists in these regions. The bowels are generally constipated. The stools are sometimes clay colored, sometimes green and bilious, and sometimes dark from blood. The breathing is apt to be

early accompanied by sighing, and, after coma occurs, the respirations are irregular and stertorous. The urine has been found to contain biliary salts by a number of observers. The small quantity present, and the difficulty in the detection of these salts, may explain some of the negative results of other observers. The amount of urea is notably diminished, especially in the latter part of the disease, when it may entirely disappear. Leucin and tyrosin are found in the great majority of cases. Leucin in the form of globules, somewhat resembling fat, is found only after evaporating the urine; tyrosin, in the form of needles, appears as a spontaneous sediment. Albumen is found in a moderate quantity. Coolness and dryness of the surface exist, except under the excitement of delirium and convulsions, when the heat of the skin is sometimes increased.

The duration of the affection is usually short. Of 28 cases, a fatal termination took place in 13 within a week, in 6 during the second week, in 5 during the third week, and in 4 during the fourth week.

The termination, in the vast majority of cases, is fatal.

Pathological Character.—As regards the anatomical changes in the liver, according to many authors they denote a diffuse parenchymatous inflammation. As opposed to this view, the alterations formerly regarded as evidence of parenchymatous inflammation are now attributed to degenerative processes. The theory, based upon the presence of leucocytes in the interstitial tissue, that the inflammation is interstitial, is not satisfactory. The wandering cells are most numerous in the red substance, and their presence may, therefore, be regarded as a secondary change. The greater number of pathologists, at the present time, regard the changes in the liver as primarily regressive and produced by an acute fatty degeneration.

As to the pathological character of the disease, there have been many speculations, most of which possess only historical interest, such as, that the changes in the hepatic cells are due to an over-production of bile, to paralysis of the bile-ducts, to disturbances in the innervation of the liver, etc. The hypothesis now most advocated is that acute yellow atrophy of the liver is an infectious disease. The changes in the liver may be regarded as the local manifestations of a general infection; or the infectious principle may be considered to act primarily upon the liver and secondarily upon the blood and other organs. According to the latter view, the special poison makes its way into the system through the liver, perhaps by means of the ingress of the infectious material (bacteria?) from the intestine into the bile-ducts.

The symptomatic phenomena which form the clinical history of the disease, are, in a greater or less degree, effects of the action of the infectious principle, the existence of which may be assumed. Certain of the grave phenomena, however, are attributable to the non-elimination of excrementitious principles which it is a function of the liver to excrete. The retention of these in the blood is denoted by the term acholia. The physiological discovery that the cholesterin in bile is an excretory product derived chiefly from the destructive metamorphosis of nerve tissue, is sustained by, and affords a rational explanation of, the phenomena in this disease referable to acholia. That these are effects of cholesteræmia is evidenced by clinical observations showing in this disease a notable accumulation in the blood of cholesterin, and by experiments showing the production of phenomena analogous to those of this disease in animals by the injection of cholesterin into the blood.[1] Uræmia is doubtless

[1] *Vide* Experimental Researches into a new Excretory Function of the Liver, by A. Flint, Jr., Am. Journ. of Med. Sciences, 1862; also, Flint's text-book of Human Physiology.

in many cases a pathological element, but the clinical history shows clearly other toxical effects than those referable to that element.

Causation.—Of 143 cases analyzed by Thierfelder, 88 were women and 55 men. Of the 88 women, 30 were attacked in pregnancy and 3 in childbed. Of the 143 cases, 93 were between the ages of 20 and of 39. Two were under one year of age and 5 were over 50. Aside from the influence of age, sex, and the state of pregnancy, as manifested in the above statistics, we have no knowledge of causative agencies. If, as held by many, the disease be specific or infectious, it involves, of course, a special cause.

Diagnosis.—The symptoms are not diagnostic of this disease prior to the occurrence of the grave toxæmic phenomena, namely, delirium, hemorrhages, etc., in connection with jaundice. The fevers—typhus or typhoid, remittent, pyæmia, yellow fever—are excluded by the absence of the diagnostic features which belong to them severally, and sometimes by the absence of a febrile temperature. Diminution of the size of the liver while the case is under observation, in connection with the clinical history, renders the diagnosis positive. But this effect does not always take place. Moreover, it is sometimes difficult to determine accurately the vertical diameter of the liver by percussion, owing to the fact that the tympanitic resonance from the colon sometimes may be conducted upward, so as sometimes even to meet the vesicular resonance, when the size of the liver is normal. There is, therefore, a liability to error in deciding that the liver is reduced in size. This difficulty applies to cases in which the transverse colon is distended with gas; generally, it may be correctly ascertained whether the size has diminished. The presence of leucin and tyrosin in the urine is diagnostic. The sex of the patient and the existence of pregnancy have some weight in the diagnosis; so, also, the gravity of the disease, as denoted by the symptoms and the rapid progress towards a fatal termination.

Prognosis.—It is questionable whether this disease ever ends in recovery. Cases of recovery have been reported, but there is, perhaps, more probability that, in these cases, there was an error in diagnosis than that the disease really existed and terminated favorably.

Thierfelder gives the following statistics in regard to the duration after the development of grave symptoms, based on an analysis of 118 cases: 24 hours or less, in 10; from 12 to 48 hours, in 46; from $2\frac{1}{2}$ to 3 days, in 26; from $3\frac{1}{2}$ to 4 days, in 17; from 5 to 7 days, in 15; 9 days, in 2; and 10 and 14 days, of each, one case.

Treatment.—A few words will embrace all that is to be said with reference to treatment. With our present knowledge nothing is to be expected, beyond palliation, from remedies. Drastic purgatives and emetics have been advised, but the propriety of these or other perturbatory measures is very doubtful. Symptoms which furnish indications for palliative remedies are vomiting and hemorrhages. For the vomiting and gastrorrhagia, ice in small pieces, bismuth, and anodynes may be prescribed. The mineral acids are appropriate. The symptoms referable to the circulation, namely, the frequency and feebleness of the pulse, with coolness of the surface, indicate tonics and stimulants. Inasmuch as the convulsions and coma may be due to uræmia, it would be desirable, if possible, to excite the action of the kidneys; and, if this be not practicable, the hot-air bath and perhaps hydragogues suggest themselves as means of effecting the vicarious elimination of urea. Hemorrhage from the bowels is to be controlled by cold applications

and opiate enemas. Revulsive applications over the site of the liver, by means of fomentations and stimulating embrocations or rubefacients, may be of some service. Quinia in full doses deserves further trial.

Syphilitic Hepatitis.

There are several forms of syphilitic disease of the liver. Diffuse syphilitic hepatitis is observed as a frequent manifestation of congenital syphilis, but very rarely, if ever, in the adult. In this condition the liver is enlarged, smooth, firm, and anæmic. The lobular markings are obscured. Upon microscopical examination there are found an increase of the connective tissue, both within and without the lobules, and a quite uniform infiltration with small round cells.

A second form of syphilitic hepatic disease is characterized by the presence of gummata in the liver. These sometimes appear in new-born children as very abundant, yellowish, miliary nodules scattered throughout the substance of the liver. In the adult, gummata generally appear in the liver as scattered nodules, varying in size from a pea to a hen's egg, with a dry, yellowish, caseous centre, surrounded by a grayish zone of fibrous tissue which encroaches upon the hepatic parenchyma.

One of the most characteristic forms of syphilitic disease of the liver, the one often called the *syphilitic liver*, is that in which the liver is greatly distorted in size and shape by coarse bands of fibrous tissue, which pass from the thickened capsule into the substance of the organ, and cause deep cicatrix-like depressions. In this condition the surface of the liver is coarsely lobulated, and presents an absolutely characteristic appearance. In the fibrous bands gummata may be present, and it is held by the majority of writers that the fibrous tissue is only developed around gummata or as cicatricial tissue in their place. Not infrequently, however, gummata are absent in these livers, and Virchow, denying that the caseous products of a gumma can ever be wholly absorbed, regards this disease of the liver as a chronic interstitial hepatitis, developed in a circumscribed form, either with or without the presence of gummata.

Finally, amyloid degeneration of the liver, either independently or complicating one of the previously described conditions, is one of the manifestations of the syphilitic taint.

Syphilitic disease of the liver, as is the case with all forms of visceral syphilis, appears chiefly in the tertiary stage. Although in itself not common, it is one of the most frequent forms of visceral syphilis.

Syphilitic disease of the liver, especially the gummatous form, may give rise to no evident symptoms. The lobulated syphilitic liver may remain latent, so far as symptoms are concerned, but it usually is accompanied with some or all of the symptoms of ordinary cirrhosis, from which it is to be distinguished by the syphilitic history of the patient and the characteristic feel of the liver. The coarse nodules which can be felt on these livers resemble very much those present in carcinoma of the liver, and the distinction between them is not always easy. The umbilication, which can sometimes be felt on the cancerous nodules, may be of assistance in the diagnosis. The spleen is usually enlarged in syphilitic liver, and is not in cancer of the liver. The history of the patient is, however, the capital point in the diagnosis, as bearing upon the presence or absence of cancer or of syphilitic disease in other parts of the body.

CHAPTER XII.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN—(CONTINUED.)

Fatty Liver. Waxy or Lardaceous Liver. Cancer of the Liver. Other New Growths in the Liver. Hydatid Tumors of the Liver. Parenchymatous Degeneration of the Liver. Pigmentary Deposit within the Liver. Hypertrophy of the Liver. Portal Thrombosis. Pylethrombosis. Adhesive and Suppurative Pyle-phlebitis.

HAVING considered inflammatory affections of the liver, structural affections are next to be considered. The more important of these are incident to an abnormal accumulation of fat, to the waxy or lardaceous alteration, to carcinoma and tuberculosis, and to hydatid tumors. They will be considered in this chapter.

Fatty Liver.

The liver is one of the normal situations for the deposition of fat. In well-nourished, healthy individuals the liver-cells contain some oil-drops. As there is great variation in the amount of fat contained in the livers of healthy persons, it is by no means easy to determine the amount which is to be regarded as abnormal.

It is customary to distinguish between fatty infiltration and fatty degeneration of the liver. The reader is referred to Part First, page 55 *et seq.*, for the grounds upon which this distinction, as adopted in this work, is based. The distinction may be here repeated: In fatty infiltration or fatty growth, the protoplasm is displaced by the fat, but does not suffer materially in its integrity, except by a slow process of atrophy from compression; if the fat be derived from the albuminous constituents of the cell, these are, in great part at least, renewed. In fatty degeneration or fatty atrophy the cell-substance is directly converted into fat, and is not at all, or insufficiently, regenerated. These are important exceptions to the rule that in fatty infiltration the fat is present in the form of large drops, whereas in fatty degeneration it appears as small drops or molecules. The most typical example of fatty degeneration of the liver is acute yellow atrophy of this organ, to which no further reference will be made in this connection, as it has been already considered. Some writers regard all the other forms of fatty liver as examples of fatty infiltration. It is true that, as a rule, they present the gross and microscopical appearances which have been considered characteristic of infiltration; but, as explained in Part First, these histological appearances do not suffice for the diagnosis between infiltration and degeneration.

A fatty liver is usually more or less enlarged, its margins rounded, and its surface smooth. The consistence is less than in health. The specific gravity in extreme cases is so light that the organ floats in water. The weight, however, owing to increase in volume, is usually greater than in health. The color is yellowish; the lobular markings are often obscured. Drops of oil adhere to the knife in making a section. The organ is anæmic. While the amount of fat which can be extracted by ether from a normal liver is estimated at about three per cent., that present in extremely fatty livers may rise as high as forty or forty-five per cent.

In the physiological accumulation of fat in the livers of women during lactation, the fat is present chiefly in the central cells of the lobules. In most other cases of fatty infiltration, the fat appears primarily in the hepatic cells in the periphery of the lobule, and extends, as the fatty accumulation increases, to the cells in the centre. The fat appears first as small drops which increase in size and coalesce until finally one large drop occupies nearly the whole of the space within the cell contour. An hepatic cell thus altered is spherical in shape, its nucleus is pushed to one side, its protoplasm forms a narrow ring around the oil-drop, and the whole cell resembles an adipose tissue cell. The fat may also exist between the hepatic cells, either free in the intercellular spaces, or in stellate cells situated there.[1]

The essential condition for the development of fatty metamorphosis of the liver is, that more fat be either introduced or produced than can be oxidized. This failure of oxidation may depend either upon an excessive introduction or production of fat in the organ, or upon a diminution in the oxidizing processes, due usually to a deficient supply of oxygen to the cells. We thus find fatty livers in conditions apparently the most opposite, namely, in cases of great obesity and in cases of extreme emaciation. The causes of fatty liver may be summarized as follows :—

1. Lactation. The accumulation of fat in the centre of the lobules before and during lactation is to be regarded as physiological rather than pathological. 2. Obesity. Persons who take little muscular exercise, whose food contains an excess of hydrocarbonaceous substances, and who often have a predisposition, either hereditary or acquired, for the deposition of fat, may develop very large fatty livers as well as an excessive panniculus adiposus. 3. Continued and excessive indulgence in alcoholic stimulants. This leads often, but not constantly, to fatty infiltration of the liver, as well as to cirrhosis. 4. Pulmonary phthisis and, less frequently, other cachectic conditions such as cancer, chronic dysentery, profound anæmias, etc. The largest fatty livers met with are those developed during chronic pulmonary tuberculosis, especially in females. 5. Phosphorus poisoning. Although the liver here presents the appearance usually considered characteristic of fatty infiltration, it is probable that poisoning by phosphorus leads to fatty degeneration of the liver, as well as of the kidneys, muscles, etc. Arsenic and some other poisons also occasion fatty metamorphosis of the liver. 6. The acute fatty degeneration of the new-born, described by Hecker and Buhl.[2] The liver takes part with other organs in the general fatty degeneration. 7. Yellow fever. The fat is present in large drops, but the process is fatty degeneration. The hepatic cells usually contain fat in cirrhosis and in chronic passive congestion of the liver. The cause here is local and referable to the interference with the circulation.

Our present knowledge is not sufficient to enable us to determine the pathological importance of fatty liver. The pressure of the fat appears to be sufficient to render the organ anæmic, but not to occasion obstruction enough to give rise to peritoneal dropsy. If the latter co-exist with fatty liver, cirrhosis is combined, or there exists some other cause for the hydro-peritoneum. The spleen does not become enlarged. There may be some obstruction to the passage of bile in the minute hepatic ducts, but this is not sufficient to occasion jaundice. The function of the secreting cells must be more or less impaired when these are filled with fat, but we are unable to refer any symptoms to this condition.

[2] Hecker and Buhl, Klinik der Geburtskunde, 1, 1861.

The diagnosis of fatty liver can only be made when the organ is enlarged. There are no subjective local symptoms, other than those dependent on the increase of size. The enlargement may be determined by percussion, and by manual exploration below the false ribs. The blunt or rounded lower margin may sometimes be ascertained. The smoothness of the surface is appreciable, and sometimes also the diminished consistence; or, at all events, the absence of induration may be ascertained. An enlarged liver presenting these characters, occurring in a patient affected with pulmonary phthisis, an intemperate person, or a person of luxurious, indolent habits, may be considered as probably fatty. The probability is greater in females than in males. Simple enlargement in this pathological connection is not sufficient for the diagnosis of fatty liver, inasmuch as waxy liver is not infrequently associated with pulmonary phthisis; and it is not always easy to determine the physical characters which distinguish from each other these two forms of enlargement.

Fatty liver occurring in cases of pulmonary phthisis does not claim treatment. In fact, the treatment of phthisis, which, in certain cases, is highly useful, namely, with cod-liver oil and alcoholics, may be supposed to favor the deposit of fat in the liver. Nor, as a general remark, with our present knowledge, does it claim treatment when associated with other important affections. Occurring in persons addicted to the use of alcohol, and to overfeeding especially as regards fatty articles of diet, it is to be treated by a reformation of the habits of living, namely, by temperance, or total abstinence, in respect to the use of alcoholic beverages, by restricting the diet, in a great measure, to articles not abounding in fat, and, if the strength will permit, by more muscular exercise. The remedies indicated are those which will tend to strengthen and invigorate the system. Fatty liver combined with chronic alcoholic gastritis offers a bad prognosis.

Parenchymatous Degeneration of Liver.

By the terms parenchymatous degeneration or cloudy swelling of the liver, is designated a condition of the organ often met with after death from fevers, diseases involving severe blood-poisoning and affections accompanied with a high temperature. The liver is sometimes enlarged and the outlines of the lobules are indistinct. The liver-cells are swollen and filled with granules which are coarser and more numerous than the normal. These granules at first are albuminous, and disappear after adding acetic acid. They may, however, give place to fatty granules and drops. Some consider parenchymatous degeneration an essential stage in the process of fatty degeneration. The clinical importance of parenchymatous degeneration of the liver is not well understood.

Waxy Liver.

The liver is one of the organs frequently attacked by waxy degeneration. This degeneration, called waxy, amyloid, lardaceous, albuminoid, consists in the deposition of an albuminous substance, the characters of which have been considered in Part First of this work (page 57). It may be repeated here that this substance strikes with a solution of iodine a reddish-brown or mahogany-brown color, with iodine and sulphuric acid a blue color, and with methylene a red color. The reaction with iodine alone suffices as a test.

In cases of advanced waxy degeneration of the liver, the organ is much enlarged. The enlargement is, in some cases, enormous. The weight may be twelve or fourteen pounds, and is not infrequently double the normal weight. The form of the organ is not materially altered. The surface is

smooth, and the edges usually, but not always, blunted or rounded. The consistence is notably stiff and board-like, so that thin slices are easily taken off. Notwithstanding its firm consistence the organ cuts easily, like uncooked bacon. The interior of the liver is dry and anæmic. The cut surface, especially when examined on thin slices held to the light, presents a characteristic translucent appearance, compared to uncooked bacon, wax, smoked salmon, and tissues soaked in glycerine. The lobular markings are obscured, but, even in extreme cases, opaque whitish lines can be seen usually about the periphery and in the centre of the lobules. The amyloid or waxy change is not, as a rule, uniformly distributed, but some lobules are more affected than others; and with the naked eye, even in advanced degrees of the degeneration, lobules and parts of lobules, usually of a yellowish color from fatty metamorphosis, can be seen without the characteristic translucence. In the lesser degrees of the waxy change, the organ is not at all, or but slightly enlarged, and the affected parts can be readily distinguished only by the chemical test with iodine. The earliest stages are to be recognized only by microscopical examination of sections stained with iodine or with iodine and sulphuric acid or methyl-violet.

Under the microscope the amyloid material appears as a white, structureless, translucent refracting substance. The amyloid degeneration begins first in the terminal branches of the hepatic artery and extends to the capillaries within the lobule. If we imagine the lobule to be divided into three concentric zones, the amyloid deposit appears first chiefly in the middle zone, and then gradually extends to the centre of the lobule, while the peripheral part remains longest unaffected. The peripheral hepatic cells usually contain oil drops, and the central cells are often stained with bile-pigment. The hepatic vein and its branches, and the interlobular branches of the portal vein may become waxy. In the arteries and veins the waxy material first replaces the muscular fibres of the middle tunic, and may then extend to the other coats. Pathologists are not agreed as to where the amyloid substance is chiefly deposited within the lobule. The probability is that it is placed either within the wall of the capillaries or between that and the liver-cells. The capillaries appear to be changed into canals with very narrow and finally obliterated lumen and thick refracting walls, between which the liver-cells are compressed and finally disappear. The amyloid substance has, however, been demonstrated in isolated liver-cells. Virchow, Rindfleisch, Böttcher, and others, maintain that the waxy substance is deposited chiefly in these cells, and only secondarily in the capillary walls, and that the cells become changed into waxy masses without traces of nucleus, protoplasm, or the natural cell contour.[1] According to either view, a large number of liver-cells are destroyed, when the whole lobule becomes transformed. Usually, when the liver is the seat of this morbid change, other organs are also affected, more especially the spleen and kidneys, then the intestine, lymphatic glands, heart, large arteries, etc. Sometimes, even in comparatively slight degrees of the degeneration, the waxy substance is deposited in the liver as a homogeneous nodule, the size of a walnut or even larger, more like a tumor than a centre of infiltration or degeneration.

The affection is rare in infancy and in old age. Of 116 cases analyzed by Frerichs and E. Wagner, 24 occurred between 10 and 20 years; 37 between

[1] These discrepancies seem to be reconciled by the investigations of Kyber, according to whom three forms of waxy liver may be distinguished: one, in which the parenchymatous cells are alone affected; a second, in which the capillary walls and the connective tissue are alone involved; and a third, in which these two varieties are combined. Virchow's Archiv, Bd. 81, p. 36, 1880.

20 and 30 years; 31 between 30 and 50 years; 16 after the age of 50; and 8 prior to 10 years. It is met with in cachectic patients who have suffered from caries or necrosis of bones. It is incident to prolonged suppuration, especially of bone, as in hip-joint disease, Pott's disease, etc.; also to cachexia from tumors, slowly growing cancers, and other causes. It occurs in persons affected with syphilis. It has been observed to follow malarial fever. It accompanies pulmonary phthisis, especially when there are suppurating cavities. In all these connections it is a secondary affection. In a small proportion of cases it is not preceded by any other disease. Cohnheim has demonstrated that three or four months suffice for the change to be brought about. It occurs in the male, oftener than in the female, sex.

The pathological importance of waxy liver and its clinical history are to be based on the study of cases in which the affection is not associated with other serious affections. Such cases are not easily collected, for, if the affection be not secondary, the kidneys, spleen, and other parts are apt to be similarly affected. It is undoubtedly an important affection. The functions of the liver must be compromised in proportion to the amount of the deposit. It may impede the portal circulation through the liver sufficiently to give rise to peritoneal dropsy. Jaundice very rarely occurs. Pain referable to the liver is wanting. If the kidneys be affected, general dropsy is likely to occur.

The diagnosis of this affection is to be based on the existence of enlargement, and the exclusion of other affections of the liver involving increase of size. From fatty liver it is to be distinguished by the greater resistance on palpation, and by the margins being in a less degree blunt or rounded. The existence of peritoneal dropsy in some cases aids in the exclusion of fatty liver. From cancer of the liver it is distinguished by the absence of tumor and the smoothness of the surface. The absence of subjective local symptoms, especially pain, aids in the exclusion of cancer. Cirrhosis leads to contraction of the organ generally; but this affection is excluded by the smoothness of the surface, when it can be felt, and by either the absence of peritoneal dropsy or the existence of only a small amount of effusion. The co-existence of enlarged spleen, and the evidence of disease of the kidneys afforded by albuminuria, general dropsy, and perhaps uræmic symptoms, strengthen the diagnosis. A capital point in the diagnosis is the co-existence of affections to which, as clinical observation shows, this affection is secondary, namely, prolonged suppuration, necrosis of bones, syphilis, etc.

The prognosis is unfavorable. The lesion must be regarded as, in most cases, incurable. There seem to be some data for believing, especially in cases of cured hip-joint disease, that patients may regain good health after waxy degeneration of the liver has been established, but it is doubtful whether the waxy material is absorbed. Frerichs, Graves, and Budd, however, have observed diminution of the size of the liver in cases in which this affection was supposed to exist. Generally, the fatal termination is, to a greater or less extent, due to the diseases with which the affection is associated.

The treatment must have reference to the morbid conditions under which the affection is developed. The iodide of potassium and the iodide of iron are considered by Frerichs as sometimes successful in cases in which syphilis is involved. In scrofulous or tuberculous patients, the therapeutic measures should be directed especially to the cachexia which is to be considered as standing in a causative relation to the affection. Budd recommends the muriate of ammonia, from five to ten grains three times daily. Frerichs attaches importance to mild alkaline remedies and the use of the sulphurous mineral waters. Dietetic and other hygienic measures are of the first importance. The body should be well nourished, the surface properly protected

against vicissitudes, and as much out-of-door life as the strength will permit is advisable. Disorders of any of the functions are to receive appropriate attention. Diarrhœa occurs not infrequently, and this will claim astringent remedies and perhaps opium in small doses. Albuminuria and general dropsy furnish indications the same as when these symptoms occur in connection with any of the renal changes which, collectively, are called Bright's disease.

Cancer of the Liver.

Of the various forms of tumor which may occur in the liver, cancer is the one of greatest importance. While primary cancer of the liver is a very rare disease, the liver is one of the most frequent seats of secondary cancer. The statistics of Leichtenstern show 74 cases in which the cancer was primary, and 358 in which it was secondary. Primary hepatic cancer may develop either from the epithelium of the bile-ducts or from the liver-cells. In secondary cancer of the liver, the primary tumor may be seated in various organs of the body, but will be found most frequently in the stomach, and then, in order of frequency, in the intestine, including the rectum, and the uterus. It has been demonstrated that the secondary cancerous nodules may be developed from emboli of cancer-cells, transmitted from the primary growth along the portal vessels or the lymphatics into the liver, and it is believed that this is the most frequent mode of propagation. A cancer in an adjoining organ, especially the stomach, may invade the liver by continuous growth.

Primary carcinoma of the liver usually presents itself in the form of a single large tumor, often surrounded with several smaller cancerous nodules, and, as a rule, is not distinctly circumscribed. The liver to a great extent, then, seems to be transformed into a cancerous mass which preserves, to some degree, the form and markings of the normal liver. A liver affected with infiltrated cancer sometimes bears considerable resemblance to a large cirrhotic liver, but the parts corresponding to the lobules are larger, and of a yellowish-white color in cancer. Secondary carcinoma of the liver is almost invariably presented in the form of multiple circumscribed nodules of varying size and number. These are usually many; the whole organ may be studded with them; but sometimes only a few nodules are present. The cancerous nodules have generally a whitish color, with scattered yellowish dots and lines. Extravasations of blood into the cancerous mass are occasionally observed. The consistence is sometimes that of scirrhous, more frequently that of medullary, carcinoma. The tumors are present as well on the surface as in the interior of the organ. A quite characteristic appearance of those nodules which rise to the surface is the presence of a cup-shaped depression in the centre. This so-called umbilication is due to degenerative and wasting changes in the central or oldest part of the tumor. Partial peritonitis, causing adhesions, is generally developed when the tumors project beyond the surface, and in some cases the peritonitis becomes general.

The type of the secondary cancer conforms generally to that of the primary growth. As a rule, the cancerous alveoli are large and close together, and contain irregularly shaped, polygonal cells. The cells may, however, be of the cylindrical epithelial type. So-called melanotic carcinoma of the liver is secondary usually to similar primary tumors of the choroid coat of the eye or of the skin. They are classified by many among the melano-sarcomata.

The cancerous affection usually gives rise to more or less enlargement of the liver. The increase in size and weight is sometimes enormous. The weight has been known to reach twenty-five pounds. Primary, as well as secondary, cancer of the gall-bladder and larger bile-ducts, has been repeatedly observed.

Cancer here, as in other situations, rarely occurs in early life. Of 472 cases analyzed by Leichtenstern, the ages in 37 were between 20 and 30 years; in 61 between 30 and 40 years; in 250 between 40 and 60 years, and in 33 over 60 years. Of 756 cases, 334 were men and 422 women.[1]

It is a singular fact that cancer in this situation is more infrequent in tropical than in temperate climates.

Cancer of the liver being generally secondary, the symptoms, in most cases, are combined with those referable to other affected organs. It is much oftener secondary to an affection of other abdominal viscera than to a primary cancer of a part not connected with the portal circulation; and when developed secondarily, under these circumstances, the hepatic affection is liable to be overlooked.

The general manifestations of the cancerous cachexia, namely, waxy pallor, progressive emaciation, and debility, are usually present, sooner or later, but in this, as in other situations, the affection sometimes makes considerable progress before cachectic phenomena are apparent. The affection in some cases remains for a longer or shorter period quite latent. The general symptoms may be manifest without local phenomena pointing to the seat of the affection; but, in the majority of cases, the affection speedily gives rise to both general and local symptoms. Pain is usually more or less prominent, referable to the liver, and shooting in different directions. Tenderness on pressure is a frequent symptom. Jaundice occurred in 67 of 146 cases analyzed by Leichtenstern. In the cases in which it occurs, the jaundice persists until death. Peritoneal effusion occurs in about the same proportion of cases, namely, 78 of 154 cases. This may be due to peritonitis excited by the cancerous tumors, or to pressure upon the portal vein. In the latter case the effused liquid is serum without lymph; in the former, more or less lymph is exuded. Occasionally blood, extravasated into the cancer, escapes into the peritoneal cavity. The accumulation of liquid may be so great as to require tapping. The appetite and digestion are early impaired, and at a later period diarrhœa not infrequently occurs. Œdema of the lower extremities is apt to occur in the latter part of life. Emaciation and loss in weight are progressive, and death takes place by slow asthenia, if the patient be not carried off by some intercurrent disease. A fatal termination may be hastened by peritonitis induced by the local affection, by abundant hemorrhage, by co-existing cancerous affections elsewhere, and by various accidental complications. Aside from these circumstances, the progress of the affection is sometimes rapid and sometimes slow. The duration varies from a few weeks to a year, rarely, if ever, exceeding the latter. The average duration is twenty weeks.

In most cases the diagnosis is made without difficulty. The enlargement of the organ, the presence of one or more nodules or tumors appreciable by the touch, with pain and tenderness, and frequently the knowledge of the existence of cancer in some other situation, render the nature of the affection sufficiently clear. The hepatic affections to be excluded are, abscess of the liver, cirrhosis, waxy liver, hydatids, and syphilitic growths. For their diagnostic characters the reader is referred to the articles treating of these affections. Tumors situated near the liver are to be discriminated, namely, aneurism, cancer of the stomach, peritoneal or omental cancer, a distended gall-bladder, and fecal masses in the ascending or transverse colon. The antecedent and co-existing symptoms, taken in connection with the local signs, are in most cases sufficient for the differential diagnosis. Progressive loss in weight and the appearances which denote the cancerous cachexia, point to a malignant disease.

[1] *Vide* Ziemssen's Handbuch.

The diagnosis is difficult when no evidence is obtained by palpation. If the cancerous growth be confined within the organ, and the latter be simply enlarged, still more, if the size be normal or below that of health, the existence of the affection can only be conjectured in view of more or less pain and tenderness over the liver, conjoined with a cachectic condition and the existence of cancer elsewhere. The diagnosis is impossible in the few cases in which there are no physical signs and the affection is latent as regards local symptoms.

The age of the patient, peritoneal effusion, persisting jaundice, and hereditary predisposition are to be taken into account in the diagnosis.

The treatment has reference only to the palliation of symptoms and the prolongation of life. Pain will often require the habitual use of opium. An advantage of an early diagnosis consists in the avoidance of injurious medication. Every debilitating measure will tend to shorten life. The system is to be supported, as far as practicable, by tonic remedies, nutritious diet, and other hygienic measures. The object in this, as in other chronic incurable affections, is to endeavor to aid the system in resisting, as long as possible, the fatal termination.

Other New Growths in the Liver.

A brief enumeration of the more common of the other tumors found in the liver must suffice, since they possess generally no clinical interest. Primary sarcoma is not known to occur in the liver. Secondary melanotic sarcoma has been mentioned under cancer. Spindle-celled sarcomata and lymphosarcomata have been observed as secondary growths in the liver. Tubercle appears in the liver in the form of countless miliary nodules of small, often microscopic, size in the course of general tuberculosis. Large, solitary, cheesy tubercles may occur in the liver, as in the brain and spleen, but are pathological curiosities in this situation. Lymphomata are present in many cases of leucocythæmia and pseudo-leucocythæmia. Little nodular accumulations of lymphoid cells in the portal canals, so-called miliary lymphomata, are often observed after death from typhoid fever, also in cases of diphtheria, smallpox, and scarlatina. Adenoma presents itself in two forms, either as a nodular hyperplasia of liver substance or as an atypical growth of bile-ducts in a nodular form. Cysts of retention developed from bile-ducts, and cysts apparently of new formation, are not infrequent, combined sometimes with cystic disease of the kidney. Little nodules of cavernous tissue are often observed in the liver. Gummata have been referred to under the head of Syphilitic Hepatitis.

Echinococcus or Hydatid Tumors of the Liver.

The echinococcus represents the larval stage of tænia echinococcus, a tapeworm, about one-sixth of an inch in length, which infests the small intestine of the dog. The embryos developed from the tænia's eggs which have been introduced into the human alimentary canal, make their way through the bloodvessels and lymphatics into the various organs of the body, where they undergo further development. It is held that these embryos may enter the liver also by way of the bile-ducts. A hydatid tumor or echinococcus cyst consists of a membranous bladder, varying in size from a pin-head to a child's head, inclosed in a fibrous capsule developed from the surrounding tissue. The hydatid vesicle is not adherent to the surrounding sac. Its wall is composed of an outer cuticular layer which appears under the microscope clear and translucent with exceedingly characteristic parallel lines indicating

a lamellated structure, and an inner granular, germinal layer provided with ciliæ. In *simple* echinococcus cysts, minute whitish particles, called *brood-capsules*, which contain several *scolices* or tapeworm heads, project as outgrowths from the inner germinative layer into the cavity of the sac which is filled with fluid. A scolex has in front four suckers and a double row of thirty to forty hooklets. It is capable of invaginating the anterior portion of the head, so that the hooklets may appear to be in the dilated posterior part. This scolex undergoes no further development in man, but finding its way into the alimentary canal of certain animals, especially the dog, it becomes a fully-developed tapeworm. Simple echinococcus cysts are not common in man. Usually there is an endogenous proliferation of so-called daughter vesicles, so that the main or mother cyst contains floating globular or ovoid cysts, varying in size from that of a pea to a hen's egg, and in number from a few to several thousand. The daughter and sometimes granddaughter cysts produce from their inner germinal layer brood-capsules containing scolices in the manner described for the mother cyst. Very rarely in man, but frequently in the ruminants, there is an exogenous instead of an endogenous growth of daughter vesicles which then appear as small sacs outside of the mother cyst. The fluid contained in an echinococcus cyst, free from regressive or inflammatory changes, is clear, somewhat opalescent, neutral or slightly alkaline, of a specific gravity between 1007 and 1015; it is devoid of albumen or has only a trace, is rich in chloride of sodium, and contains frequently grape-sugar, inosite, succinic acid and succinates, and some less important ingredients. For a description of the modifications, some of a rather complex nature, which may occur in the structure of echinococcus cysts, the reader is referred to works treating especially of entozoa.[1] Brief reference, however, must be made to the regressive changes and to the multilocular echinococcus. The fluid may be absorbed or thickened, the vesicles and scolices may undergo fatty and calcareous metamorphoses, and the fibrous capsule may shrink so that nothing is left but a fatty calcareous nodule containing usually cholesterin and hæmatoidin crystals. The hooklets are preserved among the debris and aid in the diagnosis. In this way spontaneous cure may ensue. It is maintained that the destruction of echinococci is sometimes due to the entrance of bile into the mother cyst. Inflammation, resulting in suppuration, of an echinococcus cyst may take place. Sometimes no scolices are developed. Such cysts, with or without daughter vesicles, are called *acephalocysts*.

Echinococci occur in the liver oftener than in all other parts collectively. They may be present in any organ of the body. Usually there exists a single tumor, but there may be a dozen or more. Similar tumors sometimes co-exist in other organs, more especially in the lungs and spleen. Oftener found in the right than in the left lobe, they may exist in any part of the organ. The growth of the echinococcus is very slow, extending usually over years; it is sometimes continuous, or it may become arrested at any stage by the death and consequent regressive changes of the animal.

The clinical history offers nothing which points to this or any affection of the liver until the tumor attains to a sufficient size to occasion inconvenience by pressing on the adjacent parts. As long as the tumor is contained within the gland, it is usually completely latent. It gives rise to neither pain nor tenderness, and the hepatic functions are not appreciably disturbed. Hydatids

[1] The following works may be consulted: Davaine, Traité des Entozoaires, 2me edition, Paris, 1877. Leuckart, Die menschlichen Parasiten, I., Leipzig, 1863. Heller, in Ziemssen's Cyclopædia of the Practice of Medicine, vol. iii. Cobbold's Treatise on Parasites.

of considerable size are not infrequently discovered unexpectedly in autopsical examinations. If, however, the cyst be situated near the periphery, and project considerably beyond the organ, it is apt to give rise to local symptoms directing the attention to the part. Usually, under these circumstances, pain is slight or wanting, but there is a sense of fulness and uneasiness in the neighborhood of the liver. When pain is present, it is due mainly to inflammation developed by the pressure of the tumor. The pressure upon adjacent parts gives rise to symptoms which differ according to the direction in which the tumor extends. Extending into the thoracic space, it gives rise to dyspnœa on exertion, cough, and palpitation. Pressure on the stomach and intestine is liable to produce vomiting and constipation. If the vena cava be compressed, œdema of the lower extremities follows. The growth of the tumor is attended by little or no constitutional disturbance. There is no febrile movement, and the nutrition of the body may be unimpaired.

Important local and general symptoms, however, are incident to the bursting of the cyst, or the discharge of its contents by ulceration. These symptoms will depend on the direction in which the opening occurs. Pleuritis, pericarditis, and peritonitis are results of the rupture, respectively, into the pleural, pericardial, and peritoneal cavities, and the two latter affections thus induced are uniformly fatal. The first of these three affections is very apt to prove fatal. Opening into the vena cava, it gives rise to the symptoms of obstruction of the pulmonary circulation from embolism. If the lung be perforated without general pleuritis, cough and expectoration are prominent symptoms, and in the latter are contained, from time to time, hydatids, together with bile in some cases. If perforation of the lung ensue after the evacuation into the pleural sac, the phenomena of pneumo-hydrothorax are developed. Perforation of the stomach or colon is usually attended by severe pain, and is followed by the discharge, either by vomiting or stool, of hydatids. The discharge of the hydatids into the biliary passages gives rise to jaundice. Jaundice, irrespective of this cause, is rare in cases of hydatid tumor. Dropsy of the peritoneum does not belong to the clinical history of the affection. Both jaundice and hydro-peritoneum, however, are occasionally effects of the pressure of the tumor on the biliary passages without the liver, and on the vena portæ.

A diagnosis is impracticable as long as the growth does not extend beyond the gland. The affection can only be recognized when either the tumor is discoverable by physical examination, or hydatids are discharged through some outlet. A tumor extending from the anterior surface, or from the inner or lower margin of the liver, after it has attained to a certain size, is apparent to the touch. The diagnosis now involves its discrimination from other tumors. When situated over the liver, it is to be discriminated from cancer and hepatic abscess. This discrimination may generally be made without much difficulty. From cancer it is distinguished by its smooth and globular form, its elasticity and the sense of fluctuation, the freedom from pain, and the absence of the cancerous cachexia. From hepatic abscess it is distinguished by the slowness of its growth, absence of pain and tenderness, and by its being unattended by the constitutional symptoms to which suppuration generally gives rise, namely, chills, fever, etc. Extending from the left border, it is to be discriminated from cancer of the stomach or of the pancreas, and from an aneurismal tumor. The connection of the hydatid tumor with the liver, and the disconnection of other tumors, may generally be ascertained by palpation and percussion. Cancer of the stomach or of the pancreas is usually accompanied by pain, and, in the former situation, by notable gastric symptoms. The cancerous cachexia may be apparent. The cancerous tumor is generally irregular or lobulated. An aneurismal tumor is distinguished by

its anterior and lateral pulsation, the frequent occurrence of murmur, and generally by persistent gnawing pain referable to the back.

A physical sign sometimes obtained by percussion, is highly distinctive of a hydatid tumor. If percussion be made upon the tumor, the fingers of the left hand or the whole hand being placed over the tumor, the collision of the floating hydatids with each other causes a characteristic tactile vibration known as the hydatid fremitus. The sensation is compared to that felt when percussion is made upon the hand resting on a mass of jelly. By placing the stethoscope over the tumor and practising percussion, a peculiar sound is elicited, which in some cases has a musical intonation like the sound from a violoncello. These signs are obtained in only a certain number of cases.

A hydatid tumor encroaching more or less upon the thoracic space, gives rise to flatness on percussion, and absence of respiratory murmur from the base of the chest upward in proportion to the height to which the tumor extends, with, perhaps, more or less displacement of the heart. The signs are those of pleuritis with effusion. Attention to the following point will suffice for the discrimination in many, if not most, cases. In pleuritis, the level of the liquid effusion, when the patient is sitting or standing, is denoted by flatness extending upward on the anterior aspect of the affected side of the chest, to about a uniform height. But the flatness due to a tumor extending into the thoracic space generally has an irregular limit—that is, the flatness extends higher at some than at other points. Moreover, the test of the presence of liquid effusion, afforded by the results of percussion when the position of the body is changed from the vertical to the recumbent, is not available in the case of a tumor.

The diagnosis in cases in which the tumor opens externally, or its contents are discharged by expectoration, vomiting, or stool, is established by the discovery of hydatids either entire, or the remains left after their destruction. If entire, they are easily recognized with the naked eye. If not entire, the microscope is to be employed to discover shreds of the characteristic membrane, and hooklets of echinococci.

The most certain means of arriving at a positive diagnosis in cases in which the contents of the tumor are not discharged through some outlet externally, is by withdrawing a portion of the liquid by means of an exploring canula. If the fluid withdrawn be clear, free from albumen as tested by means of heat and nitric acid, and rich in chloride of sodium, there can scarcely be room for doubt as to the nature of the tumor. The presence of succinic acid or of glucose speaks also for echinococcus. If the contents have become mixed with blood or inflammatory products, the chemical examination is not conclusive. If scolices or their hooklets, or portions of the finely striated, but otherwise homogeneous, echinococcus membrane be found in the fluid, the diagnosis is established.

Hydatid tumors are not in themselves serious except from their size. They do harm by pressure upon adjacent parts. They prove serious, also, by opening into situations in which grave or fatal diseases are thereby induced. The prognosis in these cases has been already stated. If the opening occur in a situation whence the contents are discharged from the body, namely, through the integument, into the bronchi, or the alimentary canal, recovery may be hoped for, or expected, according to the circumstances in individual cases. If recovery do not take place, the fatal termination is preceded by protracted irritation and progressive exhaustion due, generally, to suppuration within the sac.

In the treatment of hydatid tumors of the liver, there are two objects to which measures may be directed. One object is the evacuation of the tumor; the other is to arrest its growth and promote absorption of its contents. Medi-

cinal means are applicable to the last-named object only; the first object is, of course, to be effected exclusively by surgical interference.

Several internal remedies have been proposed as capable of destroying the hydatids. On the death of the parasite, the tumor ceases to grow, and, gradually diminishing in size, may finally disappear. This is the mode in which a spontaneous cure not infrequently takes place. Calomel, common salt, and the iodide of potassium, have been thought to have the power of effecting the destruction of the hydatids, these remedies acting by being absorbed and exerting a poisonous effect upon them. Their efficacy, however, does not appear to have been established by clinical observation.

An effectual surgical measure, in certain cases, is to make an incision into the tumor, sufficiently large to remove both the liquid and the hydatids which it may contain. This operation is warrantable when the tumor extends in an outward direction, provided adhesions have taken place around a space in which the opening is made, so that there is no danger of the escape of the contents into the peritoneal sac. A method of determining whether adhesions exist or not, is to ascertain if the tumor or the liver be depressed by a forced inspiration, or remain fixed in the same position. This point is readily ascertained by marking on the chest or abdomen the situation of the tumor, or the lower margin of the liver, or its upper margin, successively at the end of an expiratory and an inspiratory act. After evacuating the tumor, cicatrization may be expected to follow, but this result may be preceded by suppuration within the sac, which may be continued so as to involve danger from constitutional irritation and exhaustion.

A simple method of treatment which often suffices for the cure, is to withdraw a portion of the liquid by aspiration, puncturing the sac with a fine hollow needle or trocar. The destruction of the parasite may be in this way effected, and the risk of the escape of the liquid into the peritoneal cavity must be extremely small. The injection of medicated liquids into the sac is unnecessary, and increases the liability to suppuration. If suppuration occur, a free opening may be requisite. In order to avoid danger from a free opening, Simon recommends the following procedure: "The tumor is punctured with a fine trocar and the canula allowed to remain; in 24 hours peritoneal union will have taken place. Eight days afterward a second trocar is thrust in at some distance from the former, and the canula again allowed to remain. After about 22 hours the two punctured wounds may be united by an incision."[1] For the destruction of the parasite, electricity, transmitted through needles introduced into the tumor, has been effective.

The prophylaxis of hydatids, in the liver and elsewhere, is to be based on the source, namely, the ova of the tænia echinococcus developed in the intestine of the dog. Hence, it is important, as far as practicable, to obviate the possibility of the introduction of ova from the excreta of this animal into the human intestine.

Multilocular Echinococcus.

The echinococcus multilocularis represents a peculiar form of development of this parasite. With very few exceptions it has been found only in the liver. It forms a hard, smooth tumor often of very large size, which takes the place of the liver parenchyma. Upon section, this tumor bears a striking resemblance to a colloid cancer, with which it was formerly confounded. In the meshes of a firm, fibrous stroma are small cavities containing a gelatinous material, in which are present the characteristic echino-

[1] *Vide* Heller, in Ziemssen's Cyclopædia, Amer. ed., vol. iii.

coccus membranes, rarely in the form of vesicles. Fully formed scolices are rarely, their hooklets more frequently, found. The tumor has a tendency to form in its central part ulcerative cavities, sometimes filled with pus. Virchow, who first recognized the nature of the disease, holds that the echinococcus multilocularis develops in the lymph-vessels, Friedreich that it grows in the bloodvessels and bile-ducts.

The disease has been observed almost exclusively in south Germany and Switzerland. The symptoms are usually more pronounced and graver than those of ordinary echinococcus. They are, jaundice, often intense and rarely absent, gastric irritation, enlargement of the spleen, sometimes pain and tenderness in the region of the liver, progressive emaciation, and, at the last, often hemorrhage from different mucous membranes. The prognosis is very grave. The enlarged liver presents usually a smooth, hard surface, and not the nodular swellings of ordinary echinococcus and cancer. The duration, too, is longer than that of cancer which is not usually accompanied with enlarged spleen or such intense jaundice. There is no effectual treatment.

Other parasites which have been found in the liver are the cysticercus cellulosæ, pentastoma denticulatum and constrictum, and the psorosperms. A specimen of the pentastoma constrictum was sent to me by Dr. M. M. Campbell, of Missouri, which had been expectorated by a patient under his care. From 75 to 100 of these parasites had been expectorated. The liver was much enlarged, and their primary habitat was probably in this organ.[1]

Pigmentary Deposits within the Liver.

A deposit of dark-colored granules in the liver, giving to the organ a steel-gray, chocolate, or bronzed appearance, is observed not infrequently after death from malarial fevers. A similar deposit generally co-exists in the spleen, and may be found in other organs. It is found in the blood, especially within the portal vessels. The source of the pigmentary matter, together with its pathological relations and effects, cannot be considered as settled. (*Vide* Part I. page 82.) With our present knowledge, the pigment liver is hardly entitled to be reckoned in the list of hepatic affections. It will be referred to hereafter as entering into the anatomical characters of the periodical fevers.

Hypertrophy and Atrophy of the Liver.

Hypertrophy of the liver was supposed to be not infrequent before the several degenerative affections to which this organ is liable were as well understood as now. Klebs[2] distinguishes between hypertrophy and hyperplasia of the liver. (*Vide* Part I. page 41.) In the former there is an increase in the size, in the latter an increase in the number, of the liver-cells. According to the same author, hypertrophy of the liver occurs in diabetes mellitus; hyperplasia sometimes in drunkards; hyperplasia combined with hypertrophy in leucocythæmia and pseudo-leucocythæmia. Compensatory hypertrophy of certain parts of the liver, when other parts are compressed or destroyed, as in cirrhosis, syphilitic liver, abscess, etc., has been described by some writers. The existence of hypertrophy of the liver has not been fully established. At all events, the physician is never called

[1] *Vide* N. Y. Med. Record, Jan. 13, 1877; also Aitken's Science and Practice of Medicine.

[2] Klebs, Handb. d. patholog. Anatomie, Bd. 1, p. 370. Berlin, 1869.

upon to recognize and treat hypertrophy of this organ. Simple atrophy of the liver occurs as a senile change, and sometimes in diseases accompanied with prolonged marasmus. The liver is uniformly diminished in size, and the liver cells often contain a considerable amount of reddish-brown pigment (brown atrophy).

Portal Thrombosis. Pyle-thrombosis. Adhesive and Suppurative Pyle-phlebitis.

Thrombosis of the main trunk of the portal vein, or of its larger branches, may be due to pressure from without, caused by enlarged glands, abscesses, tumors, impacted gall-stones, fibrous bands resulting from localized or general peritonitis, or from a chronic inflammation of the surrounding connective tissue (portal phlebitis). It may be caused by foreign bodies within the vein, or calcific plates resulting from chronic endo-phlebitis. It may be secondary to cirrhosis. A blow upon the abdomen has been known to cause portal thrombosis.

In recent cases the thrombus is grayish-red or yellowish in color, and more or less adherent to the inner coat of the vessel. It either partially or completely occludes the vessel. In the so-called adhesive pyle-phlebitis, the presence of the thrombus leads to secondary changes in the wall of the vessel, resulting in what is regarded as an organization of the thrombus. (*Vide* Part I. page 29.) The thrombosed vessel is converted into a fibrous cord either solid or canalized. In the latter case, the circulation may be partially or completely re-established, and recovery takes place. If the main trunk of the portal vein be occluded, life is not prolonged sufficiently for the organizing process to take place.

The symptoms of adhesive pyle-thrombosis or pyle-phlebitis are referable to the mechanical obstruction of the portal circulation. If the occlusion be complete or nearly so, it gives rise to peritoneal dropsy. The rationale is the same as in dropsy caused by cirrhosis of the liver. From the latter it is distinguished by a more rapid accumulation of liquid, and by its occurrence in persons not addicted to spirit-drinking, this being the cause *par excellence* of cirrhosis. Hemorrhage from the stomach or intestine may occur, as in cases of cirrhosis, and sometimes precedes the occurrence of dropsy. The spleen is more or less enlarged. The superficial abdominal veins may become dilated. Anorexia and loss of digestive power are symptoms occurring without much delay. Diarrhœa occurs frequently. The lower limbs and genitals become greatly œdematous. There is progressive loss of strength, without fever, and death may take place within a few weeks by asthenia. Rapidly fatal asthenia may follow a profuse hemorrhage. Jaundice is often present. Its occurrence may be explained by the diminished pressure in the branches of the portal vein, or, in some cases, by a coincident obstruction of the bile-duct from the same causes which induce thrombosis of the veins.

The treatment embraces, as an important palliative measure, paracentesis abdominis, repeated as often as the dropsical accumulation recurs. Measures to arrest hemorrhage are indicated when this occurs. Additional measures are those to meet other symptomatic indications, and to support the powers of life.

In pyle-thrombosis, as just described, or adhesive pyle-phlebitis, inflammation is limited to the site of the thrombus. The phenomena of the disease are referable to occlusion of the portal vein. Suppurative pyle-phlebitis, on the other hand, involves the presence of emboli or thrombi which act, not only mechanically, but by the agency of a noxious principle. Owing to this

principle they give rise to multiple hepatic abscesses. The clinical history is that of pyæmia, often without symptoms pointing directly to the liver. Pain and tenderness in the right hypochondrium, jaundice, and enlargement of the liver may be present. To these symptoms are added those of obstruction, if, as may or may not be the case, the portal vein, or its principal branches, be occluded.

The most frequent causes of suppurative pyle-phlebitis relate to ulcerative and suppurative processes within the district of the portal circulation. In this category belong abscesses of the spleen, typhlitis and perityphlitis, ulceration of the gall-bladder, stomach, and intestinal tract, particularly dysenteric and sloughing ulcers, abscesses and ulcers of the rectum, such as sometimes follow surgical operations in that neighborhood, and inflammation of the umbilical vein in the newly-born infant. A foreign body in the portal vein may give rise to suppurative pyle-phlebitis. In an autopsy at Bellevue Hospital, a fish-bone two inches long was found, one-half in the superior mesenteric and the other half in the portal vein. The portal vein contained puriform matter and the liver multiple abscesses. Another similar case has been reported. A thrombus in the portal vein is sometimes a direct continuation of a thrombus primarily formed in some of the rootlets of the vein at the diseased part. Sometimes the thrombosis follows the lodgment of an embolus broken off from a thrombus situated in some of the afferent branches of the portal vein.

In suppurative pyle-phlebitis the thrombus breaks down into a puriform mass, the vascular walls become infiltrated with pus-cells, the suppurative process extends to the surrounding connective tissue and the hepatic parenchyma, the result being the production of abscesses. The abscesses are usually not of large size, but they are many, and their distribution can sometimes be seen to follow the course of the portal vessels within the liver.

The diagnosis of suppurative pyle-phlebitis is to be based on the local symptoms already stated, in conjunction with the symptoms of pyæmia, and the antecedent existence of some one of the causative conditions which have been named. Certain of the latter are not discoverable before death, and there are cases in which the post-mortem examination sheds no light on the etiology. The affection is then said to be idiopathic.

There is no ground for encouragement in the way of prognosis, and the treatment has relation solely to symptomatic indications and support.

CHAPTER XIII.

DISEASES AFFECTING THE SOLID VISCERA OF THE ABDOMEN— (Concluded.)

Diseases affecting the Biliary Passages. Jaundice, or Icterus. Functional Affections of the Liver. Affections of the Spleen. Affections of the Pancreas.

Diseases Affecting the Biliary Passages.

THE diseases affecting the liver which have been considered, relate, for the most part, to the parenchyma or substance of the organ. The biliary passages, within and without the liver, inclusive of the gall-bladder, are liable to disease. Inflammation of the mucous membrane lining the ducts is probably an affection of not infrequent occurrence. Simple or ordinary inflammation, that is, analogous to inflammation of other mucous membranes, constitutes, as there is reason to believe, the pathological condition giving rise to the affection called icterus or jaundice, in the majority of the cases in which this affection is not incidental to structural lesions of the liver or of the surrounding parts. The opportunity of obtaining autopsical proof of this is rarely offered, because ordinary inflammation in this situation does not prove fatal. The swelling of the membrane and the accumulation of mucus within the ducts occasion more or less obstruction to the passage of the bile; hence its reabsorption, causing cholæmia and jaundice. The clinical history of cases of jaundice referable to this pathological condition, generally shows the inflammation to have had its point of departure in the duodenum, extending thence into the common duct, and perhaps to a greater or less extent into the hepatic duct and its branches within the liver (page 450).

In some cases of inflammation of the mucous membrane of the ducts, an exudation of fibrin takes place, and occlusion of the ducts may follow. Complete closure of the common duct, in addition to jaundice, leads to an accumulation of bile within the gall-bladder. The gall-bladder, under these circumstances, may become enormously distended. In a case related by Van Swieten, it contained eight pounds of thick bile. In a case recorded by Benson, the space occupied by the distended gall-bladder was so great that dropsy of the peritoneum was supposed to exist, and paracentesis was resorted to. Frerichs, who cites these cases, has observed a case in which there was an accumulation of eighteen ounces. The accumulation of bile within the gall-bladder may also occur from the impaction of a biliary calculus in the common duct, or from obstruction of this duct due to other mechanical causes. Obstruction of the cystic duct, preventing the passage of bile into the gall-bladder, but not into the common duct and intestine, does not give rise to jaundice, but, under these circumstances, in some cases, the gall-bladder becomes greatly distended with a purulent liquid due to inflammation of the lining membrane of the gall-bladder. A case was reported by the late Prof. Pepper, in which the gall-bladder contained after death two quarts of purulent liquid mixed with bile, the cystic duct being completely closed by false membrane.[1] In some cases of obstruction of the cystic duct the gall-

[1] American Journal of Medical Sciences, Jan. 1857.

bladder becomes distended with a serous liquid. In these cases the affection is considered as dropsical, and has been called *hydrops cystidis felleæ*. The liquid, however, is not purely a transudation, but contains more or less of inflammatory products.

The gall-bladder distended by liquid forms a tumor which is to be discriminated from a hydatid tumor and hepatic abscess. The situation of the tumor, its form before dilatation takes place sufficiently to distort it, and (exclusive of the cases in which the obstruction is in the cystic duct) co-existing jaundice are to be relied upon in making the discrimination. The antecedent history and the accompanying symptoms are also to be taken into account. The distending liquid may be presumed to be bile when co-existing jaundice and absence of bile in the stools show the common duct to be obstructed; and the liquid is either purulent or serous if the absence of jaundice shows the obstruction to be in the cystic duct. An exploration of the tumor by means of a very small trocar or needle is warrantable, in cases of doubt, as a means of diagnosis. The liability to mistake a distended gall-bladder for a moving or floating kidney is to be mentioned.

The treatment must have reference to the circumstances in individual cases. Puncturing the gall-bladder, in order to discharge its contents, is to be resorted to when, from the degree of dilatation, there is danger of rupture taking place into the peritoneal cavity. The latter accident is followed by fatal peritonitis. If an opening be made of sufficient size to allow of the discharge of the contents without aspiration, the same precautions are to be taken, with reference to peritoneal adhesions, as in opening an hepatic abscess. But aspiration, the contents being withdrawn through a small hollow needle or canula, is to be preferred. There is little, if any, risk in this method, even if peritoneal adhesions have not taken place.

Ulceration of the gall-bladder and of the ducts, as an occasional effect of the presence of calculi, has been already referred to in treating of the passage of gall-stones or hepatic colic. Ulceration of the gall-bladder is sometimes the result of inflammation, irrespective of biliary calculi or distension from obstruction. The symptoms of *cholecystitis*, as it has been called, however, do not point to its existence, nor, perhaps, to the existence of any affection. I have met with a case of ulceration and perforation resulting, apparently, from an abscess within the coats of the gall-bladder, and in this case there were no symptoms of any disease prior to the sudden development of peritonitis due to the perforation. There were no calculi in this case.

The gall-bladder is sometimes the seat of cancer. In most cases, however, when seated here, it is secondary to cancer of the liver.

The *ascaris lumbricoides*, or round worm, occasionally migrates from the intestine into the common ducts, and may pass into the branches of the hepatic duct within the liver. Dilatation of these ducts is a lesion arising from persisting obstruction of the hepatic or common duct from any cause.

The entozoa known as the *Distoma Hepaticum* and *Distoma Lanceolatum*, or *liver-flukes*, which are common in the biliary passages of ruminant animals, have been occasionally found in man. They give rise to no symptoms by which their existence could be suspected. With our present knowledge, they have no interest or importance, in a pathological view, as occurring in the human species.

Jaundice, or Icterus.

The presence of bile-pigment in sufficient quantity to give to the conjunctival membrane of the eye and to the skin a yellow color, greater or less in degree, constitutes the morbid condition known as *Icterus*, or *Jaundice*.

The term *cholæmia* denotes the presence of bile in the blood, and under this head, in treating of the morbid conditions of the blood in *Part First*, was embraced the general pathology of the affection to be now considered (page 80). Of the two terms, icterus and jaundice, the latter is more commonly used. Both terms, as regards their significance, relate to yellowness of the surface from the presence of bile-pigment, whereas cholæmia implies the presence of all the bile constituents in the blood.

Jaundice is strictly never an individual disease. It is merely an effect or a symptom of disease. But as it is an obvious and striking morbid condition dependent, not on one affection, but on various affections, and occurring when its causation is not evident, it is regarded, for convenience in certain cases, as an individual disease. In recognizing jaundice as an individual disease, cases are to be excluded in which it is incidental to certain affections, the existence of which is clearly made out. Thus, jaundice occurs in certain cases of all the hepatic affections which have been considered, namely, acute hepatitis, cirrhosis, portal phlebitis, cancer, etc. etc. It occurs also in several general or constitutional diseases, namely, septicæmia, puerperal, remittent, and relapsing fever. Under these circumstances, it is to be regarded as merely a symptom.

The presence of bile in the blood, or cholæmia, is a result of the entrance into the blood of bile after its secretion. The pigment and the biliary salts (the glyco-cholate and tauro-cholate of soda) are formed within the liver, that is, they do not pre-exist in the blood. The bile, however, contains at least one excrementitious principle, namely, cholesterin. The latter constituent of bile accumulates in the blood if the secretion of the liver be from any cause suspended. Whether the other constituents are ever formed in the blood, is now, as heretofore, a mooted question. It is, however, generally considered as established that, under certain pathological conditions, a pigment analogous to, if not identical with, that of bilirubin may be a result of the destruction of red corpuscles, irrespective of any action of the liver, giving rise to the same appearances as when bile is reabsorbed. When thus produced, jaundice is distinguished as *hæmatogenous*, and when caused by the absorption of bile it is called *hepatogenous*. For a further consideration of this question the reader is referred to Part I. page 80.

In most, if not in all, of the cases in which it is to be reckoned as a disease, jaundice is probably hepatogenous. It is also called mechanical and obstructive jaundice. The question whether the jaundice is hepatogenous or hematogenous, pertains to its occurrence in various infectious diseases, namely, the continued and the malarial fevers, yellow fever, to poisoning by phosphorus, to snake-bites, icterus, etc.

It is to be observed that hæmatogenous jaundice relates to the presence in the blood and tissues of the bile-pigment alone, whereas, in hepatogenous jaundice, all the constituents of the biliary secretion enter the blood.

The passage of bile into the blood is due to obstruction to its passage into the intestine. The most frequent of the various causes of obstruction is inflammation of the duodenum, the passage of the bile into this viscus being obstructed by either swelling of the membrane at the opening of the ductus communis, or an extension of the inflammation into the latter (catarrhal or inflammatory jaundice). The obstruction may, however, proceed from various other causes, such as tumors seated in the stomach or duodenum, enlargement of the head of the pancreas, outgrowths from the liver, enlarged lymphatic glands, or morbid growths in the hepatico-duodenal ligament. All these produce obstruction by outward pressure on the hepatic or common duct. To these are to be added the pressure of the gravid uterus, and fecal accumulations in the transverse colon. Obstruction may also be due to peritoneal

adhesions which cause traction on the peritoneal fold which contains the common duct. Causes within the ducts, exclusive of inflammation, are gall-stones and the presence of lumbricoid worms. Obstruction of intra-hepatic ducts may be sufficient to cause jaundice; and obstruction here may be caused by inflammation and the pressure of deposits or new growths within the liver.

Cases in which, after death, no appreciable obstruction is discoverable, and also cases in which jaundice occurs suddenly after a violent mental emotion, and perhaps disappears rapidly, lend support to the theory of hæmatogenous jaundice. Spasm of the common duct, on the one hand, and, on the other hand, paralysis, have been imagined as explanatory of these cases; but these explanations are set aside by the fact that the duct is devoid of muscular fibres. Another supposition, held by Frerichs, Murchison, and others, is that bile may be absorbed unchanged from the alimentary canal in sufficient quantity to give rise to jaundice. In the opinion of some, cases of so-called hæmatogenous jaundice are to be accounted for by the latter supposition, or by mechanical obstruction, the evidence of which may not be discoverable after death.[1] It may be doubted if simple congestion of the liver gives rise to jaundice; the state of congestion offers, theoretically, an obstacle to the passage of bile into the circulation. In addition to the causes just referred to of jaundice without obstruction of bile-ducts, it is conjectured that bile may enter the bloodvessels as a consequence of diminished pressure within the portal system arising from hemorrhage into the alimentary canal, obstruction of the vena portæ, thrombi, etc. Another conjecture, based on the supposed agency in inspiration of the pressure of the diaphragm on the liver in promoting the flow of bile into the intestinal canal, is that, in cases of much enfeebled respiration, there may be a sufficient stasis of bile in the bile-ducts for the production of jaundice. In this way some authors explain the occurrence of jaundice directly after birth (icterus neonatorum). The occurrence of jaundice at the time of menstruation, is too infrequent for the supposition of any direct pathological connection, as implied in the name *icterus menstrualis* proposed by Senator.

Yellowness of the conjunctiva and skin takes place after a certain amount of bile has entered the circulation. Prior to the appearance of jaundice, the bile-pigment may be found in the blood, the urine, and the liquid of serous cavities. The coloration of the surface depends on the presence of the bile-pigment in the transuded liquid which infiltrates the tissues. Other things being equal, the intensity of the yellow color is proportionate to the degree of the cholæmia. The presence of the bile-pigment in the serum of the blood, is shown by the yellow color of the liquid beneath the epidermis, if a blister be applied.

The urine in cases of jaundice contains bile-pigment in abundance, and almost invariably hyaline, and sometimes epithelial, casts. The presence of the pigment is apparent to the eye, and it gives to linen a yellow stain. The perspiration contains it, and the body-linen may also be stained yellow, especially from the abundant cutaneous secretion in the axilla. It is rarely, if ever, contained in the saliva, nor, as a rule, is it found in mucus, but it may be found in the sputa of pneumonitis developed in a person affected with jaundice. The milk of nursing women rarely contains it, although its presence in this secretion has been observed. The humors of the eye do not contain it, except in some cases in which the jaundice is unusually intense. The "jaundiced eye" (xanthopsia) is so rare an event that the phrase is to be regarded as a poetical license.

[1] Consult treatises by Frerichs and by Murchison, Wagner's General Pathology, and article by Ponfick in Ziemssen's Handbuch der speciellen Pathologie und Therapie, Leipzig, 1878.

The tissues in the interior of the body are more or less colored. The coloration is seen especially in the areolar tissue, the serous membranes, and the muscles. The substance of the brain escapes, except in cases in which it is unusually infiltrated with serum, that is, œdematous.

Bile in the blood acts as a sedative on the circulation and nervous system. The heart's action is usually diminished in frequency. The pulse frequently falls to 50, 40, or even lower, in cases in which the jaundice is not associated with acute inflammation or fever, and, if thus associated, the frequency of the pulse is less than if jaundice did not co-exist. The effect is attributed to the presence in the blood, not of the pigment, but of the biliary acid salts. The temperature of the body may be lowered. The respirations diminish in frequency in proportion to the effect on the circulation. The mental faculties are dull, and there is a disposition to somnolency. Pruritus of the surface, especially in the axilla and inguinal region, troublesome more particularly at night, is an occasional symptom. It is sometimes a source of great annoyance. An occasional complication is urticaria, denoted by the characteristic elevations on the skin, or wheals, which present a deeper yellowness than the surrounding integument, and occasion intense pruritus.

The symptoms referable to the digestive system are frequently due to co-existing duodenitis or gastro-duodenitis. Anorexia, nausea, and sometimes vomiting, thirst, more or less pain in the neighborhood of the epigastrium, and tenderness in that situation, are symptoms denoting subacute inflammation of the gastro-duodenal membrane. In cases of jaundice disconnected from this affection, the appetite may be but little or not at all impaired, and certain articles of food are apparently digested without difficulty. Fatty food is imperfectly digested, and chemical examination of the evacutions from the bowels shows fat in more or less abundance. Patients have an antipathy to fatty articles of diet. The nutrition for a time may be but little affected, but sooner or later loss in weight takes place, and is progressive if the jaundice continue.

The appearance of the dejections is important, as affording evidence of the completeness, or otherwise, of obstruction to the passage of bile into the intestine. If complete occlusion exist, the stools are ash- or clay-colored, owing to the presence of fat. On the other hand, they have more or less of the yellowish or brownish color of health if the obstruction be only partial. The feces, when the intestines are devoid of bile, emit an odor of putrescency, and the formation of gas is frequently troublesome, bile in the intestinal canal being an antiseptic as regards the fecal contents. Generally, the bowels are constipated, but this is by no means always the case even when complete occlusion exists.

Jaundice may exist for a greater or less period without giving rise to notable disturbance. The system sometimes tolerates the accumulation of bile for a long time. Not infrequently patients are able to be up and about as in health, experiencing but little inconvenience. The symptoms and the gravity will depend, in a great measure, on the pathological conditions with which the jaundice is associated. If the jaundice depend on obstruction in connection with subacute gastro-duodenitis, the prognosis is always favorable. Simple gastro-duodenal jaundice usually continues from one to two or three weeks. If it depend on the impaction of a gall-stone in the common hepatic duct, the recovery will depend on the passage of the stone into the intestine, or, backward, into the gall-bladder. Permanent obstruction from a gall-stone or the pressure of a tumor, involves, of course, persistence of the jaundice. Under these circumstances serious results may not take place for a considerable or even a long period. Cases have been under my observation in which the nutrition of the body was not greatly impaired for one, two, and even four years. In one

case under my observation the jaundice had persisted for eight years. Life has continued for a much longer period. Sooner or later, however, the body wastes, the patient becomes anæmic and cachectic, the vital powers gradually fail, and the termination is fatal, irrespective of either the morbid condition giving rise to the jaundice, or of intercurrent affections of other organs than the liver. The color of the skin becomes dark, or almost black, in some cases of long persisting jaundice. In the majority of cases of jaundice from permanent obstruction, however, the duration of life does not extend beyond several months.

When life is destroyed purely in consequence of the retention of bile, the liver takes on important lesions. The bile-ducts within the liver become dilated; the gall-bladder may, or may not, become distended with bile; the liver is at first increased in volume from the accumulation of bile, but subsequently its volume is diminished, and it becomes flabby and wrinkled. The pesisting distension of the hepatic bile-ducts at length leads to an arrest of the secretion of bile. In proportion as the secretion of bile is arrested, the jaundice diminishes, and the patient suffers from the retention in the blood of the excrementitious portion of the bile, namely, cholesterin. In some cases death is preceded by convulsions and coma. In these cases *cholesteræmia* may be supposed to exist; but these phenomena, in a certain proportion of cases, are due to *uræmia*. Post-mortem examinations show an accumulation of granules of bile-pigment in the uriniferous tubes when jaundice has existed for a considerable or long period, and the uræmia proceeds from the morbid condition of the kidneys. Hydro-peritoneum may occur in the latter period of the affection, and general dropsy is sometimes a result of the superinduced renal affection.

The diagnosis of jaundice is readily made if the examination of the patient be in the daytime. The yellowness may not be apparent by artificial light. The yellow tint of the surface seen in some cases of cancer, intermittent fever, and chlorosis, is readily discriminated from slight jaundice, by the absence of yellowness of the conjunctiva, the latter being always present in jaundice. But to determine the causative pathological conditions in individual cases, is not always easy, nor, in all cases, practicable. The dependence on duodenitis or gastro-duodenitis, is to be inferred from the symptoms of these affections preceding and accompanying the jaundice, namely, anorexia, nausea, vomiting, and tenderness over, or in the neighborhood of, the epigastrium. The presence of a gall-stone may be inferred from the pre-existence and co-existence of the symptoms of hepatic colic. A tumor which presses upon the common duct may be discoverable by manual exploration. From the character of the tumor, and the co-existing symptoms, its cancerous nature may sometimes be inferred. Occlusion as a result of inflammation of the ducts exclusive of duodenitis, from lumbricoid worms in the common duct, and other causes, cannot be determined during life; the existence only of obstruction is determinable in such cases. Not infrequently the distended gall-bladder may be felt, and this is positive evidence that the jaundice involves obstruction of the common duct.

In the treatment of jaundice, it has been much the custom to prescribe active cathartics and emetics under an idea of removing the obstruction by their operation. If, however, the jaundice be connected with duodenitis or gastro-duodenitis, not only are these measures ineffectual, but they can hardly fail to do harm. If the obstruction be caused by a gall-stone, its passage will not be hastened by these measures; and they will weaken the patient, without doing good, if the jaundice depend on a tumor pressing on the common or hepatic duct. As remedies, then, addressed to the obstruction giving rise to the jaundice, cathartics and emetics are contra-indicated.

The treatment of jaundice, in the majority of cases, is to be addressed to a subacute inflammation of the stomach and duodenum. Laxatives or cathartics are only required for the relief of constipation; and, when required, the mildest forms are to be preferred. There is no ground for the supposition that mercury exerts any special efficacy, but a few grains of calomel and blue mass frequently prove as mild and effective as any form of cathartic or laxative, followed, if necessary, by a saline draught. The latter alone will often suffice. The saline mineral water, such as the Congress or Kissingen water, will frequently secure an adequate laxative effect. Remedies to soothe the inflamed mucous membranes are useful, such as small doses of morphia or some of the succedanea of opium, namely, belladonna, hyoscyamus, conium, etc. Conium has been considered as a remedy having a special efficacy in jaundice. Its apparent efficacy may be accounted for, in part, by its usefulness as a soothing remedy, and, partly, by its supplanting active cathartics and emetics which are injurious. The diet should be bland and digestible. Fatty articles of food should be excluded, and to these the patient generally has an antipathy. A blister over the epigastrium has seemed to me to be useful. Accidental symptoms will, of course, claim appropriate palliative measures. If a distendend gall-bladder can be felt, pressure upon it will sometimes remove the obstruction, the tumor disappearing under the pressure. This fact I have verified. Pressure, however, should not be made with such force as to incur risk of rupture. Gerhardt has found the induced current of electricity to be useful by exciting spasmodic contractions of the muscular coat of the gall-bladder.[1] A bubbling sound, caused by the passage of the bile into the duodenum, may sometimes be heard, occurring with the disappearance of the tumor.

In cases of jaundice connected with the passage of gall-stones, the palliation of pain is the chief object of treatment. The occurrence of jaundice does not add indications to those which have been already considered as pertaining to the passage of gall-stones, or hepatic colic (*vide* page 521).

Jaundice dependent on irremediable causes, such as permanent occlusion of the biliary ducts, or the pressure of a tumor, does not admit of cure. And the existence of an irremediable cause is to be inferred when the jaundice persists for several months or years. Yet I have repeatedly met with cases in which, after the persistence of jaundice for many months, recovery at length took place, and I have known recovery to take place after a persistent jaundice for several years. A fecal tumor in the transverse colon, also a movable right kidney, have been known to give rise to jaundice by pressing on the common duct. A fecal tumor may be removed, but, in general, tumors so situated as to produce obstruction are persisting. In cases not admitting of cure, the objects of treatment, as regards the jaundice, are, the elimination of bile by the renal and cutaneous emunctories, and the support of the powers of life in order to postpone, as long as possible, the fatal termination. With a view to the elimination of bile, the action of the kidneys may be excited by the vegetable diuretic remedies, and the functions of the skin maintained by the use of the warm bath and by guarding against vicissitudes of temperature. The powers of life are to be supported by a nutritious diet, together with all the hygienic means, moral and physical, of invigorating the system.

In cases of jaundice ending in recovery, it is to be borne in mind that the yellowness of the skin continues for some time after the absorption of bile has ceased. The coloring matter, being without the vessels, remains when the cholæmia no longer exists. Of the continuance of the cholæmia, or of the condition which occasioned the jaundice, the urine affords the most

[1] Ueber Icterus gastro-duodenalis, von C. Gerhardt, Leipzig, 1871.

reliable evidence. The affection is to be considered as having ended when the coloring matter ceases to be apparent in the urine. I have known yellowness of the skin to persist for several months after the disappearance of bile-pigment from the urine. In the case in which this was observed the jaundice had existed for a year. The absorption is probably slow in proportion as the jaundice has been of long duration.

Chronic Passive Congestion of the Liver. Nutmeg Liver and Red Atrophy.

The only form of general congestion of the liver which can be recognized after death, is the mechanical congestion due to some obstruction to the outflow of blood from the hepatic veins. The obstruction is seated usually either in the heart or in the lungs. The various forms of uncompensated valvular lesions of the heart, particularly mitral and tricuspid lesions, and obstructions in the pulmonary circulation, such as emphysema, chronic bronchitis, chronic pleurisy, are the most frequent causes of chronic passive congestion of the liver. In consequence of the damming back of blood upon the hepatic veins, first the central veins of the lobules, and next the lobular capillaries immediately surrounding them, become over-distended with blood. Thus the centre of the lobule presents a dark red color, which is increased usually by the presence of brownish pigment in the central hepatic cells, while the periphery of the lobule is pale and yellowish from the comparative anæmia there, and from the presence of oil-drops in the peripheral liver-cells. A liver presenting this appearance is called a *nutmeg* liver. It is usually somewhat enlarged and firm. When the congestion is long and severe, the tissue at the centre of the lobule consists of little else than dilated bloodvessels, between which the liver-cells have become atrophied from compression. Whole lobules may be reduced to this cavernous tissue which appears, on section, dark red and depressed. This change is called *red* or *cyanotic atrophy* of the liver. It affects patches of liver-substance, not the whole organ uniformly. Under these circumstances the liver is small, the patches of red atrophy are shrunken beneath the surface, the consistence firm, and the capsule usually thickened and opaque. Cyanotic atrophy is often associated with more or less increase of the interlobular connective tissue.

We are unable to assign any symptoms to the nutmeg liver during the stage of enlargement. In the so-called atrophic nutmeg liver or cyanotic atrophy of the liver, we may have the symptoms of portal congestion. In this case the ascites, which has previously been only a part of the general dropsy, becomes more intense and less easy to remove by means which reduce the latter. Jaundice and symptoms of gastro-intestinal derangement become now also more prominent.

Functional Affections of the Liver.

The functional affections of the liver relate to the circulation of blood within the organ, and to its secretory functions. The consideration of these affections will be brief. They have heretofore held a prominent place in pathological speculations, and they are still often mentioned by physicians in conversing with each other and with their patients. But, in a clinical point of view, with our present knowledge, the importance of the functional affections of the liver is in striking contrast with the frequency with which the organ is referred to as the source of morbid phenomena.

Passive congestion, considered above in its anatomical aspects, is incident to lesions of the heart involving impediment to the venous circulation. This

impediment arises especially from contraction of the tricuspid orifice, which is a rare lesion. It follows contraction at the pulmonic orifice, and this is not a frequent lesion. Mitral lesions lead to it by inducing dilatation of the right side of the heart. It also arises from over-distension and dilatation of the right side of the heart as a result of emphysema of the lungs. The accumulation of blood within the liver in certain cases of cardiac disease, occasions enlargement of the organ as determined by physical examination, and the size of the organ is sometimes observed to vary considerably at different times, owing to differences in the degree of congestion. The organ is found to be congested after death, the *intra*-lobular veins being especially conspicuous, and giving rise to the appearance characteristic of the so-called nutmeg liver.

It is difficult to say how far the hepatic congestion in these cases is important as interfering with the secretory functions of the liver. The obstruction to the flow of blood in the hepatic veins induces portal congestion, and the latter is supposed to give rise to indigestion, loss of appetite, and other symptoms referable to the digestive system. Saline laxatives are considered as useful by relieving temporarily the portal congestion. The congestion due to cardiac lesions is chronic, and admits of only palliative treatment.

Active congestion, transient or less persisting, that is, not produced mechanically, as in diseases of the heart, is attributed to over-ingestion of food, especially of a stimulating quality, alcoholic drinks, and the use of condiments which excite the stomach, such as pepper and mustard. The heat in tropical climates, and the special cause of periodical fever, are supposed to give rise to hepatic congestion. A sense of weight in the right hypochondrium, impaired appetite and digestion, sometimes nausea and vomiting, a bitter taste in the mouth, pain in the head, and a sallow complexion, are symptoms often attributed to hepatic congestion. It is by no means certain that this pathological condition is represented by the foregoing symptoms. Hepatic congestion from other than mechanical causes doubtless occurs, but the agencies producing it and its morbid effects are not understood. The diagnosis, with our present knowledge, is not practicable, and the physician, therefore, in treating it acts upon the suspicion of its existence.

Hemorrhage into the liver is an extremely infrequent event which may be due to hepatic congestion. In most cases, however, this event occurs in connection with hemorrhages in other situations, as in purpura and yellow fever. It has been observed in some cases of pernicious intermittent fever. It may be a result of an injury over the liver. There are no means of determining its occurrence during life.

Functional disorders of the biliary secretion are a morbid excess, a morbid deficiency, and a vitiation of the bile. A morbid excess of bile is supposed to enter into the etiology of diarrhœa, colic, and sporadic cholera in certain cases. Deficiency of bile is often treated as a functional affection under the name *torpor of the liver*, remedies being given to increase the biliary secretion. A whitish or ashy color of the stools is probably evidence of deficient secretion, although this appearance may arise from undue absorption of bile from the intestinal canal. Every practitioner is familiar with this appearance of the stools in young children, and after the administration of opium. The production of the so-called *bilious stools* by the use of mercury is well known. Torpor of the liver is a phrase often applied to cases in which the morbid condition is obscure. It affords an acceptable explanation to patients, owing to the popular notion that the liver plays an important part in the ailments referable to digestion and the nervous system; and, whatever may be the rationale, a mercurial cathartic or laxative often affords relief of the symptoms which are vaguely called *bilious*. A deficiency of precise knowledge respecting excess and deficiency of the secretion of bile, as functional dis-

orders, must be confessed, but as regards vitiation of bile, the deficiency of knowledge is still greater. Acrid bile is supposed to be sometimes secreted, and the greenish color of the stools, often observed, especially in children, has been considered to denote a morbid quality of bile. It is not improbable that a vitiated bile may be secreted, but it is impossible to determine whether morbid changes are due to a faulty secretion or to causes acting within the alimentary canal; and nothing can be more vague than to regard a vitiated secretion of bile as a functional disorder furnishing therapeutical indications.

Affections of the Spleen.

Owing to the large size of the splenic artery, and the fact that its branches are distributed to the lobular divisions of the spleen without anastomosing with each other, emboli from the left side of the heart or from aortic aneurisms are apt to be carried into this organ and occasion infarctions which are usually hemorrhagic, but may be white or anæmic (see page 31). Patches showing caseation, calcification, or cicatricial contraction, often found in autopsies, are usually the results of embolism. Clinically these have little interest, inasmuch as they give rise to no diagnostic symptoms, nor to therapeutical indications. Emboli here, as in other situations, may have properties which, in addition to the effects of arterial obstruction, produce suppurative inflammation. In rare instances, purulent collections coalesce, and form an abscess of greater or less size. The quantity of pus in some cases of splenic abscess is enormous. The abscess may be evacuated in different directions, namely, into the chest, stomach, peritoneal cavity, and externally. Except in the infrequent instances of the abscess presenting a fluctuating tumor, a positive diagnosis from symptoms and signs is impracticable. Sudden enlargement of the spleen, accompanying symptoms and signs denoting endocarditis with pain and tenderness in the left hypochondrium, are data for a probable diagnosis. Under these circumstances, an exploratory puncture may demonstrate the presence of pus. This procedure may be resorted to without apprehension of harm.

The prognosis and treatment in cases of splenic abscess are essentially the same as in abscess of the liver (*vide* page 607).

In connection with embolic abscess of the spleen, gangrene sometimes occurs. Acute splenitis and abscess of the spleen, except as incident to embolism, and as sometimes caused traumatically, are among the rarest of diseases.

Enlargement of the spleen occurs in connection with acute specific, or infectious, diseases, and with certain chronic affections. Regarding the enlarged organ as a tumor, late writers use the terms acute and chronic tumors of the spleen.

Acute diseases in which the spleen becomes, as a rule, more or less enlarged, are malarial, typhoid, and puerperal fever, pyæmia, and yellow atrophy of the liver. Diseases in which this organ is often affected, are scarlet fever, measles, smallpox, epidemic cerebro-spinal meningitis, acute miliary tuberculosis, erysipelas, pneumonia, and diphtheria.

It is a pathological question whether the enlargement, in connection with these diseases, is inflammatory. Another question is, whether it is an effect of the increased body-heat. Still another question is, whether it be not due to the presence of bacteria in the spleen. The affirmative to the last question is rendered probable by experiments which demonstrate the retention in the spleen of foreign substances injected into the blood, and by the fact that in

some of the infectious diseases organisms have been found in abundance in this organ after death.[1]

Chronic enlargement of the spleen is an effect of malaria. It is of frequent occurrence in cases of chronic interstitial hepatitis and of obstruction of the portal vein from other causes. It is not infrequent in cases of cardiac disease. It is an element in leucocythæmia, Hodgkin's disease, and splenic anæmia (*vide* Part I. pages 380 and 388). The enlargement in these pathological connections is due to congestion and to hyperplasia of the anatomical elements of the organ.

The diagnosis, as regards these pathological connections, is to be based on the symptoms which are diagnostic, generally, of the diseases with which the enlargement is connected.

Enlargement of the spleen, acute or chronic, is not attended with much pain or tenderness on pressure. If not greatly enlarged, there may be no local symptoms directing attention to an affection of the organ. If much enlarged, its weight occasions a sense of uneasiness and tension in the left hypochondrium. Disconnected from the pathological associations under which it is generally presented, it may exist without notable general symptoms.

Splenic enlargement is generally ascertained without difficulty by palpation and percussion. In some cases the enlarged organ extends upward, pushing up the diaphragm, and causing an evident projection of the false ribs of the left side of the chest. Its upper border is accurately indicated by the line of demarcation between pulmonary resonance and flatness on percussion, and the lower border is determined, approximately, by finding the upper limits of tympanitic resonance. In other cases the organ is dragged downward by its weight, and it may descend as low as the brim of the pelvis. Under these circumstances, if the abdominal walls be thin and relaxed, the organ may be grasped by the hand, and restored to its normal position. The form will serve to distinguish it from the other abdominal tumors. The notches on the anterior border may sometimes be felt through the abdominal walls. An enlarged spleen is depressed by the act of inspiration and recedes in the act of expiration. Its normal limits, in the left intra-axillary region, are the ninth and eleventh ribs. When enlarged, its lower border extends downward and anteriorly.

The treatment of acute enlargement involves the indications belonging to the infectious diseases with which it is associated. Associated with malarial fever, experience shows a special influence of large doses of quinia, salicin, and other antiperiodic remedies upon the spleen. These remedies are also indicated in chronic malarial enlargement. There is ground for attributing to quinia, given in full doses, an effect upon the enlargement in other infectious diseases than malarial fever. The treatment in chronic enlargement not due to malaria, has reference to the associated diseases, namely, cirrhosis of the liver, leucocythæmia, etc. There is no special course of medication to be pursued. Generally, chalybeate tonics, continued steadily for a long time, are useful. They are indicated in proportion as the symptoms and signs denote anæmia. Changing the form of the chalybeate tonic from time to time is important. Da Costa has reported a case of splenic leucocythæmia in which an apparent cure was effected by the hypodermic injection of ergot.[2]

Extravasation sometimes occurs in connection with vascular engorgement of the spleen, and the hemorrhage may lead to rupture of the capsule and the escape of blood into the peritoneal cavity. This has been observed in cases of intermittent fever, of typhoid fever, and during an epileptic paroxysm. It

[1] *Vide* article by Mosler in Ziemssen's Cyclopædia, Am. ed., vol. viii.
[2] *Vide* Am. Journ. of Med. Sciences, January, 1875.

occurs, also, in connection with pregnancy, both before and after labor. Death may take place immediately, from the loss of blood, and, in most of the cases which have been observed, the duration of life, after the rupture, has not exceeded twenty-four hours. The symptoms resemble those which follow intestinal perforation, and the differential diagnosis cannot be made with positiveness. Were it practicable to recognize the accident by the symptoms, the treatment would be the same as in cases of perforation, namely, opium in full doses, with perfect quietude of body. It would be proper to apply cold over the abdomen. Nothing is to be expected from treatment beyond palliation.

The different structural affections which have been considered as seated in the liver, are sometimes found in the spleen, namely, waxy degeneration, syphilitic growths, tuberculosis, cancer, and hydatids. These may involve the whole, or only a portion, of the organ. They occasion enlargement, in some instances giving rise to splenic tumors, properly so called, of greater or less size.

Waxy degeneration of the spleen rarely exists except in connection with a similar affection in other situations—liver, kidneys, intestinal canal. There are two forms of waxy spleen, namely, the sago-spleen and the diffuse waxy spleen. In the former the Malpighian corpuscles are chiefly affected, in the latter the splenic pulp. The enlargement of the organ, as a whole, or in part, is sometimes very great. The diagnosis is to be based on the affection of other organs and the causative conditions, namely, suppurative disease of bones or syphilis.

Tuberculous disease may be manifested anatomically by either miliary granulations or by cheesy collections, called solitary tubercles. The former are almost invariably present in the acute miliary tuberculosis of adults, and in tuberculous disease affecting children. The spleen is never the seat of a tuberculous affection either singly or primarily. The organ becomes in some cases moderately enlarged. Pain and tenderness are rarely present, and the enlargement is generally the only evidence that this organ participates in the tuberculous disease.

Cancer of the spleen is never primary, and its occurrence is infrequent. It is always secondary to cancer of the liver or some other of the abdominal organs. Cancer is to be inferred from the development of splenic enlargement or tumors in the course of cancer seated elsewhere.

Syphilitic affections of the spleen, in the form of gummata, causing enlargement or appreciable tumors, are to be diagnosticated by taking into account other antecedent or co-existing evidences of syphilis, and excluding waxy degeneration. As stated by Mosler, syphilitic affections in this organ "are more frequently the object of anatomical, than of clinical, observation."

Hydatid tumors in the spleen are extremely rare. Their history and the means of diagnosis are the same as when they are seated in the liver (*vide* page 629).

With reference to the anatomical characters, pathology, prognosis, and treatment of the foregoing structural affections of the spleen, it suffices to say that, in these regards, they are the analogues of the corresponding hepatic affections.

Our present knowledge does not enable us to understand fully the consequences of the impairment or loss of the functions of the spleen. It is well known that this organ may be removed from inferior animals without the destruction of life or serious injury to health. This fact goes to show that whatever may be its functions they are adequately performed by other organs in its absence. There is reason to believe that this statement is applicable to man as well as to inferior animals. A case was communicated to me in

1861 by Dr. John L. Alston, of Texas, in which, after an abdominal wound by a musket ball, a portion of the spleen protruded three and a half inches in length and two and a half inches in width. The protruding portion was ligated and dropped off on the fourth day. Recovery took place rapidly, and the patient was in a short time discharged from the hospital entirely well. Cases have been reported in which the entire spleen, having escaped through a wound, was removed, recovery taking place and the health remaining good for years afterward. Within the last twenty-five years, several surgeons have ventured upon the removal of this organ for great enlargement. In the majority of instances patients have died from the immediate effects of the operation. In view of the danger, the operation is not warrantable.

Affections of the Pancreas.

Owing to their infrequency, and their obscurity as regards diagnosis, affections of the pancreas require, in this work, but a passing notice. This gland may be the seat of inflammation, acute or chronic. Of all the glandular organs—liver, ovaries, testes, kidneys, etc.—the pancreas is perhaps the least liable to become inflamed. Acute *pancreatitis* has been found, on examination after death, to occur in cases of continued fever, of puerperal fever, of pyæmia, and apparently as a result of the employment of mercury. The morbid appearances denoting acute inflammation are engorgement, softening, enlargement, and suppuration. Gangrene has been observed, and even the discharge of necrosed portions of the pancreas by the rectum. The symptoms which have been observed are, pain referable to the epigastrium, vomiting, diarrhœa, chills, and more or less febrile movement. The data for determining the clinical history of the affection are insufficient. A discharge, by vomiting and stool, of a liquid resembling saliva, supposed to be the pancreatic secretion, has been thought to be a diagnostic symptom, but there is no reliable evidence of the correctness of this opinion. It remains to be ascertained whether the presence of fat in the stools is a diagnostic symptom. The diagnosis, with our present knowledge, is impracticable. An abscess of the pancreas has been known to open into the stomach. Chronic pancreatitis is, if possible, even more obscure, as regards diagnostic symptoms, than the acute form of the disease. In a case observed by Wilks, death followed extreme emaciation without any symptoms pointing to the seat of the disease.[1] From what has been stated with regard to the diagnosis, it follows that it is impossible to form an opinion as to the proportion of cases in which either acute or chronic pancreatitis ends in recovery.

The pancreas may be the seat of either primary or secondary cancer.[2] Primary cancer most frequently springs from the head of the pancreas. It is usually of the scirrhous variety. Cylindrical celled epithelioma also occurs in this situation. Enlargement of the head of the pancreas from chronic inflammation, cancerous disease, or the formation of cysts, may constitute a tumor discoverable by manual exploration. The diagnosis involves its discrimination from other tumors in the same situation. It is most likely to be confounded with aneurism of the aorta and cancer of the pylorus. A pulsation may be communicated to the tumor from the aorta, and this is suggestive of aneurism. The diagnostic symptoms and signs of aneurism of the abdominal aorta are to be sought for, and this affection excluded by their absence. Cancer of the pylorus is to be excluded by the absence of the gastric symp-

[1] Pathological Anatomy.

[2] For an analysis of 37 cases by Da Costa, *vide* Proceedings of the Pathological Society of Philadelphia, 1858.

toms which usually accompany this affection. (*Vide* page 467.) The connection of structural disease of the pancreas and fatty diarrhœa has been considered in treating of the latter. (*Vide* page 526.) The presence of free fat in the alvine dejections, taken in connection with a tumor supposed to be an enlarged pancreas, is undoubtedly a point of much weight in the diagnosis. The absence of fatty dejections, under these circumstances, is not proof against, but their existence is strong evidence for, the supposition that the tumor is pancreatic.

Enlargement of the head of the pancreas may give rise to serious results from pressure upon adjacent parts. The duct leading from the pancreas is sometimes compressed, and dilatation of its branches within the organs ensues. Pressure upon the *ductus communis*, involving obstruction to the flow of bile, is followed by the retention of this secretion, causing persistent jaundice, dilatation of the bile-ducts, and, at length, disorganization of the liver. An enlarged pancreas may cause obstruction of the pylorus or duodenum, and this renders it difficult to differentiate the affection from cancer of the pylorus. Pressure upon the portal vein may exist to an extent to give rise to hydroperitoneum.

Disease of the pancreas has been found associated with glycosuria sufficiently often to render not improbable a pathological connection with the latter disease.

An abnormal deposit of fat occurs in the pancreas in two forms: first, as fatty degeneration of the glandular cells of the pancreas, and, second, as lipomatosis or development of adipose tissue between the acini which may be thereby obliterated. We know no symptoms referable to lipomatosis of the pancreas. Zenker[1] has described three cases of sudden death in which the only important lesion found was hemorrhage within and around the pancreas, combined with fatty degeneration. Similar cases have since been reported under the name acute hemorrhagic pancreatitis, in which the interstitial tissue of the gland was also infiltrated with lymphoid cells. Sudden death has also been known to attend carcinoma of the pancreas.[2] The symptoms in some of these cases have been severe epigastric or abdominal pain, sometimes icterus, vomiting, subnormal temperature, and collapse. The explanation offered by Zenker for the sudden death, is the occurrence of a reflex paralysis of the heart from a coincident affection, by pressure or otherwise, of the cœliac plexus and semilunar ganglion.

Finally, calculi sometimes form within the pancreatic ducts, varying in size from that of a pea to an almond. These have been found in considerable number. In their journey along the excretory passage to the duodenum, they may occasion severe pain, resembling that caused by biliary calculi. Paroxysms of pain due to the passage of pancreatic calculi, or attacks of pancreatic colic, are doubtless sometimes attributed to gall-stones, nor is it practicable, with our present knowledge, to make the differential diagnosis. The differential diagnosis is not, practically, very important, since the indications for treatment are the same in either case. Clinical observation with reference to the presence of free fat in the dejections, may show this symptom to be present in cases in which, without special attention, it is overlooked, and it may be found that this symptom is of much value in the diagnosis of affections of the pancreas.[3]

SECTION FIFTH.

DISEASES AFFECTING THE NERVOUS SYSTEM.

CHAPTER I.

DISEASES RELATING TO THE CEREBRAL AND THE SPINAL CIRCULATION.

Cerebral Hyperæmia. Cerebral Anæmia. Cerebral Embolism and Thrombosis. Cerebral Hemorrhage. Localization of Cerebral Diseases. Meningeal Hemorrhage. Insolation or Sunstroke. Hyperæmia and Anæmia of the Spinal Cord and its Meninges. Spinal Hemorrhage.

OF the diseases affecting the nervous system, the greater number relate to the nervous centres—the brain and spinal cord. Important affections, however, are seated in the nervous trunks or their branches, that is, in the peripheral portion of the cerebro-spinal system. I shall consider first those diseases of the brain and the spinal cord, together with their meninges, which, as regards pathological character, are common to all the anatomical systems, namely, hyperæmia, hemorrhage, embolism and thrombosis, inflammation, and various structural lesions, taking up afterward the diseases peculiar to the nervous system, or the *neuroses*. This chapter will embrace hyperæmia, anæmia, embolism and thrombosis, hemorrhage, and insolation or sunstroke, these diseases forming a group in which are involved morbid conditions pertaining especially to the circulation within the skull and the spinal canal.

Cerebral Hyperæmia.

From the assumption that the contents of the cranium are incompressible by any amount of force which the heart can exert through the arteries, and from the fact that they are inclosed in an air-tight case, Monroe, in the last century, drew the conclusion that the quantity of blood within the skull can never vary. The incorrectness of this conclusion, however, has been abundantly established, particularly by Magendie on rational grounds, and by the direct observations of Donders. Magendie demonstrated that the cerebro-spinal fluid is an important regulator of the cerebral circulation, inasmuch as it recedes from the cranial cavity when the bloodvessels become distended, and is increased when the quantity of blood in the intra-cranial vessels is diminished. It has since been shown that a similar and equally important role is played by the lymph in the peri-vascular lymph-spaces. Donders adopted the ingenious device of observing in animals the degree of fulness of intra-cranial vessels through a glass plate accurately adjusted, and hermetically sealed, in an opening made through the skull by trephining. He and afterward other observers were able to prove conclusively by this method that the amount of blood in the intra-cranial vessels under various influences increases and diminishes. While the possibility of cerebral hyperæmia is

now universally admitted, there is not the same unanimity as to its frequency, importance and etiology. Within the last few years there has been a decided tendency, especially among neurologists, to deny the clinical importance of this affection. But while it is to be admitted that in former times the diagnosis of cerebral congestion was made too frequently and upon insufficient evidence, and while our knowledge of its pathogeny and symptomatology is still imperfect, there remains sufficient evidence of its occurrence and importance to justify a careful consideration of it.

The morbid appearances of congestion of the brain are to be sought chiefly in the brain-substance, and not in the meninges. The mistake is too often made of deciding upon the existence of cerebral congestion merely from fulness of the meningeal veins. Distension of these vessels with blood is no index of cerebral hyperæmia during life, being dependent upon the position of the body after death, the length of time during which the blood remains fluid, the manner of dying, and whether the head or the trunk is opened first at the post-mortem examination. It is probable that transient hyperæmia of the brain, as of other organs, may leave no trace of its existence after death. When, however, the congestion is intense, and has lasted some time, there are found flattening of the convolutions from turgescence of the brain, a rosy color mixed with the gray of the cortical substance, and numerous red points (*puncta vasculosa*) disseminated over the cut surface of the white matter. The vessels of the meninges, especially the smaller vessels, are also injected. The perivascular spaces are diminished in size or disappear. Cerebral hyperæmia, especially of the passive or venous variety, may be followed by transudation of serum into the meshes of the pia mater, the choroid plexuses, and the ventricles. The presence of a large amount of reddish-brown amorphous pigment in the walls of the vessels and in the perivascular spaces, has been held as an evidence of long-standing congestion. The presence of a certain amount of this pigment is physiological rather than pathological.

Congestion of the brain, as of other parts, may be active or passive. In active congestion an increased amount of blood is brought to the cerebrum by the arteries; in passive congestion the blood accumulates in the brain in consequence of some obstacle to its return by the veins.

It is thought that a full or plethoric habit predisposes to active determination of blood to the brain. Increased force of the heart's action, especially when resulting from simple hypertrophy of the left ventricle, may cause active cerebral congestion. Hypertrophy of the left ventricle is, in the great majority of cases, developed in compensation of some obstruction to the circulation, and has no tendency to produce cerebral congestion. But, in the hypertrophy accompanying certain forms of chronic Bright's disease, and in the rare cases of so-called idiopathic cardiac hypertrophy, active cerebral congestion is sometimes developed.

Paralysis of the vaso-motor nerves supplying the cerebral arteries, and, perhaps, irritation of vaso-dilator nerves, are to be reckoned among the causes of active cerebral hyperæmia. It has been experimentally demonstrated that division of the sympathetic in the neck causes hyperæmia of the intracranial vessels.[1] It may be suspected that strong mental emotion may cause hyperæmia by an affection of the vaso-motor nerves. Nitrite of amyl produces cerebral congestion in this way. There are reasons for believing that one form of migraine or hemicrania is the result of unilateral vaso-motor paralysis causing cerebral congestion.[2]

Collateral fluxion of the cerebral vessels, resulting from some obstruction

[1] Ackerman, Virch. Arch., Bd. 15, p. 431, 1858.
[2] Möllendorff, Virch. Arch., Bd. 41. Berger, Virch. Arch., Bd. 59.

to the flow of blood from the aorta into other branches, has been considered as giving rise to cerebral hyperæmia. As causes of this collateral fluxion have been regarded, stenosis of the aorta at the point of entrance of the ductus Botalli; compression of the abdominal aorta and its branches by distended intestine, tumors, and exudations; and obstruction to the cutaneous circulation by the action of cold. The adequateness of these causes, however, is doubtful. Excessive mental or emotional activity and alcoholic stimulation are efficient causes. Cerebral hyperæmia is an element, but probably not the most important one, in insolation.

Rapidly induced *active congestion* of great intensity may produce sudden coma which may disappear after a few hours, or may prove speedily fatal. This is the pathological explanation of apoplectic attacks in the cases which have been distinguished as cases of *congestive apoplexy*. An instance of sudden death from active congestion incident to simple hypertrophy of the heart, has fallen under my observation. When, thus, the encephalic functions are suspended, this effect is attributable to intra-cranial pressure. The coma is produced by the pressure of the blood within the vessels, as it is by the extravascular pressure in cases of meningeal hemorrhage. The pressure of the blood in the large vessels interrupts the circulation in the brain-substance; hence the suspension of the cerebral functions. It is an apparent paradox that an over-accumulation of blood within the skull should cause coma, and, perhaps, destroy life by depriving the mass of brain of a due supply of arterial blood, yet the fact is sufficiently intelligible. Apoplexy attributable to active hyperæmia is a rare event, but of its occurrence there can be no doubt.

The symptoms of active hyperæmia of more or less intensity, but falling short of a degree sufficient to produce coma, are as follows: Pain in the head, varying in degree, sometimes intense, with a sense of heat, fulness, bursting or weight. The pain is not limited to one side, nor to any particular part of the head. There is inability to sleep, or if sleep be obtained, it is incomplete and unrefreshing. Delirium sometimes occurs, and, if present, is active. This symptom occurs especially when the congestion is due to excessive alcoholic stimulation. Convulsions occasionally occur in the adult; they are less infrequent in infancy, but active congestion, as a primary affection is not frequent in infantile life. The countenance is usually, but not invariably, flushed, the eyes are suffused or injected, with intolerance of light and sometimes scintillations. The head is hot; the carotids and temporal arteries pulsate strongly, and the patient is conscious of a throbbing sensation in the head. Inability to control mental operations, mental confusion, and momentary loss of consciousness are occasional symptoms; also vertigo, tinnitus aurium, and some embarrassment in speech. The symptoms are more or less marked in proportion as the hyperæmia is greater or less in degree.

Simple hyperæmia is merely a functional affection. It involves no lesion; if the congestion be removed without much delay, the structures are left intact. In a slight or moderate degree, it involves no immediate danger. As already stated, however, it may be developed rapidly in a sufficient degree to produce apoplectic coma which sometimes proves speedily fatal. Congestion may prove an exciting cause of cerebral hemorrhage if the minute arteries of the brain be the seat of miliary aneurisms or other lesions. Without morbid changes in the coats of the vessels, cerebral hyperæmia, however intense, is very rarely causative of hemorrhage.

The diagnosis of congestive apoplexy involves the discrimination from sudden coma caused by cerebral or meningeal hemorrhage, cerebral embolism, alcoholic intoxication, and uræmia. The differential points cannot be stated

without anticipating the clinical histories of these affections. Suffice it to say here that apoplexy from cerebral hemorrhage and embolism is excluded by the absence of hemiplegic paralysis, and that the symptoms pointing to congestive apoplexy are those which denote a determination of blood to the head—a flushed countenance, strong pulsation of the carotids, etc. Circumstances causative of active hyperæmia are also to be considered—simple hypertrophy of the left ventricle, alcoholic excess, mental excitement, etc.

Intense active hyperæmia calls for bloodletting. Relief is obtained most promptly by this measure. If the symptoms do not denote a degree of congestion sufficient to call for bloodletting, relief may be obtained by the cold douche, ice to the head, stimulating, hot pediluvia, dry cups applied to the neck, and an active purgative. The bromide of potassium and the other bromides are potential remedies, the rationale of their operation being that they diminish the amount of blood within the cranium. They may be employed when the degree of congestion does not indicate either bloodletting or active purgation. Faradization of the cervical sympathetic nerve and ergot relieve active congestion by inducing contraction of the intra-cranial arteries. Antimony relieves by its sedative effect upon the heart, but it should not be given in doses which produce vomiting. Sinapisms and other excitants of the skin relieve by revulsion.

These measures are for the removal or diminution of existing congestion. The treatment, in addition, should embrace, if possible, the removal of the causes; and, if the patient be of a full habit, regulation of diet, and occasional saline laxatives are advisable.

Passive congestion differs from the form just considered. Intra-cranial pressure from over-distended vessels exists alike in both; but in active congestion there is an overplus of arterial blood, and in passive congestion there is an excess of venous blood. This difference accounts for disparity in the symptoms.

In a degree to constitute a morbid condition, passive congestion may be produced by any mechanical impediment to the return of blood from the head. This may be due to pressure on the jugular veins in cases of goitre, or of enlargement of the lymphatic glands of the neck, and by the pressure of an aortic aneurism, or other tumors, on the vena cava. Prolonged efforts of expiration, as in some forms of spasmodic cough, and in playing on wind instruments, have this effect. Diseases of the lungs occasioning interference with the pulmonary circulation, namely, pleuritis with large effusion and emphysema, give rise to passive congestion by leading to overloading of the right cavities of the heart. It is incident to certain diseases of the heart, especially to obstruction at the right side of the heart from valvular lesions on that side, but more frequently from dilatation of the right ventricle and auricle, together with tricuspid insufficiency, as a result of mitral lesions. Obstruction or obliteration of the cerebral sinuses by coagula induces passive congestion in the communicating veins. Diminished force of the arterial circulation, that is, weakness of the *vis a tergo*, is also a cause.

The symptoms denoting passive congestion are, somnolency, dulness of mind, blunted perceptions, and, in children, sometimes convulsions. Throbbing of the carotids and temporal arteries, active delirium, increased heat, and other symptoms denoting active congestion, are wanting. The veins of the head are turgid and the face not infrequently cyanosed. The symptoms are due, in part, to intra-cranial pressure, and, in part, to the excess of venous, or the deficiency of arterial, blood.

Passive congestion of the brain is to be considered as, not an individual affection, but a morbid element entering into various affections. When

dependent on a mechanical impediment to the return of blood from the head, caused by cardiac lesions, tumor of the neck, etc., the object of treatment is, if possible, to diminish the obstruction. It can do no good to diminish the mass of blood by bloodletting. It is doubtful if aught is to be effected by revulsive measures. Anything which weakens the force of the circulation tends to increase the congestion. If dependent on feebleness of the circulation, the therapeutical indications are, to remove, if possible, the causes of exhaustion, and to increase the force of the circulation by digitalis and other cardiac tonics, stimulants, and nutritious diet. The degree of toleration of great venous congestion in some instances, for example, in dilatation of the right side of the heart, or when an aneurismal tumor presses on the descending vena cava, is worthy of note, as showing that symptoms are probably often incorrectly attributed to this cerebral condition.

In the foregoing account of cerebral hyperæmia, reference has been had to this condition as general, that is, affecting the entire encephalon, not limited to certain portions of the brain. Hyperæmia more or less circumscribed, occurs in connection with tumors which may produce obstruction of vessels, or cause a determination of blood within a limited area. Of these two modes, the former gives rise to passive, the latter to active, congestion. Passive congestion limited, more or less, in extent, is a result of thrombosis of veins, and, also, of both thrombosis and embolism of arteries.

Cerebral Anæmia.

In cerebral anæmia the brain is pale. The puncta vasculosa in the white substance are few or absent. The contrast in color between the gray and white substance is less than normal. The perivascular spaces are dilated. Cerebral anæmia is often accompanied by increase in the amount of cerebro-spinal fluid in the subarachnoid space, and by serous transudation into the ventricles. This œdematous condition of the brain is often found in persons who have died of wasting diseases, and who may not have presented any cerebral symptoms during life. A wet brain, as it is called, is often found as the chief pathological lesion in individuals who have died of acute or chronic alcoholism, and who may have been comatose during the last hours of life.

The quantity of blood sent to the brain is diminished whenever the mass of blood in the body undergoes diminution, as after hemorrhages, and in all diseases in which the constituents of the blood are expended without a proportionate renewal by means of alimentation. An over-accumulation of blood in other organs than the brain has the same effect. Mitral obstruction or regurgitation also occasions a defective supply of blood to the brain. An increase of the subarachnoidean liquid, and œdema of the brain, which may be effects of venous congestion, must diminish the amount of arterial blood by pressure on the cerebral arteries. An obstacle to the passage of blood in the distributing arteries, may arise from their spasmodic contraction excited by influences exerted through the vaso-motor nerves; and certain mental emotions which are accompanied by notable pallor of the face and a tendency to syncope, produce this effect. Anæmia from vaso-motor spasm exists in the first stage of an epileptic paroxysm.

A deficiency of arterial blood in either the whole or a part of the brain, is an important pathological element in certain affections of the nervous system which are to be presently considered, the deficiency arising from plugging of a cerebral artery (embolism and thrombosis), the pressure of a clot, of the products of inflammation, namely, fibrin, serum, and pus, and of tumors of different kinds. Inasmuch as the red globules are the chief constituents of

the blood on which depends the normal condition of the nervous centres, a paucity of these, as regards morbid effects, is equivalent to a diminished supply of arterial blood to the brain. Cerebral anæmia, therefore, is incident to impoverishment of the blood. Thus produced, it is an important element in many affections. Cephalalgia, mental depression, hysteria, and the phenomena referable to nervous asthenia, are often attributable to a deficient supply to the brain of fully oxygenated blood, in consequence of its impoverishment, or, in other words, a morbid deficiency of the carriers of oxygen, namely, the red globules. Impoverishment of the blood, together with feebleness of the circulation, resulting from intestinal transudation, occasions, in children, that condition of semi-coma described by Marshall Hall under the name "hydrencephaloid affection," a condition involving, with deficiency of arterial blood, or of red globules, venous congestion.

The immediate effect of a sudden and considerable diminution of arterial blood in the brain is syncope. Consciousness is lost, the face presents a death-like pallor, and convulsions may occur. Syncope occurs in cases of abundant hemorrhage, or after a copious venesection; and it may be produced by feebleness of the heart's action without any loss of blood. The phenomena of syncope are due to a sudden deficiency of arterial blood in the brain. It is especially apt to occur when the mass of blood in the body is deficient; and impoverishment of the blood also predisposes to it, inasmuch as the efficiency of blood in maintaining the functions of the nervous system depends chiefly on a normal quantity of the red globules. Epileptiform convulsions were produced by Kussmaul and Tenner in rabbits, by tying the arteries which supply the brain. Convulsions are not infrequently symptomatic of the anæmia induced by severe post-partum hemorrhage. Coma and paralysis in cases of cerebral hemorrhage, embolism, etc., are attributable to an interruption of the free circulation of arterial blood in the substance of the brain. Notable diminution of the arterial blood sent to the brain may be tolerated in a remarkable degree. This fact was exemplified in a case which came under my observation, in which were absence of arterial pulsation in both upper extremities, and an extremely feeble pulsation in both carotids, the autopsy showing complete embolic occlusion of the innominate artery; also, complete occlusion of the left subclavian artery, and the left carotid artery so nearly occluded as to admit of the passage only of a fine probe. There were aortic lesions, and the heart was found enlarged. The patient suffered from frequent attacks of vertigo and blindness, and was incapable of taking any active exercise. Pressure on the carotids produced syncope. There were no other noteworthy cerebral symptoms, and death was due to an attack of pneumonia.

The treatment of syncope embraces measures to increase the quantity of oxygenated blood sent to the head. Recumbency, with the head low, to secure the effect of gravitation, is important. Internal stimulants, to increase the force of the heart's action, are indicated. Dashing cold water upon the face is an efficient measure which acts by causing deep inspiratory efforts. The application to the nostrils of the vapor of ammonia has the same effect. These measures generally are promptly successful, unless the syncope be caused by an excessive hemorrhage, or the loss of blood continue. If not successful, another efficient measure consists in compressing the abdominal aorta and the arteries of the upper limbs. In this way, advantage is taken of collateral fluxion.

Cerebral anæmia, as incident to impoverishment of the blood, calls for the remedies and hygienic measures which have been already considered in treating of anæmia as one of the diseases of the hæmatopoietic system (page 337). The importance of recognizing this condition, with reference, not only

to a correct interpretation of pathological phenomena pertaining to the brain, but to disorders in other organs, and to its morbid agency when it is an element of nervous affections, cannot be too strongly enjoined.

It is to be noted that a deficiency of arterial or oxygenated blood may coexist with venous congestion within the skull. The former may lead to the latter in consequence of the contents of the skull being free from atmospherical pressure; and, on the other hand, congestion of the cerebral veins due to some impediment to the return of blood from the head may be an impediment to freedom of circulation in the distributing arteries, and thus occasion a deficiency of arterial blood.

Cerebral Embolism and Thrombosis.

The fact has been pointed out in Part First of this work (page 31) that the presence of an embolus or a thrombus in an artery, the branches of which freely anastomose with each other, as, for example, in an artery of a voluntary muscle, produces, as a rule, no appreciable disturbance of the circulation; while the occlusion, by embolus or thrombus, of an artery belonging to the terminal arterial system, that is, of one whose branches do not inosculate, is followed by an infarction, either hemorrhagic or simply necrotic, in the district supplied by the occluded vessel. It has been demonstrated by Heubner and by Duret that the arteries supplying the so-called basal district of the brain, that is, the region occupied chiefly by the corpus striatum, nucleus lenticularis, optic thalamus, and adjoining cerebral substance, are terminal arteries, and that those supplying the cortex cerebri freely anastomose with each other in the pia mater, in which they become much reduced in size before they enter the gray matter. We are thus able to explain why an embolus lodging in one of the cortical arteries in the pia (whither, however, it rarely finds its way), produces little permanent disturbance, while an embolus or thrombus occluding one of the basal arteries beyond the circle of Willis, is apt to be followed by destructive changes in the region in which the blood supply has been cut off.

The source of the emboli conveyed into the cerebral arteries, in the great majority of cases, is the left ventricle of the heart. They consist usually of masses of fibrin which have been deposited on the aortic or mitral valves in consequence of acute or chronic endocarditis, and which are washed away by the blood-current into the circulation. Thrombi formed in the heart from any other cause may also give origin to emboli. Cerebral emboli may also be derived from the pulmonary veins, the first part of the aorta, the carotid and the vertebral arteries. Next to disease of the left ventricle, aortic aneurism and atheroma of the aorta form the most frequent source of emboli. The emboli usually consist of portions of a thrombus, but they may be calcareous concretions, fragments of connective tissue, bits of new growth, bacteria, other vegetable parasites, fat, etc. (*Vide* page 30.)

An embolus may lodge in any artery of the brain, but, in the majority of cases, it occludes the middle cerebral artery not far from its origin. Next in order of frequency comes embolism of the internal carotid, and then embolism of the basilar artery. The statistics compiled by Gelpke[1] showed that, out of 100 cerebral emboli, more than 90 affected the arteries which supply the basal ganglia. An embolus enters the left middle cerebral artery more frequently than the right. The explanation of this is afforded by the difference in angle at which the left common carotid and the innominate come off from the aorta. But the predominance in frequency of embolism of the left cerebral arteries over that of the right has been exaggerated. According to Gelpke,

[1] Gelpke, Arch. d. Heilkunde, 1875, p. 501.

of 131 emboli of the carotid artery or of its branches, the left side was affected 64 times, the right side 54 times, and both sides 13 times.

An embolus usually leads to the formation of a thrombus about it. The cause of spontaneous thrombosis of the cerebral arteries is to be sought in some change in the walls of the affected vessels. The most frequent change is atheroma of the arteries of the brain; but other forms of chronic arteritis, especially syphilitic endarteritis, may also occasion thrombosis. Other and rarer causes are simple fatty and calcareous degenerations of the arteries, compression of the arteries, as by a tumor, extension of a thrombus primarily formed in one of the carotid arteries, and possibly mere slowing of the circulation from weakened heart's action.

Cerebral thrombosis occurs chiefly in old age, because the arterial changes to which it usually owes its origin are most frequent at this period of life. When it is present in the earlier periods of life, it is due usually, but not necessarily, to chronic alcoholism or to syphilis. Embolism, on the other hand, may occur at any age.

The effect of the occlusion by an embolus or a thrombus of an artery of the brain belonging to the terminal system, is softening of the portion of brain, the blood-supply of which has been cut off. For reasons which have already been given, embolic softening, in the vast majority of cases, is located in the corpus striatum or caudate nucleus, the internal capsule, the lenticular nucleus, the optic thalamus, or the island of Reil. According to the size of the artery occluded, a greater or less portion of this region of the brain will be affected. It is especially to involvement of the internal capsule in the softening, that we attribute the hemiplegia which attends embolism of the middle cerebral artery, for in this narrow band of white matter, situated between the lenticular nucleus externally and the caudate nucleus and optic thalamus internally, are compacted together the motor fibres which supply the opposite half of the body.

The first effect of embolism of a cerebral artery is anæmia of the district supplied by that vessel. If a sufficient collateral circulation be established, this anæmia passes off without permanent damage; but, if the branches of the artery do not anastomose, the anæmia is followed by a gradually progressive necrobiosis or death of the part, which may or may not be accompanied by hemorrhage. A true hemorrhagic infarction, like that which follows embolism of one of the branches of the pulmonary artery, or of the splenic artery, occurs very rarely in the brain, but a certain amount of extravasation of blood in a punctate form is not infrequently present in the anæmic district. It is not quite clear why, in some cases, embolic softening is accompanied by so much blood-extravasation as to resemble a primary cerebral hemorrhage, while, in other cases, no blood is extravasated. It is probable that increase of pressure in the veins coming from the anæmic spot favors a regurgitant current with hemorrhagic softening, and that low venous pressure opposes it. When a spot of embolic softening is stained with extravasated blood, the process is called red softening; if there be simply anæmic necrosis without hemorrhage, it is spoken of as yellow softening by some, and white softening by other writers. It may be mentioned here that the term cerebral softening has ceased to have any exact significance as a pathological process, and that each of the varieties—red, yellow, and white softening—may occur from various causes and indicate various pathological conditions.

In the early stages of embolic softening (what is said in this connection of embolic, applies equally to thrombotic, softening), the volume of the affected portion of brain is somewhat increased; its consistence is diminished; its boundaries are not distinctly marked off from the surrounding healthy tissue, and its color is red, or yellow, or whitish-yellow. At a later period the

softened spot is diminished in volume, and its consistence may be nearly fluid. The final stage of the process is not always the same. Frequently a cyst with fluid contents remains. If the first stage have been red softening, the cyst-wall and the fluid contents are stained with blood-pigment, and the cyst cannot be distinguished from one following a primary cerebral hemorrhage; if hemorrhage have not attended the process of softening, the cyst-wall and its contents are unstained, and the embolic origin of the cyst is evident. Sometimes, instead of a cyst, there is left a reticulum of connective-tissue fibres and bloodvessels inclosing in their meshes fluid or semi-fluid contents frequently of a white color. This is called the cellular infiltration of Durand-Fardel. Other terminations are in a cicatrix and in a dry caseous mass. Finally, the affected tissue may remain indefinitely as a spot of yellow or white softening. In the sequence of changes, a spot of primary red softening becomes one of yellow softening in consequence of pigmentary alterations in the blood.

The microscopic examination reveals, as the most characteristic element throughout the stages of softening, the so-called granular corpuscles, formerly called the inflammatory corpuscles of Gluge. These are large, usually spherical, cells so densely filled with fat globules as to appear dark by transmitted, and white by reflected, light. They are usually present in large numbers. They probably have different origins. They consist of emigrant white blood-corpuscles which have taken up the fatty matter resulting from the disintegration of nerve-elements, or they may represent neuroglia-cells, ganglion-cells, adventitious cells of the bloodvessels, or endothelial cells distended with fatty globules. Similar granular cells are found in pathological processes accompanied with fatty degeneration in various other parts of the body, as in ovarian cysts, pneumonia, etc. In the early stages, the disintegrated nerve-elements can be recognized in the shape of broken nerve-fibres, drops of myeline, and fatty ganglion cells. These gradually disappear. Corpora amylacea and red blood-corpuscles, later, amorphous and crystalline hæmatoidin, and crystals of the fatty acids, may be detected.

Certain secondary degenerations in the spinal cord, which may follow softening of the internal capsule and some other parts, will be noticed under cerebral hemorrhage.

The preceding description of the anatomical changes resulting from cerebral embolism has been based on the assumption that the embolus is bland in its nature, which is usually true. If, however, the embolus be infectious, it leads to the formation of an abscess as in other situations; or, if an embolus come from a gangrenous focus, such as may be present in the lung, gangrene of the affected portion of the brain, that is, necrosis accompanied by decomposition, follows.

Clinical History.—Cerebral embolism is one of the several pathological conditions which are causative of sudden coma or apoplexy. This effect does not occur as a rule, but it is not infrequent. The apoplectic attack is not preceded by premonitions. If antecedent cerebral symptoms existed, they had no connection with the occurrence of the embolism, the latter depending entirely on the dislodgment of the embolus at its source, and being wholly independent of any previous affection within the brain.

The apoplectic coma may be complete, or the patient may be aroused to consciousness by more or less effort. There may be stertor, infrequency of the pulse, vomiting, and immobility or inequality of the pupils; but these symptoms are rare in embolic apoplexy as compared with apoplexy from cerebral hemorrhage. Convulsive movements occasionally occur.

Hemiplegic paralysis almost always is an effect of embolism of the middle

cerebral artery, and this effect is coincident with the apoplexy, if the latter occur.

The duration of the coma varies from a few moments to many hours. A fatal termination, the coma existing until death, is rare. The hemiplegia, with few exceptions, persists for a longer or shorter period after the coma has disappeared. It may be permanent. It may or may not include the muscles of the face. It affects the side opposite to the hemisphere in which the embolism is seated. It is chiefly or exclusively motor. Owing to the fact that the embolism is seated oftener in the left than in the right hemisphere, the hemiplegia, in the majority of cases, affects the right side.

It is not easy to give a satisfactory pathological explanation of embolic apoplexy. The localized anæmia, limited to the district supplied by the occluded artery, and the increased pressure by the arteries dilated in consequence of arterial flexion, seem *à priori* inadequate to account for the sudden coma, and other causes are not apparent.

In a considerable, perhaps the larger, proportion of cases, embolic hemiplegia is not preceded by an apoplectic attack. The hemiplegia occurs suddenly, without premonitions. The paralytic, like the apoplectic, stroke, takes place unexpectedly, the patient being free from any cerebral symptoms up to the instant of its occurrence.

Cerebral thrombosis very rarely causes apoplectic coma. Coma, if it occur, is developed gradually, and is due to an extension of the embolus by fresh deposits, thus enlarging the district from which the arterial supply is cut off. Hemiplegia takes place, not by a sudden stroke, but by degrees, not infrequently becoming greater by successive steps, instead of by a continuous increase. Moreover, the occurrence of coma or of hemiplegia is preceded by premonitions, such as vertigo, impairment of mental faculties, difficulty in speech, etc. These premonitions may, in some instances, be due to embolism which causes a partial obstruction, the occlusion being rendered complete by a thrombus added to the embolus.

Disturbances of speech often occur in cases of cerebral embolism and thrombosis. Loss of speech, not from any affection of the organs concerned in phonation nor from mental imbecility, is expressed by the term *aphasia*. The terms *aphemia* and *alalia* have the same significance, but are not generally used. Aphasia is to be distinguished from *aphonia*, a term denoting inability to speak in consequence of either laryngeal disease or paralysis of the laryngeal muscles. Aphonia is the loss of voice, and aphasia is the loss of speech; the former relating exclusively to the vocal organs, the latter proceeding from a cerebral affection. In aphasia the patient is mute from an inability to use words expressive of the ideas which are in the mind. The loss of speech may be complete or partial; the patient in some instances is absolutely dumb. Sometimes a single word can be spoken, such as "yes" or "no," and this is uttered whenever the attempt to speak is made; in other instances the vocabulary is larger, but limited to a few words, and, in different cases, there is every degree of incompleteness in the aphasic condition. A difficulty of speech may consist in an inability to use the proper words to express the mental ideas. Things are not called by their right names, and the language in sentences, either spoken or written, is incongruous and unintelligible. This difficulty is sometimes distinguished as *paraphasia*.

An important distinction is denoted by the terms *amnesic* and *ataxic aphasia*. In ataxic aphasia the mind recognizes the proper signification of words; the difficulty consists in an inability to give utterance to the words. The name ataxic implies that this inability proceeds from a lack of power to co-ordinate the muscles concerned in speech. Something more than simple ataxia, however, would seem to be involved. A lack of co-ordinating power

would be manifested by movements responding to, but not governed by, the will, and the result would be inarticulate phonetic sounds. This evidence of ataxia is sometimes manifested, but generally the patient will not make any effort to speak, that is, if the aphasia be complete; and if a few words be uttered, these may be spoken with distinctness. In amnesic aphasia there is inability to recollect words as the symbols of ideas; language is lost to the memory.

If the aphasia be purely ataxic, the ability to use language correctly in writing is not lost, and may not be impaired, provided the intellectual faculties are intact. The ability to read is retained, and language spoken by others is comprehended. So far as can be judged, in some cases of ataxic aphasia absolute mutism is not incompatible with undiminished intelligence. Frequently, however, the cerebral affection which causes the aphasia, impairs, in a greater or less degree, the mental faculties. In amnesic aphasia, on the other hand, the loss of speech is accompanied by inability to use written language (agraphia). The loss of the memory of words does not necessarily carry with it inability to understand their meaning when they are heard or seen. The patient may understand both spoken and written language. Inability in these respects involves, in a greater or less degree, mental imbecility.

In ataxic aphasia, the ability to interpret signs or gestures is preserved. If this be lost in either ataxic or amnesic aphasia, there is imbecility in a greater or less degree. Patients affected with ataxic aphasia, even when it is evident that the intelligence is well retained, cannot repeat words after dictation. Patients with purely amnesic aphasia are able to do this, provided the intelligence is not too much impaired. The inability to repeat words is evidence either that the aphasia is not purely amnesic, or that there is imbecility.

The ataxic and amnesic forms of aphasia may be combined. The patient can then express ideas neither by spoken nor written language, and is unable to repeat words after dictation.

In cases of either ataxic or amnesic aphasia, it is not an easy problem to determine whether or not, or to what extent, the mental powers are impaired. This problem is sometimes presented to physicians in medico-legal cases. The instances must be rare in which persistent aphasia, associated with hemiplegia, does not involve more or less impairment of mind. Ataxic aphasia, as an isolated affection, may exist with the intellect apparently unaffected. It is doubtful if this can be said of amnesic aphasia. Words are the instruments of thought as well as the expression of ideas, and it is difficult to believe that the inability to recollect words is possible without deterioration of the reasoning faculties. The inability to understand spoken or written language and signs, is proof of impaired intellect.

A large accumulation of clinical observations within the last few years has established the connection of aphasia, in the vast majority of cases, with lesions localized in a particular part of the brain, namely, the island of Reil, and especially the posterior part of the third frontal convolution. These lesions are not alone those incident to embolism and thrombosis, but those caused by cerebral hemorrhage, morbid growths, abscess of the brain, etc. Aphasia is, therefore, a symptom belonging to the clinical history of diseases which are to be hereafter considered. In a small number of cases, lesions have been found in the similar parts of the right hemisphere, or the aphasia has been associated with left-sided hemiplegia. In a certain proportion of the latter cases, it was ascertained that the patients were left-handed. It may be doubtful if in any case of well-marked persistent aphasia, an autopsy has shown conclusively absence of any lesion affecting the island of Reil or proximate parts in one

or the other hemisphere. For statistical facts on which these statements are based, the reader is referred to other works.[1]

The theory which, with our present knowledge, furnishes the most satisfactory explanation of these facts, assumes the following postulates: The third convolution and the island of Reil are in a direct physiological relation to language. This is true of the left, and not of the right, hemisphere in most persons, owing to the habitual use of the left, instead of the right, hemisphere in the exercise of the function of language. As exceptions to the rule, some persons habitually use the right, instead of the left, hemisphere in the exercise of the function of language, and these persons are generally left-handed. Injury of the parts in the left hemisphere which are in relation to language do not, in these persons, cause aphasia, but this result follows injury of the parts in the right hemisphere. The parts in the right hemisphere which are in a physiological relation to language, although their functional activity has been in abeyance, owing to non-use, may assume, in some instances, activity after the parts of the left hemisphere have been incapacitated by lesions; hence, improvement or recovery from aphasia may sometimes take place, the lesions in the left hemisphere remaining unchanged.

Aphasia attributable to embolism sometimes occurs without apoplexy or paralysis. The following case is an example: A young man, having ridden all day in an open wagon, the weather being cold, after eating a hearty supper was suddenly unable to utter a word. He went to bed, hoping that the ability to speak would return in the morning. He slept perfectly well, but, on awakening, he was still unable to speak. In the course of the day he began to use some words, often using wrong words, but in the course of a few days he recovered his speech, although ever since he had had some difficulty in selecting right words. He saw me a year after this occurrence. Meanwhile nothing had occurred to denote any cerebral disease, except that he was conscious of an uneasy sensation in the left side of the head. He had an aortic regurgitant and a mitral direct murmur, with considerable enlargement of the heart. It can hardly be doubted that in this case the temporary aphasia was due to embolism of one of the branches of the middle cerebral artery.

Cases have been reported of the occlusion, after an interval, of the middle cerebral artery on the two sides, giving rise to double hemiplegia. These cases have furnished examples of left hemiplegia without aphasia, followed by right hemiplegia with aphasia.

Diagnosis.—The diagnosis in most cases of embolic apoplexy requires the exclusion of apoplexy from cerebral hemorrhage. The latter is presently to be considered. If the apoplexy be due to occlusion of the middle cerebral artery, it is accompanied by hemiplegia. This is true also of apoplexy due to cerebral hemorrhage in the situations where it is most likely to take place. As a rule, the other pathological conditions which stand in a causative relation to apoplectic coma, do not give rise to hemiplegia. The differentiation, therefore, in the great majority of cases, is between embolism and hemorrhage in cases of apoplexy with hemiplegia. The following are differential points.

Embolism may occur at any period of life, and it is as frequent in early as in middle or advanced age. Cerebral hemorrhage is rare below the middle period of life. An apoplectic seizure, the patient not having reached the latter period, is, therefore, more likely to be due to embolism than to hemor-

[1] *Vide* the very comprehensive article on Aphasia, by Kussmaul, in Ziemssen's Cyclopædia, vol. xiv.

rhage. The occurrence of hemiplegia on the right side weighs somewhat in favor of embolism. The existence of endocarditis or of valvular lesions in the left side of the heart, renders embolism probable. The absence of symptoms denoting cerebral congestion which often, but by no means uniformly, precede cerebral hemorrhage, has some weight in the diagnosis. The absence of cerebral prodromes, which applies to all cases of embolism, is not as constantly applicable to cases of hemorrhage. Vomiting, an infrequent pulse, stertor, changes in the pupils, and convulsions, are more frequent and more marked in cases of apoplexy due to hemorrhage. The diagnosis of embolism is strengthened by the occurrence of symptoms denoting embolism of the spleen and kidneys. Unilateral amaurosis from embolism of the central artery of the retina, preceding or accompanying the attacks, is diagnostic of embolic apoplexy.

These differential points suffice often for a highly probable diagnosis. They do not warrant a positive diagnosis. The physician who ventures upon the latter, incurs a risk of being convicted of an error at the autopsy. If, however, the patient speedily emerge from the apoplectic condition, rapid improvement, as regards the paralysis, subsequently taking place, and ending in complete recovery, the diagnosis of embolism is very probable.

Embolic hemiplegia is to be differentiated from hemiplegia due to cerebral hemorrhage, and also to other conditions, namely, morbid growths, abscess, etc. The difficulty in the diagnosis, however, is chiefly in excluding hemorrhage. The other conditions generally involve antecedent symptoms of cerebral disease, whereas the paralysis caused by embolism is devoid of these, and this is often true of hemorrhage. Both embolism and hemorrhage may give rise to sudden hemiplegia without apoplexy; but in much the larger proportion of cases this is true of embolism. In sudden hemiplegia without apoplexy, therefore, the chances are that it is embolic. Other differential points are embraced in the list of those which relate to the differentiation of apoplexy from embolism and hemorrhage. Rapid improvement is much more likely to take place in paralysis from embolism, and complete recovery, which is not infrequent in embolic hemiplegia, is rare in paralysis from hemorrhage. Increase of the body heat two or three days after an apoplectic or paralytic stroke, has been regarded as denoting the presence of a cerebral clot, but observations have shown that an equal increase sometimes follows when the apoplexy and paralysis are due to embolism.

For the differentiation of embolism from thrombosis, the most important point has been stated, namely, the effects of arterial occlusion occur by the former suddenly, and by the latter more or less gradually. This point of distinction, however, cannot always be relied upon. A thrombus may, exceptionally, form so rapidly as to simulate, in the abruptness of its effects, embolism. An attack of hemiplegia, either with or without apoplexy, may occur during sleep, and, under these circumstances, this differential point may not be available. Again, as already stated, an embolus may cause only a partial obstruction, complete occlusion afterwards being produced by a thrombus formed at the seat of the embolus.

Other differential points are as follows: The conditions for thrombus belong to middle or advanced age. The youth of the patient is, therefore, a point in evidence for embolism. The existence of endocarditis or valvular lesions of the heart, points to embolism, and their absence, to thrombosis. Calcification of the radial arteries is a ground for inferring that the cerebral arteries have undergone the same change, this being the most frequent of the conditions which are causative of thrombus.

Embolism and thrombosis of the basilar artery may produce coma, either suddenly or more or less slowly, without hemiplegia. Death takes place, in

some cases, within a few hours. In other cases, patients recover, although the artery remains occluded. These statements have been verified by cases under my observation.

Prognosis.—An apoplectic attack caused by embolism of the middle cerebral artery, is less likely to prove immediately fatal than apoplexy from cerebral hemorrhage; hence, the probable diagnosis has a bearing on the prognosis. In most cases, after a few hours the coma disappears, hemiplegia remaining.

The persistence of hemiplegia, whether preceded or not by apoplexy, depends on the occurrence of softening from necrosis, and extravasation of blood, as effects of the arterial obstruction. If the circulation within the district in which the blood supply was furnished by the occluded artery be restored within two or three days, so as to prevent the changes incident to defective nutrition, rapid improvement takes place and complete recovery. These changes are to be inferred from the persistence of the paralysis. There may be more or less improvement which will be in proportion to the favorable course of the local process as described in connection with the anatomical characters. Complete recovery from the paralysis is not to be expected. If the local process be not favorable, more or less impairment of the mental faculties is added to the persistent paralysis. The duration of life is indefinite. Death is generally caused by antecedent or intercurrent disease.

The prognosis if hemiplegia be caused by thrombosis, is less favorable than if it be due to embolism, as the patients are more enfeebled. The prognosis is extremely unfavorable if coma supervene upon hemiplegia.

The prognosis as regards the continuance of aphasia, is a matter of much interest to patients and their friends. The restoration of speech may accompany recovery from the paralysis, but it may be otherwise. In a hospital case under my observation, the hemiplegia entirely disappeared, the general health was excellent, and the mental faculties were apparently not in the least affected, but complete mutism persisted. The patient made no attempt to speak; when asked why he was silent, he placed his finger on his lips and shook his head. He was discharged in this condition. If, owing to the pathological changes in the affected district of the brain, the paralysis persist, aphasia generally continues. There may, however, be more or less improvement. There are no means of judging beforehand what degree of improvement will take place. Adopting the views stated in regard to the duality of the parts which stand in a physiological relation to language, if the injury destroy the functional capacity in the hemisphere to which the exercise of the function has been limited (usually the left hemisphere), the recovery of speech or the degree of improvement will depend on the ability to develop functional activity of the corresponding parts in the other hemisphere which had previously been in abeyance. The probability of success is greater in proportion to the youth of the patient. If the aphasia continue without improvement for several months, none is to be expected.

The prognosis is favorable when aphasia occurs without apoplexy, hemiplegia, or other evidence of cerebral disease.

Treatment.—The object of treatment in the early stage of embolism and thrombosis, is the re-establishment of the circulation within the district deprived of blood-supply, in order to prevent the changes incident to defective nutrition. Blood-letting, cathartics, and any measures which weaken the heart's action, contravene this object, and are, therefore, contra-indicated. On the contrary, it is often important to increase the strength of the heart's action by tonic remedies, a nutritious alimentation and alcoholics. If there

be feebleness and irregularity of the heart's action, in connection with valvular lesions and dilatation, digitalis is indicated. All forms of counter-irritation are contra-indicated. Cold applications to the heart are inappropriate. Warm applications may be useful.

This plan of treatment is to be pursued for several days, until it be determined whether or not the patient escape the local changes which ensue if the circulation be not re-established in the affected district of the brain. If softening take place, the objects of treatment relate to the general condition of the system and to the hemiplegia.

The first of these objects embraces measures for improving and maintaining the nutrition of the body, namely tonic remedies, a good diet and an invigorating regimen. In cases of embolism, diseases of the heart will often furnish indications for treatment.

Hemiplegia incident to the brain lesions resulting from embolism and thrombosis, claims the same treatment as when it is due to a blood-clot in the brain (*vide* Cerebral Hemorrhage). It consists of passive movements, together with rubbing and kneading the paralyzed limbs, the employment of electricity, and as much voluntary exercise of the muscles as practicable. These measures are important in order to prevent degenerative changes in the muscles and nerves of the paralyzed limbs, to promote the circulation and nutrition in these parts, and to develop, as far as possible, their functional capacity.

The treatment which has special reference to aphasia, consists in persistent efforts to regain the memory of words and their vocal utterance. If the mutism be not complete, perseverance in exercises for these ends may sometimes accomplish much, and its importance is to be enjoined.

Thrombosis of the Cerebral Sinuses.

Thrombosis of the cerebral sinuses, especially of the longitudinal and lateral sinuses, may be the result of slowing of the circulation from weakened heart's action in patients, particularly children, who are greatly enfeebled by some wasting disease. This form is called marantic thrombosis.

Thrombosis may also be occasioned by inflammation of the walls of the sinus, or phlebitis of the sinus, secondary, as a rule, to disease of the cranial bones. Thrombi thus formed are usually infected or purulent. Caries of the petrous portion of the temporal bone following inflammation of the middle ear or of the mastoid cells, may be taken as one of the most frequent and typical causes of this variety of sinus-thrombosis. The lateral, petrosal, and, in a less degree, the cavernous sinuses, are most frequently the seat of purulent thrombi. Large carbuncles and severe erysipelatous inflammation about the head and neck may lead to sinus-thrombosis. Thrombosis of the cerebral sinuses is accompanied by no very characteristic changes in the meninges and brain. Punctate hemorrhages in the membranes and in the cortex *cerebri* are often observed. Sometimes more extensive hemorrhages follow. The purulent thrombi are apt to be accompanied with meningitis, and, not infrequently, abscess of the brain; also they may lead to the formation of embolic abscesses in the lungs and other parts of the body.

Thrombosis of the cerebral sinuses can rarely be diagnosticated with any approach to certainty. The marantic variety in young children gives rise to symptoms analogous to those attributed to anæmia in the so-called hydrencephaloid affection of Marshall Hall, namely, somnolence and coma, with general and progressive prostration. The symptoms which, added to these, render thrombosis probable, are tonic contraction of the muscles of the neck

and back, strabismus, and ptosis. In adults, indefinite cerebral disturbance eventuates gradually in coma. Turgidity of the external veins limited to certain situations on the cranium, is a diagnostic feature in some cases. Thrombosis of the lateral sinus sometimes occasions venous congestion and œdema behind the ear. Thrombosis of the cavernous sinus has been observed to give rise to congestion of the intra-orbicular veins, with prominence of the eyeballs and swelling of the eyelids.[1]

Prominent encephalic symptoms accompanying pyæmia, if preceded by caries of the bones about the ear, by carbuncles or erysipelas of the face, head, or neck, may be referable to purulent thrombosis of the cerebral sinuses.

Capillary Embolism and Thrombosis of the Brain

Our knowledge of embolism and thrombosis of the cerebral capillaries is too limited for determining their pathological effects, symptomatology, and diagnosis. Pigment embolism is incident to malarial fevers, especially in their pernicious forms. (*Vide* page 83.) Emboli or thrombi may consist of leucocytes, fat drops, or the salts of lime. Future observations may establish an importance which does not at present belong to occlusions of the cerebral capillaries, regarded from the standpoint of practical medicine.

Cerebral Hemorrhage.

Intracranial hemorrhages may be conveniently divided into cerebral and meningeal. In cerebral hemorrhage, which will be first considered, the extravasation of blood is into the substance of the brain. Hemorrhages, usually punctate in character, are frequently found in and about tumors, around abscesses, and in foci of embolic softening, but only the so-called *spontaneous* cerebral hemorrhages will be treated of under this heading.

The ultimate cause of spontaneous cerebral hemorrhage is, probably without exception, disease of the cerebral arteries. Various changes of the arterial coats, such as atheroma, fatty degeneration, syphilitic endarteritis, were formerly assigned as efficient causes; but since the publication, in 1868, of the important investigations of Charcot and Bouchard,[2] the bursting of miliary aneurisms of the smaller cerebral arteries has been recognized as the predominant, and, by several careful observers, as the exclusive, cause of spontaneous cerebral hemorrhage. Charcot and Bouchard examined seventy-seven cases of spontaneous cerebral hemorrhage without missing miliary aneurisms in a single one. Zenker[3] also found the aneurisms in all cases which he examined, and Roth[4] missed them in only one case out of eight. These aneurisms are, for the most part, visible, with the naked eye, as little nodules of the size of a millet seed or the head of a pin. But they may exceed these dimensions, or, on the other hand, may be microscopic in size. In some cases considerable expenditure of time and skill is required for their detection; in other cases they are present in large number. In the majority of cases the whole circumference of the artery takes part in the aneurismal dilatation. The aneurisms are usually fusiform, but they may be round, and are sometimes sacculated. The order in frequency of their occurrence in the different regions of the brain, corresponds, according to Charcot and Bouchard, to the scale of frequency of hemorrhages in these regions, namely,

[1] *Vide* Nothnagel, Ziemssen's Cyc., Am. ed., vol. xii.

first the optic thalamus, corpus striatum, and surrounding brain-substance; then, the convolutions, pons Varolii, cerebellum, centrum ovale, superior cerebellar peduncles, crura cerebri, and medulla oblongata. Pathologists are not agreed as to the anatomical processes which precede the formation of these aneurisms. According to Charcot and Bouchard, they owe their origin to a primary periarteritis causing atrophy of the muscular coat; according to Roth, to a primary fatty or amyloid degeneration of the media; and according to Zenker, whose views are confirmed by the recent careful studies of Eichler,[1] the aneurisms are the result of a primary endarteritis deformans. If the last view should be confirmed, atheroma would still maintain its old position as a most important element in the causation of cerebral hemorrhage. It is, however, to be noted that, while atheroma of the arteries at the base of the cerebrum is present in the majority of cases of cerebral hemorrhage, there is no necessary connection between atheroma in this situation and aneurisms of the intracerebral arteries; for, on the one hand, miliary aneurisms are present without atheroma of the basal arteries, and, on the other hand, extensive atheroma of the arteries at the base may exist without miliary aneurisms. These aneurisms are developed with progressive frequency after forty years of age, but they have been found in youths and young children. Even Charcot and Bouchard, who deny any relation of cause and effect between atheroma and the development of these aneurisms, admit that for both alike the most prominent predisposing cause is advanced age. At present we are unable to say whether diseased conditions of the intracerebral arteries without the development of aneurisms, such as simple atheroma, fatty degeneration, obliterating endarteritis, periarteritis, can so weaken the vascular walls as to prove a cause of spontaneous hemorrhage, although it is probable that some of these conditions are efficient causes.

Increase in the arterial tension, more particularly that referable to hypertrophy of the left ventricle, has long been recognized as an important element in the etiology of cerebral hemorrhage. In fact, hypertrophy of the heart has been regarded as in itself an efficient cause of cerebral hemorrhage. It is to be borne in mind that hypertrophy of the heart in compensation of valvular lesions, is not attended by increase of arterial pressure, so that only the simple hypertrophy complicating some forms of Bright's disease and the rare form called idiopathic hypertrophy, could enter into consideration in this connection. No relation has ever been observed to exist between idiopathic hypertrophy, such as that of soldiers, and cerebral hemorrhage. On the other hand, there is abundant evidence of a more than accidental coincidence between cerebral hemorrhage and the existence of cardiac hypertrophy accompanying the small granular kidneys of Bright's disease. Miliary aneurisms, however, have already been found in cases of cerebral hemorrhage complicating these conditions; and this fact, taken in connection with many, to be sure not very satisfactory, observations regarding changes in the arteries of the body in certain forms of Bright's disease, justifies us in rejecting cardiac hypertrophy as in itself a cause of cerebral hemorrhage. But when the walls of the intra-cerebral vessels are weakened by local changes, increase of the vascular tension from hypertrophy of the left ventricle, or from any other cause, is the most important influence in bringing about rupture of the vessels.

The etiology of the cerebral hemorrhages which in rare instances complicate diseases characterized by morbid changes in the blood, such as typhus fever, scurvy, pyæmia, pernicious anæmia, malignant icterus, is not well established. Here, too, the most probable hypothesis is that of changes in the vessel-walls. The cerebral hemorrhages occasionally observed in leuco-

[1] Eichler, Deutsches Archiv f. klin. Med., Bd. 22, p. 1, 1878.

cythæmia are attributed by Ollivier and Ranvier to stasis of the white blood, corpuscles. These hemorrhages attending blood diseases are very rare and not often extensive.

The fact has already been mentioned that hemorrhage occurs most frequently in the opto-striate bodies (corpus striatum and optic thalamus) and in their neighborhood. The explanation of this is to be found in the fact that the arteries which supply these parts are given off from the anterior, middle, and posterior cerebral arteries near their origin, and penetrate directly, as comparatively large vessels, into the brain-substance, where they divide as terminal arteries. These arteries are subjected, therefore, to a relatively high pressure, whereas the arteries which supply the cortex of the cerebrum become almost capillary in size before they dip down from the pia mater into the gray substance, and are therefore less exposed to the effects of increased blood-pressure. In the majority of cases the hemorrhage is due to rupture of some of the branches of the middle cerebral artery, which are destined for the supply of the lenticular nucleus, the internal capsule, the greater portion of the caudate nucleus, and a part of the optic thalamus. It rarely happens that a hemorrhage involves only one of these parts, as, for instance, the lenticular nucleus, or the internal capsule; usually one or more of the ganglia here situated, together with a part of the internal capsule, are affected. In post-mortem examinations it is important to note to what extent the internal capsule is involved, as lesions of most parts of the internal capsule are followed by permanent hemiplegia, whereas the hemiplegia which immediately follows hemorrhages confined to the lenticular nucleus, or caudate nucleus, is usually temporary, or, at least, capable of great improvement, in case the internal capsule is not permanently involved by pressure or otherwise.

Cerebral hemorrhage occurs in the form of capillary extravasations, and in that of so-called apoplectic foci in which the extravasated blood is collected into a mass. The capillary hemorrhages are the least important. They appear as isolated small red points, either scattered through the brain or collected together in a small space. The capillary hemorrhages may unite to make apoplectic foci. They are often found around the large extravasations; they are present around tumors, abscesses, centres of softening; and they may result from active congestion of the brain and from diseases attended with severe blood changes. An apoplectic focus is usually about the size of a hazel-nut or a pigeon's egg; but it may be no larger than a pea, or it may occupy nearly the whole of one cerebral hemisphere. If the extravasation take place in the vicinity of one of the lateral ventricles, the blood not infrequently finds its way into the latter. The blood may reach the outer surface of the brain either by breaking directly through the peripheral cerebral substance, or by penetrating the third and thence the fourth ventricle, from which it can reach the exterior. Usually only a single hemorrhagic focus is present, but there may be several foci. It is not very uncommon to find remains of a previous hemorrhage.

If the hemorrhage in the interior of the brain be of considerable size, the corresponding hemisphere is swollen, the convolutions flattened, and the dura mater tense. If the hemorrhage be recent, the apoplectic focus consists of a dark red clot of blood mingled with the debris of cerebral tissue, and contained in a cavity, the wall of which is composed of lacerated nerve-tissue surrounded by œdematous cerebral substance. Frequently, in proximity to the clot, numerous capillary extravasations are present. If the extravasation be large, the substance of the corresponding hemisphere is anæmic. Careful examination by proper methods will usually reveal miliary aneurisms in or around the focus. Care must be exercised not to mistake for these aneurisms, hemorrhages into the perivascular sheaths, the so-called dissecting

aneurisms which are usually to be found about cerebral extravasations. If life be prolonged, retrograde metamorphoses occur in the extravasated blood. The color changes from dark red to brownish or yellow, in consequence of the formation of blood-pigment, in the form of granular and of crystalline hæmatoidin, out of the red blood-corpuscles. From dissolved coloring matter, the surrounding brain-substance becomes stained diffusively yellow or brown. The fibrin and the lacerated nerve elements undergo disintegration and are absorbed, granular corpuscles making their appearance. While these regressive changes are going on, a connective-tissue capsule is formed by reactive inflammation around the focus. The final result is the production of a so-called apoplectic cyst. This cyst consists of a fibrous capsule inclosing a brownish or yellowish, rarely a clear, fluid. The cyst-wall and the fluid are stained by blood-pigment. Usually delicate threads of connective tissue traverse the cavity between the cyst-walls. Sometimes the walls of the cyst come together and only a pigmented cicatrix is left. It is probable that a cicatrix may also be formed without the intervention of a cyst. It rarely happens that the inflammation around the extravasated blood is sufficient to cause extensive softening, and abscess seems never to follow. When the hemorrhage is situated in the periphery of the convolutions, the changes are essentially the same, only here the pia mater forms the outer covering of the focus.

The lungs of those dying in the early stages of cerebral hemorrhage are usually congested and œdematous, often containing extravasations of blood, particularly in the lower lobes.

The secondary degenerations which follow, after a certain time (six weeks to several months), hemorrhagic foci situated in certain regions of the brain, deserve a brief mention here. These secondary degenerations, first studied exhaustively by Türck, follow, not only hemorrhage, but softening and other destructive lesions cutting across the group of motor fibres which, beginning in the anterior and posterior central convolutions, pass through the corona radiata, the internal capsule, the pes pedunculi, the pons, the anterior pyramids of the medulla oblongata to the crossing of the pyramids, where the greater portion cross over and descend in the posterior part of the lateral column of the opposite side, a small portion continuing in the median region of the anterior column of the same side. Destructive lesions of the internal capsule especially, and also of the central convolutions, lower portion of the corona radiata and of the pes pedunculi, are followed by atrophy of the motor fibres below the seat of lesion. The secondary degeneration not only consists in atrophy of the nerve fibres, but is also accompanied by increase of the connective tissue between the fibres. It is at first characterized by the appearance of large numbers of granular cells. The atrophied bundles are visible on fresh specimens as gray bands following the course which has just been described as that of the motor, or, as they are called, pyramidal, fibres. Upon making a cross section of the spinal cord in a case of secondary descending degeneration, a triangular gray patch will be observed in the posterior part of the lateral column on the side opposite the lesion in the brain, and a narrow gray band, not always visible to the naked eye, in the anterior column near the median fissure on the side of the lesion. The contrast in color between the healthy and the degenerated parts, becomes more distinct upon specimens hardened in chromic acid. Lesions confined to the corpus striatum, or to other regions of the brain than those named, are not followed by these secondary degenerations. The degeneration does not affect the peripheral motor nerves.

Clinical History.—Of the several pathological conditions which occasion sudden coma, or apoplexy, cerebral hemorrhage is the most frequent in

its occurrence. Some writers limit the term apoplexy to sudden coma caused by extravasation of blood. In a large majority of cases the apoplectic attack is without premonition. It is, however, sometimes preceded by certain cerebral symptoms, such as a sense of weight or fulness, vertigo, tinnitus aurium, flushing of the face. These symptoms, however, are not sufficiently significant to warrant a prediction of impending apoplexy, especially if the patient have never had an attack. It is not uncommon for an attack to occur at a time when the person attacked feels unusally well.

In an apoplectic attack, the loss of consciousness may be so abrupt that the patient, if standing or walking, falls to the ground as if felled by a blow; but, in most instances, the coma is developed, not instantaneously, but during a period ranging from a few moments to half an hour, or even longer. It has happened to me to witness an attack which occurred when I was interrogating a patient who had just stated that he had felt on that day unusually well. I noticed suddenly a change in his appearance, as if he were mentally agitated; his expression changed, and he winked with his left eye only. He made an effort to rise, and fell from the chair. The right side was paralyzed. He did not become at once unconscious, but was irrational, attempting to speak, being unable to articulate, and frequently making efforts to get up from the sofa on which he had been placed. The respiration soon became heavy, with slight stertor and puffing of the lips. He vomited freely. He became profoundly comatose in about half an hour. He remained in the comatose state, and died within twenty-four hours.

The coma in different cases is more or less profound. When complete, the patient cannot be roused, in any degree, by efforts to awaken consciousness; but in many cases there is not this total loss of mental faculties. Volitional movements in some cases are entirely wanting; except that the movements of respiration continue, the body is as motionless as a cadaver. But in the majority of cases, the patient exerts the will, although all manifestations of intelligence may be wanting. In this way the existence of unilateral paralysis becomes apparent. The movements are limited to the upper and lower extremity of one side, and it is evident that hemiplegia is added to the apoplexy. The paralysis is generally at first complete; the paralyzed limbs are motionless as regards volition. The respirations are slow, the rhythm sometimes irregular, and the inspirations stertorous or snoring. If the coma be profound, the buccinator muscles and the lips are flaccid, and are puffed out in expiration. The pulse is usually diminished in frequency, full, and hard, the artery striking against the finger like a metal rod. Exceptionally the pulse is small and feeble. The face is frequently flushed, and, if respiration be much embarrassed, more or less livid; but it is sometimes pallid. The surface in most cases is warm, but sometimes is cool. At first the temperature of the body, as determined by the thermometer, is lowered from one to two and a half degrees; but after twenty-four hours there is usually a considerable increase of the body-heat. The pupil may be contracted or dilated, or, without either contraction or dilatation, immovable, and a disparity between the two pupils is not uncommon. The muscles are generally flaccid, but in some cases rigid. Convulsive movements are infrequent, but they sometimes occur. These are usually limited to one side, and to the side not paralyzed. To this rule there are exceptions. The limbs are sometimes rigid on the non-paralyzed side. Vomiting is usual at, or shortly after, the attack.

These are the prominent symptoms which characterize the apoplectic state. Its duration varies. It may last for a few moments only, the patient gradually emerging from it; or unconsciousness slowly disappears after the lapse of a few hours; or the state may continue for days and then pass off. As a rule,

if the coma persist without any improvement for eight or ten hours, and, more especially, if, during this period, the coma become more and more profound, improvement is not be expected, and the attack will prove fatal. On the other hand, the attack may prove fatal in a few moments, the mode of dying being by apnœa; or death takes place after several hours; or, again, the apoplectic state continues, and proves fatal after the lapse of several days, in the latter case the mode of dying being by asthenia and apnœa combined.

Patients emerging from the coma appear as if awakened from sleep, and rarely evince surprise, or ask what has happened to them. A noticeable appearance, lasting for several days, is a lateral deviation of the eyes and sometimes a rotation of the head in a direction opposite to the paralyzed side. With more or less increase of the body-heat, pain is referred to the head, sometimes there is delirium, and spasmodic movements or contractions of the paralyzed muscles may occur. These symptoms denote circumscribed inflammation of the brain surrounding the blood-clot. As a rule, they disappear after a few days.

The symptoms in apoplexy dependent on cerebral hemorrhage, are essentially the same as when coma from compression of the brain follows an injury to the head. The extravasation of blood produces a shock or stunning effect upon the brain, proportionate to the rapidity and the amount of the hemorrhage, and the pressure affects the circulation in the whole mass of brain. The pressure impedes the circulation in the substance of the brain, and the apoplectic phenomena are, measurably, due to the want of a proper supply of blood therein. The production of apoplexy depends on the suddenness of extravasation. If it take place gradually, apoplexy is not induced, and if it be not sufficient to destroy life within a brief period, the circulation may become restored sufficiently for the restoration of consciousness.

Hemiplegia is a constant effect of cerebral hemorrhage when the extravasation takes place in the situations in which it occurs in the great majority of cases. After the apoplectic state disappears, the hemiplegia remains. But in a small proportion of cases the hemiplegia occurs without loss of consciousness; this proportion being much smaller than in cases of cerebral embolism. The attack of hemiplegia without apoplexy is often sudden, but the paralysis is sometimes developed gradually. The difference, as regards this point, probably depends on whether the extravasation takes place quickly or slowly. The hemiplegia, however, may be at first complete, although unaccompanied by any impairment of consciousness. The following account of the hemiplegia dependent on cerebral hemorrhage is applicable to cases with or without an apoplectic attack.

The paralysis may embrace both motion and sensation, or it may be limited to motion. In the great majority of cases, if sensation be at first lost, it is shortly regained, the motor paralysis continuing. The paralysis may be complete or incomplete, and, if incomplete, it may be of every gradation, as regards degree. The paralysis may be complete in one, and incomplete in the other, extremity. If incomplete in both extremities, the degree of paralysis is generally greater in one than in the other extremity, and in the vast majority of cases the greater degree is in the upper extremity.

In cases of complete motor paralysis, movements may frequently be produced by pricking the integument, tickling the sole of the foot, or applying a heated iron to the surface. These movements take place without volition, and much to the surprise of the patient, if the mental faculties be intact. They are purely reflex. They are produced in the lower, but rarely in the upper, extremity. There is a notable difference in different cases as regards

the condition of the muscles of the paralyzed limbs. They are in some cases soft and flaccid, offering no resistance to the movement of the limbs in different directions; but in other cases they are hard and rigid, resembling, sometimes, muscles in tetanic contraction, and offering much resistance to movements of the limbs.

The paralysis generally involves the muscles of the face, the side affected, as a rule, corresponding to the paralyzed limbs. Exceptionally, the limbs on one side and the face on the opposite side are affected. This is called crossed paralysis (paralysie alterne). On the paralyzed side of the face, the expression is abolished, and when the facial muscles are excited to action, as in speaking or smiling, the mouth is drawn to the opposite side. Voluntary power over the orbicular muscle of the eye is rarely lost; the patient is generally able to close the eye on the affected side, but he cannot, as a rule, close the eye on the affected side while the other eye remains open. The power over the orbicular muscle, in a certain proportion of cases, is very obviously impaired. The patient usually winks on the affected side.

If the patient protrude the tongue, the extremity frequently points to the paralyzed side of the face. In the instances in which the tongue has been thought to point to the opposite side, there was probably an error of observation. The tongue may appear to be thus deflected, owing to the different situations of the upper lip and angle of the mouth on the paralyzed side. If the mouth on this side be drawn by the finger laterally so as to be in symmetry with the opposite side, the tongue, which had appeared to be deflected, may be seen to be protruded in a direct line or to point to the paralyzed side. The loss of certain teeth may cause the tongue to protrude in an abnormal direction. The deflection of the tongue to the paralyzed side may be explained by the action of the stylo-hyoid muscles and of the posterior belly of the digastric, which effect the protrusion of the tongue by elevating the base attached to the hyoid bone. When only the muscles of one side act, the base is elevated upon this side only, and the tip of the tongue is protruded to the opposite or paralyzed side. The velum pendulum palati, on the side of the paralyzed limbs, is sometimes involved in the paralysis. This is shown by an abnormal flaccidity of the velum on one side, which remains motionless when the muscles of the other side are seen to contract on depressing the tongue with a spatula. The uvula in these cases is deflected to the unaffected side; but this alone is not evidence of paralysis, as deflection of the uvula to one side is frequently observed in healthy persons. Occasionally there are ptosis, diverging strabismus, and dilatation of the pupil, sometimes on the same side, but in the great majority of cases on the side opposite to that of the paralyzed limbs. These symptoms show that the third cranial nerve is involved. The other nerves distributed to the eye are very rarely involved. The fifth nerve usually escapes. The eighth nerve is unaffected, save in certain cases of hemiplegia with coma about to terminate fatally. The nerves of special sense almost always escape. The muscles of respiration are not usually involved in the paralysis; the respiratory movements on the two sides are equal. The muscles of the neck and trunk in general remain unaffected. It is a law that muscles which usually act co-ordinately or consensually, such as the muscles of the eye and the respiratory muscles, escape in hemiplegia.

The clinical history of hemiplegia from cerebral hemorrhage, presents much diversity in different cases. It is impossible to judge at first of the prospect as regards the amount of improvement which will take place. More or less improvement takes place in the majority of cases. The improvement is usually gradual. The sensibility, if this have been lost, is first restored, and it may become abnormally increased on the affected side. The paralyzed

condition of the face may diminish or disappear in a short time. Improvement, as a rule, begins sooner and progresses more rapidly in the lower, than in the upper, extremity. Frequently the patient is able to walk without much difficulty while the upper extremity remains almost completely paralyzed. The manner of walking varies in different cases. If the rotating muscles of the thigh be relatively but little affected, the limb is thrown forward so as to describe the arc of a circle; but frequently the body is inclined to the opposite side and the limb is dragged after its fellow. Sometimes it is brought forward with a jerking movement. Tremulousness of the limb in walking is sometimes observed. The patient often experiences difficulty in walking from a depression of the toes, which renders him liable to trip.

Remote effects upon the paralyzed parts are deficiency of volume or wasting, these effects being proportionate to the degree of permanent paralysis. Atrophy of the paralyzed muscles, however, occurs later, and is much less in degree than in cases of paralysis from affections of nerves or of the spinal cord. The atrophy which takes place is due to deficient use of the muscles. Paralyses dependent on cerebral lesions are distinguished by the absence of a trophic influence on the affected muscles. The paralyzed muscles also, as a rule, respond to the excitation of electricity; that is, their electro-contractility is preserved. The temperature in hemiplegia becomes less on the paralyzed than on the opposite side; the pulse has less amplitude, and the veins sometimes show congestion. Remote effects relate to the contraction of certain muscles. Permanent contraction of the flexor muscles, especially of the forearm, is frequently observed. It is in some cases due to a contraction sufficient to overcome antagonizing muscles, and, in other cases, to a greater degree of paralysis of the extensor muscles, the flexors contracting simply because they are not antagonized. In the latter case, the flexed parts are restored with a little force; in the former, the contracted muscles offer resistance to efforts for extension. It is customary to distinguish a primary and a secondary contracture. The primary contracture appears a few days after the attack and is attributed to reactive inflammation. It generally disappears. The secondary contracture appears several months after the attack and is permanent. It is attributed by many to secondary degeneration of the spinal cord. It is a bad prognostic sign. Weir Mitchell has observed that the growth of the nails on the limbs of the affected side is arrested, and that a resumption of their growth is a forerunner of a return of power over the paralyzed muscles.

The mental condition in different cases of hemiplegia from cerebral hemorrhage, presents great variation. The faculties of the mind are generally, if not invariably, more or less impaired. Patients are moved to tears or laughter by trivial circumstances. A marked change in character is frequently observed. They are apt to become impatient and irritable. They lose self-reliance, and are easily influenced by those around them. This fact sometimes has important medico-legal bearings. The tendency is to progressive impairment of the mental faculties, ending at last in imbecility. Cases differ much as regards the rapidity of progress toward this result. The mental deterioration doubtless often depends, in no small measure, on the deficiency of the exercise of the mental faculties after paralysis has occurred.

Aphasia has been already considered as incident to cerebral embolism and thrombosis (*vide* page 657). It occurs in a certain proportion of the cases of hemiplegia caused by cerebral hemorrhage. There may be either total loss, or more or less impairment, of speech, and the aphasia may be either ataxic or amnesic. As regards the dependence of this symptom on the situation of the clot, the facts stated in connection with cerebral embolism and thrombosis are applicable. Recovery from the aphasia is less likely to take place when

dependent on the presence of a clot than when it depends on occlusion of an artery. Aphasia is to be distinguished from the difficulty in articulation arising from paralysis of the tongue and lips.

Causation.—The dependence of cerebral hemorrhage on conditions pertaining to the vessels within the brain, has been considered in connection with the anatomical characters; also its relation to disease of the heart. The local conditions are rarely present prior to the middle period of life; hence, apoplexy and hemiplegia, caused by cerebral hemorrhage, seldom occur in persons under 40 years of age. In the majority of cases, the age is over 60. As already stated, simple hypertrophy of the left ventricle of the heart may have a causative relation to cerebral hemorrhage by increasing arterial tension, assuming the existence of the lesions of the arteries of the brain which have been described. Hypertrophy associated with mitral stenosis or insufficiency, or with aortic lesions, has no causative agency. It is doubtful if venous congestion, incident to dilatation of the right side of the heart, or other causes, ever has much agency in determining the occurrence of hemorrhage. Active congestion from other causes than simple hypertrophy of the heart may have this effect. Persons have been attacked when under mental excitement as in public speaking, or in a fit of anger. In a case under my observation, an apoplectic attack took place during sexual intercourse. Straining at stool, violent muscular exercise, the throes of labor, and drunkenness have, in some cases, appeared to produce an attack. All these are exciting causes. In the larger proportion of cases, the hemorrhage takes place without any obvious exciting cause. In a considerable proportion of cases it occurs during sleep.

Formerly much importance was attributed to a so-called *apoplectic constitution*, consisting of shortness of the neck, with considerable *embonpoint*, and what is known as a full habit. An analysis of a considerable number of cases shows that no reliance is to be placed on these or any other external characters, as denoting a predisposition to cerebral hemorrhage.

Diagnosis.—Apoplexy from cerebral hemorrhage may be confounded with several morbid conditions which involve coma more or less complete. There is little risk of confounding apoplexy and syncope except for a short time, for syncope is of brief duration. It is characterized by death-like pallor, coldness, catching of the breath, and great feebleness or extinction of the pulse—symptoms which do not belong to the clinical history of cerebral hemorrhage. The coma which sometimes follows an epileptic paroxysm bears a resemblance to apoplexy. Knowledge of the fact that the comatose state has been preceded by violent convulsions, with difficult and noisy respiration from laryngeal spasm, will at once settle the character of the attack. Without this knowledge, the foam or blood on the lips and the wounded tongue show that epileptic convulsions have occurred. The doubt can only arise when the patient is a stranger found in an unconscious state. The physician generally is aware, or is able to ascertain, that the patient is subject to epileptic fits. A paroxysm of epilepsy may act as an exciting cause of apoplexy. Hysterical coma is another condition which may suggest the existence of apoplexy. This is to be discriminated by the characteristic phenomena of hysteria having preceded the comatose state; by convulsive movements in some cases, into which volition enters more or less; by the absence of stertor, the mobility of the iris, and the restoration of consciousness on resorting to the cold douche. The co-existence generally, in uræmic coma, of epileptiform convulsions, if dropsy do not co-exist, suggests the probable existence of renal disease, and the urine is found to contain either albumen or casts, or both.

Profound alcoholic intoxication may be mistaken for apoplectic coma. The following are the differential points: The odor of spirits or of wine in matters vomited and in the breath of the patient; absence of hemiplegia; the pulse usually feeble or soft, and increased in frequency—not diminished in frequency and hard, as it is usually in apoplexy; the pupils dilated. The patient can generally be roused sufficiently to exhibit some of the manifestations of drunkenness in the manner of speaking. Pouring cold water upon the head from a considerable height is a ready mode of partially arousing the patient. It is important to make this discrimination. To call apoplexy drunkenness would be an unfortunate error, and the reverse would be annoying to the practitioner.

In deep narcotism due to opium-poisoning, the patient, by vigorous efforts, can generally be roused for an instant. The respirations are notably diminished in frequency, but there is no stertor. The pupils are contracted. There is no hemiplegia.

Apoplectic coma caused by active hyperæmia (congestive apoplexy), and by meningeal hemorrhage, is excluded by the co-existence of hemiplegia. Hemiplegia may generally be ascertained during the apoplectic state. The patient moves the extremities of one side, while those of the other side remain motionless. He may manifest sensibility only when the integument of one side is pinched or pricked. The face may be drawn to one side, especially if manifestations of pain can be produced. The paralyzed members, when raised and allowed to drop, fall as if inanimate. On the other hand, meningeal hemorrhage and cerebral hyperæmia do not, as a rule, give rise to hemiplegia. The existence, or otherwise, of hemiplegia is, of course, ascertained after the patient emerges from the apoplectic state. The exclusion of embolism as the cause, is more difficult, and is not always practicable. For the differential points, the reader is referred to the diagnosis of embolic apoplexy (page 659). Hemiplegia without apoplexy may be caused by other cerebral affections than hemorrhage, embolism, and thrombosis, namely, by tumors and abscess of the brain. These affections give rise to cerebral symptoms prior to the occurrence of hemiplegia, and not infrequently to paralysis limited to one or more of the cranial nerves. If the hemiplegia be not preceded by symptoms pointing to tumor or abscess, and if functional hemiplegia be excluded, the differential diagnosis lies between hemorrhage, embolism, and thrombosis. If the hemiplegia have occurred suddenly, thrombosis may be excluded. The points involved in discriminating embolic hemiplegia have been stated. The occurrence of spinal hemiplegia in rare instances is to be recollected in the diagnosis.

The importance of a careful examination of the head for the evidence of injury in cases of coma when nothing is known of the history, may be here alluded to. A patient admitted into hospital, comatose, without this precaution, may be supposed to have apoplexy when subsequently, perhaps at the autopsy, fracture of the skull, with meningeal hemorrhage, may be found.

Prognosis.—An attack of apoplexy from cerebral hemorrhage may prove fatal within a very short period, sometimes within a few moments. When it proves suddenly fatal, the coma is at once profound and accompanied by great disturbance of respiration, with loss of deglutition, death taking place by apnœa. A fatal termination frequently takes place after the lapse of from twelve to twenty-four hours. The coma, in these cases, continues and becomes more profound, the respiration is more and more embarrassed, tracheal rales occur, deglutition is gradually lost, the urine is retained or flows away involuntarily, involuntary dejections occur, and the mode of dying is chiefly by apnœa. If no improvement take place within ten or twelve hours, the

coma remaining or becoming complete, disturbance of the respiration and deglutition being more marked, there is little room for the expectation of amendment, and the case will probably end fatally within a short period. In other cases, life is prolonged for several days, the patient not emerging from the apoplectic state, but more or less improvement as regards consciousness in some cases taking place. The mode of dying, in these cases, is by apnœa and asthenia combined.

On the other hand, the apoplectic attack may pass off in a few moments or a few hours, hemiplegia remaining. The paralysis at first is generally complete, and the sensibility on the affected side, as well as the power of motion, is often lost. The latter usually returns more or less speedily, and, more gradually, there is improvement as regards the power of motion. In most cases this improvement goes on progressively until a certain point is reached, and at this point, which varies much in different cases, the improvement stops. More or less of the paralysis remains permanently, as a rule. It is impossible to judge beforehand of the degree of improvement, as regards the paralysis, which may be expected. The completeness of the paralysis at first is probably due to the shock or contusion of the parts of the brain in proximity to the extravasated blood. After recovery from this, the amount of paralysis will depend on the extent of damage which the brain-substance has received.

The occurrence of cerebral hemorrhage involves liability to its recurrence. Of those who recover from a primary attack, a considerable proportion are again attacked after intervals of varying duration in different cases. As a rule, the hemorrhage in successive attacks is greater, rendering them more severe or dangerous. It is, however, to be borne in mind that recurrences do not always occur. Patients with hemiplegia resulting from a clot in the brain, sometimes live for twenty years, or longer, a second hemorrhage not taking place. In a recurrent attack, the hemorrhage may be on the same side or in the other hemisphere, more frequently the former. Instances have occurred in which a hemorrhage occurred simultaneously in both hemispheres, causing double hemiplegia. The mental condition after the occurrence of hemorrhage has been already referred to.

Treatment.—To bleed or not to bleed is the first question which arises in the treatment of an attack of apoplexy from cerebral hemorrhage. The answer is neither affirmative nor negative, as regards cases collectively, but it may be either, according to the symptoms in individual cases.

If the apoplectic attack be accompanied by symptoms denoting determination of blood to the head and increased arterial tension—a flushed face and strong pulsation of the carotids—venesection is indicated, especially if the patient be robust or full-blooded and the action of the heart be abnormally strong. Under these circumstances it is fair to infer that the giving way of the cerebral artery was due, in a measure, to the hyperæmia or to the arterial tension as an accessory or exciting cause. Bleeding will not undo the mischief which has already taken place, but it may prevent an increase or a renewal of the hemorrhage. In a certain proportion of cases the symptoms are essentially different. The face may be pallid, the carotids do not beat strongly, and the pulse may be small and weak. Venesection, under these circumstances, is contra-indicated. If the abstraction of blood be decided upon, it should be by venesection. It is important that the effect of the bleeding be produced promptly, and for this reason cups or leeches do not as well meet the indication. The amount of blood abstracted should be determined by the effect; a large bleeding is rarely indicated.

Generally it is advisable to administer an active cathartic. Croton oil,

from the facility with which it is administered, its efficiency and quickness of operation, is to be preferred to any other cathartic. Three or four drops may be given at once and repeated in three or four hours if free purgation be not produced. Its operation may be promoted by large stimulating enemas. An active cathartic should not be given if the pulse be notably small or feeble.

The patient should be placed in a cool, airy apartment; the head should be moderately raised; cold or evaporating lotions should be applied to the head, or, if the head be hot and flushed, the ice cap; stimulating pediluvia may be employed if the extremities be cool, and everything constricting the neck and chest should be removed. Attention is to be directed to the bladder, and, if required, the use of the catheter is not to be delayed.

These are the measures to be pursued until it is decided whether the patient is to emerge from the apoplectic state. If, after the lapse of several hours, the symptoms denote a hopeless condition, the physician must content himself with measures which appear to contribute to the comfort of the patient, for he is, in fact, unconscious of suffering. Purgatives and other perturbating remedies, under these circumstances, will only tend to hasten the fatal termination. If, on the other hand, the attack pass off, the measures indicated are simply quietude and an unstimulating diet until symptoms denote inflammation around the clot. These do not call for active treatment. Cool applications to the head, a sinapism to the neck, saline laxatives, and perfect quietude are sufficient. The vital powers should not be impaired by active treatment. The recovery is effected by the disintegration and absorption of the clot, and requires many weeks or months. The processes of disintegration and absorption are not promoted directly by any medicines. There is no ground for supposing that mercury, iodine, or other drugs have any direct influence over these processes. Blisters or other modes of counter-irritation are of no utility. Electricity applied to the brain is a doubtful measure, and not without hazard of injury. As regards the clot, nothing can be done except by nourishing the patient well, avoiding stimulants, preventing as far as possible everything which disturbs body or mind, and meeting any symptomatic indications. The case is now one of hemiplegia dependent on the presence of the clot and the damage which it has occasioned.

Active treatment directed to the paralyzed muscles is contraindicated while the symptoms denote inflammation or irritation at the situation of the hemorrhage. Gentle rubbing of the paralyzed limbs and passive movements, however, may be resorted to with but little delay. More energetic measures are indicated after two or three months. The objects of treatment are the promotion of the circulation and nutrition in the paralyzed muscles, together with the increase, as far as possible, of their functional capacity. The means are massage or kneading, rubbing with stimulating liniments, passive movements, electricity, and volitional exercise. Kneading, rubbing, and passive movements should be systematically and perseveringly employed. If they do not occasion fatigue, they cannot be too much employed. It is to be borne in mind that paralyzed muscles do not, of themselves, resume at once their normal functional capacity, even after the conditions causative of the paralysis are removed; and, having been for a considerable period paralyzed, they may remain so indefinitely, if appropriate measures be not made for their restoration.

Electricity is a potential agent in promoting the objects stated, especially when the paralyzed muscles respond not at all, or feebly, to the will. It promotes circulation, nutrition, and is a substitute for the will as regards the functional exercise of the muscles. With respect to the choice between the two currents, the methods to be adopted, etc., the reader is referred to treatises on the practical use of electricity or works devoted to nervous diseases.

This agent is apt to be inefficiently employed; it may be injudiciously used, and it is potential for harm as well as good. When practicable, therefore, its employment should be under the direction of an experienced physician who has given special attention to electro-therapeutics.

When the paralysis is not complete, the most efficient measure for securing as much improvement as is compatible with the amount of danger which the brain has received, is voluntary exercise of the paralyzed muscles. A patient who has been for some time a paralytic, is in a condition not unlike that of the infant who has not learned to use the muscles. Persistent exercise, in the one case, as in the other, is the means by which development and power are to be acquired. There is reason to believe that in not a few cases paralysis continues until it becomes fixed at a certain point, when persevering exercise, in conjunction with other measures, might have led to more or less improvement. It is often difficult to enforce this measure on account of its simplicity.

The liability to the recurrence of cerebral hemorrhage, renders it important to observe all possible precautions by way of prophylaxis. Placing the system in the best possible condition by means of a well-regulated diet and regimen, and avoiding exciting causes, will afford all the security which can be obtained. It is not probable that any protection is afforded by reducing the powers of the system, and injury may thereby be produced. It is injudicious to adopt a diet which is insufficient for the wants of the system, or to resort to repeated bloodlettings, cathartics, or other lowering measures. In striving to avoid excesses and imprudences of all kinds, care must be taken not to err in the opposite extreme. Mental occupation within certain limits is advisable.

A liability to hemorrhage, if an attack have never occurred, cannot be estimated with any degree of certainty. Apoplexy and paralysis are affections which many persons apprehend, and, if certain cerebral symptoms be experienced, especially vertigo, the apprehension is often the source of much unhappiness. The suggestion by the physician that there is danger of these affections, is an indiscretion which I have known to prove most calamitous. When apprehension is felt, the physician is warranted in giving assurances that vertigo and other cerebral symptoms are sufficiently common without being followed by apoplexy or paralysis, and that these affections are rarely preceded by obvious premonitions. Needless uneasiness may oftentimes be removed by these assurances.

The treatment of hemiplegia from cerebral hemorrhage is the same whether it occur with or without the occurrence of apoplexy.

In connection with the subject of cerebral hemorrhage, the question arises, can the particular situation of the extravasated blood be ascertained by means of the symptoms. This question arises in respect to the particular situation of softening from embolism and thrombosis; also with reference to the localization of circumscribed inflammation or abscess of the brain, cerebral tumors, and atrophy. In order to avoid repetitions, the facts at present known concerning the localization of cerebral diseases, are concisely stated under a separate heading.

Localization of Cerebral Diseases.

Within the last decade, important contributions have been made to our knowledge of the localization of diseases of the brain, partly as a result of anatomical and physiological discoveries, but chiefly in consequence of the careful analysis of clinical and pathological observations. The subject of the

topical diagnosis of cerebral diseases, however, is not yet sufficiently developed and positive to justify more than a summary of those conclusions which are most important and best established. A very comprehensive and critical treatment of the subject will be found in a recent work by Nothnagel,[1] upon which are based, in the main, the facts here presented.

Of the local cerebral diseases, in the widest sense, it is important to distinguish two varieties, namely: *first*, diseases, the effects of which are strictly limited to the seat of lesion, and *second*, those, the influence of which extends by pressure or otherwise to neighboring parts. The former may be called strictly localized lesions, in distinction from the latter which may be designated encroaching lesions. The requirements for a strictly localized lesion are that it should be stationary and not progressive, and that it should not act upon adjoining parts in any way by pressure, by disturbances of the circulation, or by inflammatory reaction. Inasmuch as the degree and extent of the action of encroaching lesions upon other parts cannot be estimated with accuracy, the topical diagnosis of such lesions cannot usually be made with exactness. It is the study of the strictly localized lesions, especially of those which are small and circumscribed in definite nerve centres or groups of fibres, which has yielded the most satisfactory results as regards the localization of cerebral diseases as well as of cerebral functions. These localized lesions offer the best prospect of an accurate topographical diagnosis. As such strictly localized lesions are reckoned by Nothnagel, hemorrhages and foci of softening, either embolic or thrombotic, after they have ceased to exert their influence upon surrounding parts, also stationary abscesses, which are then usually encapsulated, old foci of encephalitic softening, and in some instances tumors. A fresh hemorrhage, situated for instance in the lenticular nucleus and the anterior part of the internal capsule, may give rise, in addition to hemiplegia of the side opposite to the seat of lesion, to anæsthesia, aphasia, strabismus—symptoms which are referable, not, like the hemiplegia, to destruction of the parts named, but to an influence exerted upon other parts by pressure, inflammatory œdema, etc. After a time anæsthesia and the other secondary symptoms disappear and the hemiplegia remains. A hemorrhage, and the same is true of softening, is at the onset an encroaching lesion, and, at that time, the diagnosis of its exact localization cannot usually be made. After a time, stated by Nothnagel to be six or eight weeks at the maximum, it becomes a lesion, the effects of which are strictly localized to the parts involved in the extravasation, and now the diagnosis of its situation may be attempted with a fair prospect of success. For various reasons mistakes are particularly apt to be made in the topical diagnosis of tumors. Not only do tumors often grow in parts of the brain whose function is very imperfectly understood, but they give rise, in many cases, to diffuse rather than local symptoms, and by their slow development they frequently displace and irritate nerve elements without destroying them. Hughlings Jackson has graphically designated as *discharging lesions* those which irritate nerve elements, and as *destroying lesions* those which annul their functions. A discharging lesion in a motor tract produces spasm, a destroying lesion paralysis.

After these few remarks by way of introduction, the lesions situated in the different parts of the brain will be briefly considered with reference to their topical diagnosis.

[1] Nothnagel, Topische Diagnostik der Gehirnkrankheiten, Berlin, 1879. In addition the writings of Charcot may be profitably consulted, to whom we owe the most important discoveries relating to localization of cerebral diseases. Charcot, Lecons sur les Localisations dans les Maladies du Cerveau, Paris, 1876; also Charcot et Pitres in the Revue Mensuelle for 1878 and 1879; also Grasset, Des Localisations dans les Maladies Cérébrales, Paris, 1878.

1. *Cerebellum.*—Hemorrhage in the cerebellum occurs much less frequently than in the cerebrum. The proportion is variously estimated as from 1 to 12 to 1 to 35. Embolism of the cerebellar arteries is even rarer. Other local diseases of the cerebellum are abscesses, encephalitis, tumors, and atrophy.

Lesions, often extensive, of the cerebellum may remain entirely latent during life. This is believed by Nothnagel to be the case only when the lesion is localized in one cerebellar hemisphere, and when its influence does not extend beyond the seat of disease. In a remarkable case reported by Ebstein,[1] nearly the whole left hemisphere of the cerebellum was occupied by an osteoma which did not encroach upon surrounding parts. The patient died of a pulmonary affection, having manifested no symptom referable to the nervous system. Characteristic, although not pathognomonic, for lesions of the cerebellum, are disturbances of co-ordination designated as cerebellar ataxia, and dizziness. These symptoms are believed to be the result of an affection of the vermiform process or middle lobe of the cerebellum, either directly when it is the seat of disease, or indirectly by an encroaching lesion. The gait in cerebellar ataxia, which affects chiefly the lower extremities, resembles that of a drunken man, and not that of a patient affected with locomotor ataxia or posterior spinal sclerosis, although mixed forms of ataxia may appear in cerebellar disease. The symptoms in the great class of cerebellar lesions, such as fresh hemorrhages and tumors which act upon adjoining parts, particularly upon the pons and medulla oblongata, are various, but can sometimes be utilized in making the diagnosis. Of symptoms produced by cerebellar disease, but not directly referable to disturbances of function of the cerebellum itself, may be mentioned vomiting, amblyopia and amaurosis, headache, most frequently in the occipital region, hemiplegia, either corresponding to the side of the lesion or to the opposite side, less often epileptiform convulsions and spasm, sometimes irregular and infrequent action of the heart.

2. *Crura cerebelli.*—No characteristic symptoms of lesions of the superior or of the inferior peduncles of the cerebellum have as yet been discovered. On the other hand, lesions of the middle peduncles, the crura ad pontem, have repeatedly been observed to be attended by so-called forced or compelled movements. These peculiar movements appear, according to Nothnagel, when the lesion acts as an irritant, and does not completely sever the connection of the affected crus with the cerebellum. Recognized forms of these compelled movements are rotary movements of the body around its long axis; the assumption of a compelled position upon one side, to which the patient instantly returns when moved; the tendency to fall to one side accompanied with dizziness; and the deviation of the head and of the eyes, most characteristic when one eye is turned upwards and the other downwards. These movements may occur during coma, but are more characteristic of disease of the crura cerebelli when present in the waking state. With the exception of the rotary or "circus" movements and the peculiar deviation of the eyes, similar compelled movements have been observed in diseases located in other parts of the brain. The movements may be toward the side of lesion or toward the opposite side.

3. *Pons Varolii.*—Hemorrhages occur in the pons with about the same frequency as in the cerebellum. Emboli rarely lodge in the basilar artery because its size exceeds that of either vertebral artery, and because the latter is unfavorably placed for the reception of an embolus; on the other hand, thrombosis of the basilar artery in consequence of atheromatous degeneration, followed by softening in the pons, has been repeatedly observed. It is important to keep distinct from each other tumors of the pons and tumors exterior

[1] Ebstein, Virchow's Archiv, Bd. 49, p. 145.

to the pons situated at the base of the brain, although they may have many symptoms in common.

Fresh hemorrhages in the pons can be diagnosticated almost with certainty when alternating or crossed paralysis (that is, facial paralysis on the side of the lesion and paralysis of the extremities on the opposite side) can be made out. The diagnosis of pontine hemorrhage is also probable when, at the outset, general convulsions and contraction of the pupils set in, death ensuing within a few hours. But in many cases, perhaps the majority, of fresh hemorrhage in the pons, there are no characteristic symptoms present, and the topical diagnosis is impossible. Often the symptoms are those of an ordinary apoplexy, such as follows hemorrhage in the basal ganglia of the cerebrum. When it is considered that through the pons pass the bundles of motor and of sensory fibres which connect the cerebrum with the spinal cord, that here are situated the roots of origin of the trigeminus, abducens, facial, and acoustic nerves, and taking into view the close relation of the pons to the medulla oblongata, it cannot occasion surprise to find that the symptoms of stationary lesions, such as of old hemorrhages and foci of softening, and particularly of slowly progressive tumors, may present a variety and complexity somewhat diagnostic of affections of this part. It would be beyond the limits and scope of the present summary to enumerate the possible, or even many of the frequent, combinations of symptoms which may attend diseases of the pons. The most characteristic, and, when occurring suddenly, probably a pathognomonic, symptom is crossed paralysis (paralysie alterne). When this variety of paralysis is due to a stationary non-encroaching lesion, this lesion will almost always be found in the lower half of the pons. In crossed paralysis, while the extremities are always paralyzed upon the side opposite to the lesion, there is paralysis of the facial, abducens, or hypoglossus nerves upon the side of the lesion. The facial paralysis of crossed hemiplegia resembles peripheral facial palsy, that is, all of the muscles supplied by the facial nerve (including the occipito-frontalis, corrugator supercilii, and orbicularis palpebrarum) are involved, and the reaction to the faradic current is rapidly lost. Crossed hemianæsthesia may likewise occur, but less frequently than crossed hemiplegia.[1] It must not be inferred that the facial paralysis is necessarily on the side of the lesion in affections of the pons; it is sometimes on the same side as the body paralysis, in which case the hemiplegia is in no way characteristic of disease of the pons. Thickness of speech and difficulty of articulation, designated dysarthria and anarthria, in consequence of paresis of the hypoglossal nerve, are met with more frequently in disease of the pons than in localized lesions of any other part of the brain, except of the medulla oblongata. Some observations would seem to show that a conjugated deviation of the eyes, in consequence of paralysis of the external rectus on the side of the lesion and of the internal rectus on the opposite side, is characteristic of affections of the pons. In a remarkable case of tumor of the posterior portion of the pons, reported by Wernicke,[2] there existed paralysis only of cranial nerves, and not at all of the extremities. Of individual nerves, more weight is to be placed upon paralysis of the abducens than of any other in determining the existence of a lesion of the pons. When crossed paralysis fails, it is, however, from the grouping of the symptoms and by a careful analysis of individual symptoms that the diagnosis of a pons lesion is to be made, rather than by the presence of any one characteristic symptom. Bilateral paralysis is rare—in fact, much less frequently met with than was formerly assumed or

[1] The manifold variations under which crossed paralyses of motion and of sensation may appear have been tabulated by Sigerson, Dublin Med. Journ., Feb. 1878.

[2] Wernicke, Arch. f. Psych., Bd. vii. p. 513.

would seem probable on theoretical grounds, if we except those extensive hemorrhages which lead to death during the stage of apoplectic coma.

4. *Medulla oblongata.*—Hemorrhage into the medulla oblongata is not frequent. It leads almost invariably to death, either instantaneously or within a few hours, in consequence of injury to the centres of respiration and of circulation. Tumors occur in the medulla oblongata, but they are rare, and their symptomatology is very imperfectly understood. The most interesting and carefully studied of the local diseases of the medulla oblongata (chronic bulbar paralysis is not considered here), is softening which results from occlusion by an embolus or a thrombus of the vertebral artery[1] or some of its branches, or, in rare instances, from inflammation. Ischæmic softening has been found to be the lesion in the majority of cases of so-called apoplectiform or acute bulbar paralysis. This group of symptoms is referable to an affection of the nuclei of the hypoglossus, accessorius, and vagus, and is usually combined with disturbances of function in other parts of the medulla oblongata. The symptoms are paresis of the tongue with difficulty of articulation (dysarthria and anarthria), dysphagia, sometimes aphonia, and disturbances in the rhythm of respiration and of circulation. These symptoms are usually combined with paralysis of the extremities, either hemiplegic or paraplegic. The sudden onset of the symptoms, the fact that certain of the symptoms, for example, the paresis of the tongue, may fail, the combination with other disturbances, such as hemiplegia, and usually the lack of progressive character, distinguish the acute from the chronic bulbar paralysis. Lesions of the medulla are the only central lesions which can cause aphonia. Trismus has been observed to attend lesions both of the pons and of the medulla oblongata. Lesions of the medulla oblongata may be followed by paralysis of the extremities without the coincidence of characteristic symptoms. Diabetes mellitus and diabetes insipidus have been occasionally observed to attend lesions (tumors) affecting the floor of the 4th ventricle.

5. *Pedunculus cerebri.*—Lesions confined to one of the peduncles are rare. Nevertheless, localized hemorrhages, foci of softening, and tumors, particularly tuberculous tumors, have been observed in this situation. It is, as a rule, only when the affections are situated in the basal portion of the peduncle near the pons, that their effects are limited to this structure. The peduncles are composed essentially of centripetal and centrifugal nerve-fibres connecting the cerebrum with the spinal cord. The motor fibres are chiefly in the inner or median portion of the pes pedunculi and the sensory in the outer or lateral. The intimate relation between the inner border of the crus and the oculo-motor nerve is to be borne in mind. Characteristic of localized lesions of the crus cerebri, are paralysis of motion and often of sensation of the side of the body opposite to the lesion, and paralysis of the third or oculo-motor nerve on the same side as the lesion, in other words, a species of crossed paralysis. The symptoms of paralysis of the third nerve are ptosis, external strabismus, dilatation of the pupil, often combined with double vision and vertigo. It is only when the ocular paralysis and the crossed facial or body paralysis occur at the same time, that it is safe to diagnosticate an affection of the crus. Lesions of the crus may produce simply hemiplegia or hemianæsthesia without ocular paralysis, in which case the topical diagnosis would be impossible.

6. *Corpora quadrigemina.*—Of the anatomical facts bearing upon the functions of these bodies, the most important is the termination of a part of the

[1] A very interesting study of the vascular supply of the medulla oblongata and deductions as to the effects of occlusion of the different arterial branches have been made by Duret, Arch. de Physiologie, 1873, p. 97.

fibres of the optic tracts in the anterior pair of the nates, which, it may therefore be concluded, contain centres for vision. According to Meynert, this pair is also connected with the nuclei of the third and sixth nerves by fibres which convey reflex impulses. Some experiments would seem to show that the posterior pair or testes are connected in some way with coördination of movement. Destructive lesions of the anterior pair of the corpora quadrigemina lead to diminution of vision or to blindness. This amaurosis is characteristic of lesions of the corpora quadrigemina when it occurs acutely, is combined with immobility of the pupil, and with symptoms of a localized cerebral affection, and when the ophthalmoscopic investigation reveals nothing. Paralysis of the oculo-motorius, or of some of its branches (most characteristic when the paralysis is bilateral), has been observed in lesions of the corpora quadrigemina. Whether disturbances of coördination resembling cerebellar ataxia may attend affections of these bodies is not yet established, although it seems probable that such is the fact. On account of their infrequency, we are very imperfectly informed as to the symptomatology of localized lesions of the corpora quadrigemina.

7. *Thalamus opticus.*—Although the optic thalamus is very often involved in hemorrhage, softening, and other affections of the internal capsule and the basal ganglia, it is rare that a lesion is confined exclusively to this body. Contrary to former views, it is now believed that lesions localized in the optic thalamus, their influence not extending beyond the seat of disease, produce paralysis neither of motion nor of sensation. No symptoms which can render certain the topical diagnosis, are as yet known to attend localized lesions of the optic thalamus.

8. *Corpus striatum* (*nucleus caudatus*, *nucleus lenticularis*, *and internal capsule*).—The corpus striatum, according to the nomenclature of most English and French anatomists, includes two masses of gray substance, of which the internal is called caudate or intraventricular nucleus,[1] and the external is called the lenticular or extraventricular nucleus. The internal capsule, which is composed, in great part, of fibres derived from the pes pedunculi, is divisible into an anterior portion situated between the caudate and lenticular nucleus and a posterior portion between the optic thalamus and lenticular nucleus. The sensory fibres are situated most posteriorly in the internal capsule, while motor fibres occupy the anterior and a part of the posterior division. The region of the corpus striatum, for reasons which have been previously explained, is the most frequent seat of hemorrhage, and of softening whether embolic or thrombotic. Hence the symptoms which attend extensive lesions in this situation are usually taken as the basis for the description of the clinical history of cerebral hemorrhage or of cerebral embolism. The majority of lesions in this situation involve, at least, one nucleus and a part of the internal capsule, and are followed by the symptoms of an ordinary hemiplegia, less frequently of hemianæsthesia. We owe to Charcot the discrimination between lesions involving only the nuclei and those affecting the internal capsule, together with the knowledge of the fact that lesions in this region produce permanent hemiplegia only when they involve the anterior or a part of the posterior division of the internal capsule (its anterior two-thirds, according to Charcot), and permanent hemianæsthesia only when they destroy the posterior third or the adjoining part of the corona radiata.

Hemorrhages or softening, *confined* to the lenticular nucleus, or to the caudate nucleus, generally produce, at first, hemiplegia, but this hemiplegia

[1] The term corpus striatum is confined by most German, and some recent English writers, to the nucleus caudatus.

is subsequently either wholly, or in greatest part, recovered from. It is impossible to distinguish, by their symptoms, localized lesions of the lenticular nucleus from those of the caudate nucleus. The hemiplegia which follows lesions of the anterior two-thirds of the internal capsule, involves the extremities of the opposite side, and, as a rule, the lower branches of the opposite facial nerve. Sometimes the hypoglossal nerve, and often the muscles of the trunk of the opposite side, are paretic. Secondary contracture of the affected muscles in most cases ensues when life is sufficiently prolonged. Permanent hemianæsthesia, usually, although not necessarily, accompanied by hemiplegia, follows lesions of the posterior part of the internal capsule. A lesion may be situated in this part, however, without producing anæsthesia. This cerebral hemianæsthesia may affect only common sensation upon the opposite side, but, as a rule, it involves also the nerves of special sense of the opposite side, and so resembles hysterical hemianæsthesia. Besides diminution or loss of the power of hearing, of taste, of smell upon the opposite side, there is diminution in the acuteness, rarely complete loss, of vision in the opposite eye. This amblyopia accompanying cerebral hemianæsthesia, is characterized by concentric narrowing of the field of vision, especially for colors. The ophthalmoscopic examination is negative. Usually amblyopia in a less degree exists in the eye on the side of the lesion. Post-hemiplegic hemichorea and athetosis are often combined with hemianæsthesia following lesions of the posterior part of the internal capsule, but they may also attend lesions of the pons.

The topical diagnosis of tumors seated in the corpus striatum (for which they have no particular predilection) is attended with greater difficulties than that of stationary foci of hemorrhage or of softening. It is certain that tumors may be situated in the lenticular and in the caudate nucleus, where they may even press upon the internal capsule, without giving rise to hemiplegia. Still, there are recorded a number of cases of tumors situated in this region and involving the internal capsule, which were attended by slowly and progressively developed paralysis of the opposite side, often combined with symptoms of irritation and with the eye-symptoms common to intracranial tumors.

9. *Centrum ovale.*—We know of no symptoms diagnostic of lesions localized in the white substance or centrum ovale of the cerebral hemispheres. Lesions destroying those fibres of the corona radiata which connect the region to be presently described as the motor cortical zone, with the internal capsule and the basal ganglia, are followed by paralysis of the opposite side. This paralysis may affect only the face or one extremity, as in cortical lesions, or may present the picture of an ordinary hemiplegia. In either case there is nothing diagnostic of the situation of the affection in the centrum ovale. Non-encroaching lesions seated elsewhere in the centrum ovale (in the occipital, temporo-sphenoidal, and portions of the frontal and parietal lobes) may be, and often are, latent.[1]

10. *Cortex cerebri.*—Since the publication by Fritsch and Hitzig, in 1870, of their discovery of psycho-motor centres in the cortex of the brain, much

[1] One reason why our knowledge of the symptomatology of lesions of the centrum ovale is so imperfect, is the difficulty of describing the exact situation of a lesion in this part, so that most of the recorded cases are not available for the study of their topical diagnosis. To obviate this difficulty, a method has been devised by Pitres (Recherches sur les lésions du centre ovale des hémisphères cérébraux étudiées au point du vue des localisations cérébrales, Paris, 1877) for so dividing the cerebral hemispheres as to admit of an accurate description of the seat of a lesion. The method has been modified and somewhat simplified by Nothnagel (Topische Diagnostik, Berlin, 1879).

attention has been directed, and with fruitful result, to the clinical and pathological study of localized lesions of the cerebral cortex. In confirmation of physiological experiment, pathological observations have demonstrated that lesions of a certain region of the cerebral cortex are followed by motor disturbances. This region, designated as the *motor cortical zone* by Charcot, to whom we owe the most valuable observations in this department, embraces the ascending frontal and the ascending parietal convolutions (also called the anterior and the posterior central convolutions), and the paracentral lobule. The opinion, to which Charcot inclines, that the adjoining bases of the three frontal convolutions are possessed of motor functions, is not demonstrated. This motor zone receives nearly the whole of its blood from the middle cerebral artery, a fact which explains the greater frequency of embolic softening in this district than in other parts of the cortex. Hemorrhages are not frequent in the cerebral cortex. The symptoms following small circumscribed lesions in the motor zone, justify the recognition of isolated centres for motion in this part. Destroying lesions confined to the lower third of the ascending frontal and the ascending parietal convolutions, are followed chiefly or exclusively by paralysis of the lower (oral and nasal) branches of the opposite facial nerve, and sometimes of the hypoglossal nerve; lesions confined to the middle third of the ascending frontal convolution, by paralysis of the opposite arm; lesions of the paracentral lobule, of the upper third of the ascending frontal and two-thirds of the ascending parietal convolutions, by paralysis of the two opposite extremities. A separate centre for the lower extremity has not been determined, as it is rarely alone affected. Very extensive lesions of the motor cortical zone, following embolism or thrombosis of the middle cerebral artery, are attended by the symptoms of an ordinary hemiplegia, and then cannot usually be distinguished from lesions of the internal capsule. Characteristic, although not pathognomonic, of cortical affections are the localized paralyses of the opposite side which attend partial circumscribed lesions of the motor zone. The terms monoplegia and dissociated hemiplegia have been applied to these localized paralyses. The following forms of cortical monoplegia have been observed: 1, isolated ptosis; 2, facial paralysis, sometimes combined with paralysis of the hypoglossus; 3, paralysis of one extremity, usually of the upper; 4, paralysis of both extremities; 5, paralysis of the arm and face; 6, paralysis of certain groups of muscles in one extremity.

In progressive lesions, a paralysis at first confined to one arm or to the face, may advance to total hemiplegia, the cortical localization then being characterized by the development of the hemiplegia out of several monoplegias. Secondary contracture appears in the paralyzed muscles with great frequency, but is not distinctive of cortical affections. It is attributed by Charcot to the secondary degeneration of the spinal cord, which follows motor cortical lesions as well as lesions in certain parts of the internal capsule, pes pedunculi, and pons. There are certain symptoms of motor irritation which have great diagnostic value for the localization of cortical affections. These are spasm of isolated groups of muscles, and general epileptic convulsions with certain characteristic peculiarities. The isolated spasms, designated by Charcot as partial epilepsy of cortical origin, may be confined to the muscles of one side of the face, or to certain muscles of the extremities of the side opposite to the lesion. These spasms, which may be tonic, or clonic, or both combined, may accompany the onset of a lesion and be followed at a greater or less interval by permanent paralysis of the affected muscles, or spasm may attack muscles which have been paralyzed for a variable length of time. In the first case a lesion in the motor cortical zone is probable, in the latter it is almost certain. The partial epilepsies are not usually attended with loss of

consciousness. The general epileptic convulsions of cortical origin resemble in most respects the ordinary form of epilepsy, but present a certain regularity in the onset of the paroxysms not observed in other forms. In cortical epilepsy the spasm begins regularly in the same muscles of one side of the face or of one extremity. In the most characteristic forms, the consciousness is not lost at the onset of the paroxysm, the patient observes the progress of the convulsions from one group of muscles to another, and finally loses consciousness when the convulsions become general. This variety of general epileptic convulsions is always preceded by paralysis, usually in the form of dissociated hemiplegia, and may then be regarded, in the light of our present knowledge, as a pathognomonic symptom of a cortical lesion. Anæsthesia and other marked disturbances of general sensation do not accompany uncomplicated lesions of the motor zone.

Reference has already been made to aphasia as a symptom of lesions of certain parts of the cerebral cortex. Both ataxic and amnesic aphasia are referable, in the great majority of cases, to an affection of the left third frontal (Broca's) convolution in its posterior part (pars opercularis of Schwalbe), or of the left island of Reil. When aphasia follows a lesion of these parts of the right hemisphere, it will usually be found that the centre for the co-ordination of speech has been developed on the right side instead of on the left, in consequence of some defect, congenital or acquired, of the speech-centres of the left hemisphere; or the patient may be left-handed. The disturbance of speech called by Wernicke *sensory aphasia*, and by Kussmaul *word-deafness* and *word-blindness*, has been observed to follow lesion of the first temporosphenoidal convolution of the left side. Sensory aphasia is characterized by an inability to understand spoken or written words, and is usually combined with some degree of ataxic aphasia. On superficial observation the patients are thought to be deaf. It is decidedly the exception to the rule for aphasia to follow lesions of parts other than those named.

In striking contrast with our knowledge of the symptoms of diseases of the motor cortical zone, and of the speech-centres, is our ignorance concerning the effects of lesions situated in other parts of the cerebral cortex. These lesions in other parts may remain entirely latent. Disturbances of vision in the form of hemiopia, and of peculiar manifestations of amblyopia, have been observed to attend lesions of the occipital convolutions. Hemiopia occurring suddenly as the only symptom, the ophthalmoscopic examination being negative, speaks for an affection of the occipital lobe. Some physiological observations render probable the existence of centres for hearing in the temporosphenoidal lobe, but other auditory disturbances than the peculiar form called word-deafness are not known to result from cortical lesions.

Meningeal Hemorrhage.

One of the most important varieties of meningeal hemorrhage is hæmatoma of the dura mater, due to pachymeningitis hæmorrhagica, under which head it will be considered.

The extravasated blood in meningeal hemorrhage may be seated as follows: 1, between the dura mater and the skull, 2, in the so-called arachnoid cavity, and 3, in the subarachnoid space or the meshes of the pia mater. When seated between the dura and the skull, the most frequent cause is traumatism. In the majority of cases of traumatic meningeal hemorrhage, but not in all, there is fracture of the skull. The hemorrhage resulting from traumatism may be in any of the three situations mentioned, as well as in the substance of the brain; it may be most abundant at the base or on the convexity. The study of this important variety of meningeal hemorrhage belongs to the domain of

surgery. Another cause of meningeal hemorrhage is the rupture of aneurisms of the arteries of the base, most frequently of the basilar or the middle cerebral. The lodgment of calcareous emboli in the cerebral arteries may lead to aneurism and hemorrhage. The occasional occurrence of meningeal hemorrhage in consequence of thrombosis of the sinuses, and in consequence of an intracerebral hemorrhage bursting through the peripheral brain-substance, has already been mentioned. In a case given in the last edition of this work, the hemorrhage was attributable to wounding of a vessel by needle-shaped spiculæ of bone in the dura mater, without any injury of the skull. Hemorrhages, usually in the form of ecchymoses, are often observed in the meninges in infectious diseases. Meningeal hemorrhage has been known to follow a paroxysm in whooping-cough, to occur during Bright's disease, and rarely under other conditions when no especial cause could be assigned.

Large meningeal hemorrhages are always fatal. Small ones can be absorbed, leaving only a pigmented spot behind.

Meningeal hemorrhage, if the extravasation be considerable and rapid, gives rise to sudden coma or apoplexy, which is very rarely accompanied by hemiplegia. It may destroy life speedily. In a case reported in the last edition of this work, death took place two hours after the apoplectic seizure. Cases which prove fatal in the condition of coma, cannot be differentiated, by means of the symptomatology, from cases of embolism or thrombosis of the basilar artery. The diagnosis is rendered probable by a traumatic causation. From congestive apoplexy it is distinguished by the absence of the symptoms which denote determination of blood to the head.

In the case referred to, in which the hemorrhage was caused by spiculæ of bone, epileptiform convulsions occurred. Symptoms of irritation, such as convulsions, are more frequent in meningeal than in cerebral hemorrhage. If the hemorrhage be not large, it may give rise to no symptoms pointing to a grave affection. In the case of Daniel Webster, the autopsy showed that slight meningeal hemorrhage had occurred some time prior to his fatal illness. The hemorrhage was connected with an injury which had not incapacitated him from subsequent intellectual efforts, in which were manifested no diminution of his mental powers.

It follows from what has just been stated in regard to the symptomatology and diagnosis, that the treatment is to be governed by symptomatic indications.

Insolation—Sunstroke.

The terms *insolation* and *sunstroke* are applied to an affection, or, perhaps more properly, different affections, occasioned, not exclusively by exposure to the sun's rays, as the terms signify, but by the action of great heat combined generally with other causative circumstances. The terms denote a sudden attack, in extremely hot weather, after exposure to the direct rays of the sun or to great heat, the attack characterized by loss of consciousness, followed frequently by stertor and convulsions, death taking place, in a considerable proportion of cases, within the space of a few minutes or a few hours. Now, in a certain proportion of these cases the morbid condition, as judged by the symptoms, is expressed by the term exhaustion ; the vital powers are prostrated, the forces carrying on the circulation give way, and death takes place by syncope. In another class of cases the affection apparently is similar to congestive apoplexy. In still another class of cases the symptoms show a combination of apoplexy and exhaustion. The cases last referred to probably constitute the majority of the cases of so-called insolation, or sunstroke. In other cases the condition is referable to the abnormally high temperature

of the blood. Other names than insolation and sunstroke have been proposed, namely, solar asphyxia, heat-apoplexy, thermal or heat fever, etc.

Morbid appearances found after death are as follows: The blood is dark and imperfectly coagulated, often fluid, and collected in the large veins. The heart is usually firmly contracted, the left ventricle empty, the right containing a small amount of dark, fluid, or partly clotted blood. Ecchymoses, especially subserous hemorrhages, are, as a rule, present. Extravasations of blood into the sympathetic ganglia of the neck, about the vagus in the neck, and in the connective tissue are sometimes met with. The lungs are deeply congested, sometimes contain hemorrhages, and are often œdematous. A moderate amount of serous transudation into the pleural and pericardial sacs and in the ventricles of the brain, is not uncommon. The spleen is sometimes swollen and soft. Parenchymatous degeneration or cloudy swelling of the kidney, liver, spleen, and heart-muscle, has been described as a lesion of insolation. The larger veins of the pia and dura mater are usually distended; injection of the smaller vessels of the membranes and of the cerebrum is occasionally, but not constantly, found. The consistence of the brain and cord is sometimes notably soft.

The premonitions are slight or wanting. Dr. Swift, in a report based on the observation of 60 cases in the New York Hospital, gives the following account of the attack: "The patients are suddenly seized, while in the performance of their labors, with pain in the head, and a sense of fulness and oppression in the epigastrium, occasionally nausea and vomiting, general feeling of weakness, especially of the lower extremities, vertigo, dimness of vision, and insensibility. Surrounding objects appear of uniform color. In a great majority of cases, this was, so far as could be ascertained, blue or purple. In one instance everything appeared red; in another green; and in another white."[1] It has been stated that irritability of the bladder precedes the attack. Pain in the head, although generally present, does not always precede unconsciousness. It was wanting in the case of a medical friend of the author who had a severe attack, accompanied by violent convulsions.

The attack may consist of only a transient insensibility. But in severe cases the patient passes quickly into a comatose state. It is in this state that cases come under medical observation. The pupils are in some cases dilated, in some contracted, and sometimes the size is normal but the respondency to light is lessened or lost. There may be contraction and dilatation at different periods in the same case. The pulse may be at first infrequent and full, but it often becomes frequent and feeble toward the fatal termination. I have observed death to take place purely by apnœa, the pulse having considerable force until after the cessation of breathing. The respirations in some cases are stertorous, in other cases suspirious and accompanied by moaning; they are increased in frequency in the majority of cases. In most cases the temperature of the body is notably raised. The maximum rise, in cases at Bellevue Hospital, in July, 1868, was 109½° Fahrenheit, and the lowest observed was 99½°. In a case observed in July, 1872, the temperature in the axilla was 110½°. If the thermometer indicate a rise to 107° or upward, a fatal termination is to be expected. In the case, however, just referred to, in which the temperature was 110½°, the patient recovered. Convulsions and rigidity of the muscles are of frequent occurrence. Vomiting frequently occurs, and, towards the close of life, there are involuntary evacuations from the bowels. The prognosis is rendered extremely unfavorable by the occur-

[1] Observations on Exhaustion from the Effects of Heat. By H. S. Swift, Resident Physician of the New York Hospital, N. Y. Journal of Medicine, July, 1854.

rence of vomiting and purging. The duration varies from a few minutes to several hours. The average duration in the fatal cases observed by Swift was four hours. If the patient emerge from the comatose state, convalescence is usually speedy. Of 20 cases observed by Pepper, in 3 insanity followed. This sequel did not occur in over 100 cases received at the New York Hospital. Temporary delirium succeeding the attack is occasionally observed. Paralysis is very rarely a concomitant or a sequel. I have, however, known of the occurrence of incomplete transient hemiplegia in one case after recovery from the attack, and in one case before recovery. In the latter case it lasted but a few hours.

As already stated, the pathological character of the affection in all cases of insolation, is not uniform. Cases of sudden death from exhaustion or syncope produced by heat and over-exertion, are reckoned among cases in which the morbid condition is quite different. In a certain proportion of cases, the appearances after death, the character of the attack, and all the symptoms denote congestive apoplexy. In other cases, which probably constitute the majority, the pathological character is mixed; an apoplectic condition is combined with exhaustion. It is highly important to take cognizance of these differences as regards pathological character, in treating the different cases which are grouped together under the name insolation. The notably increased temperature of the body probably stands in a causative relation to certain of the phenomena. Regarded from this point of view, insolation is, in a marked degree, a febrile disease. That toxical changes in the blood play an important part in the pathology is probable. Vallin, of Paris, has reported a series of observations upon dogs and rabbits destroyed by insolation. These animals, placed upon the back, fastened in this position, and exposed to the direct rays of the sun, in the months of July and August, in the climate of Paris, presented phenomena analogous to insolation in man, and died generally after an exposure of from half an hour to two hours. Examinations after death showed hyperæmia of the brain and lungs, the cavities of the heart, especially the left ventricular cavity, being empty. These experiments have been repeated by Prof. Horatio C. Wood, Jr. Vallin is led to attribute these conditions and death to coagulation of the liquid of the muscular tissue (suc musculaire, myosin) of the heart and diaphragm. He does not, however, apply this explanation to all the cases embraced under the name insolation. In some cases he attributes the death to toxical changes in the blood, the action of the heart being arrested by a morbid agency acting through the pneumogastric nerve. In the latter cases the heart-cavities may be filled with blood.[1] The observations of Prof. Horatio C. Wood, Jr., lead him to the conclusion that the contraction of the ventricles of the heart found after death, especially when autopsies are made within a short time after death, is, in most cases, of post-mortem, not of ante-mortem, occurrence.[2]

Excessive heat is the chief agency in causing insolation, but other circumstances co-operate in the causation. Muscular exertion, unduly great or prolonged, is a powerful auxiliary cause. Persons are generally attacked when engaged in labor, but there are exceptions to this rule. Dr. Swift states that, of the cases which he observed, a large proportion were attacked shortly after dinner. The concentration of innervation upon the processes of digestion, the distension of the stomach with food and liquids, the latter being frequently taken in large quantity, and perhaps, in some cases, the disengagement of gas from chemical changes arising from indigestion, will account for the fact stated by Swift. In most cases, persons are attacked

[1] *Vide* Archives de Médecine, Feb. 1870.
[2] On Thermic Fever or Sunstroke, Boylston Prize Essay, 1872.

when exposed to the direct rays of the sun, but there are exceptions to this rule. Swift states that eleven patients were attacked on the same morning in the laundry of one of the largest hotels in this city, and several cases were brought to the hospital from a sugar refinery. Soldiers are not infrequently attacked after they have retired to their tents.

Cases are more frequent by far in tropical than in cold or temperate latitudes, and, in the latter, they occur during the heated term of summer when the weather is unusually and continuously hot. Atmospheric influences other than heat have been supposed to be involved in the causation, namely, an unusual accumulation of electricity, dryness and rarefaction of the air; but facts showing the importance of these influences are wanting. The number of cases in the same place in different years varies greatly. According to Dickson more persons died in Charleston, S. C., from sunstroke in 1824 than in any twelve other years; and in the city of New York in the summer of 1853 there were 260 cases reported, whereas in no previous year had there been more than 36 cases.[1]

The attack generally takes place at periods when the heat of the day is at its maximum. Of the 60 cases observed by Swift, 40 occurred between 11 A. M. and 4 P. M., 17 between 4 and 9 P. M., and 3 between 8 and 11 A. M.

The diagnosis is, in general, made without difficulty. The circumstances connected with the attack, and the symptomatic phenomena, are sufficiently distinctive. Apoplexy with extravasation of blood is to be distinguished by the existence of hemiplegia. Persons deeply intoxicated are not infrequently brought into hospitals as cases of sunstroke, but the characters of alcoholic coma suffice for its discrimination.

Exclusive of mild cases in which there is transient stupor or insensibility, the danger in cases of isolation is always very great. The death-rate ranges from forty to fifty per cent. If, with deep coma, the breathing be stertorous, sighing, or moaning, the prognosis is extremely unfavorable. Great frequency and feebleness of the pulse, relaxation of the sphincters, tracheal râles, and complete immobility, are forerunners of a fatal termination. Convulsions are extremely unfavorable; yet I have known recovery to take place after violent convulsions. In accordance with the difference in pathological character in different cases, the mode of dying is sometimes by rapid asthenia or syncope. This mode of dying is exemplified among the cases in which the death is notably sudden, taking place in the space of a few moments after the attack. The mode of dying in other cases is by apnœa, but, in the larger proportion of cases, by apnœa and asthenia combined.

The treatment is to be adapted to the pathological character of the affection, as represented by the symptoms, in individual cases. Pursuing this course, therapeutical measures, so far from being the same, will be diametrically opposite in different cases. In cases of nervous exhaustion, the danger being of death by rapid asthenia or syncope, complete rest is of the first importance. The removal of patients to their homes or to hospitals, in this condition, may contribute in no small measure to a fatal result. Stimulants are to be administered by the mouth very cautiously in order to avoid exciting vomiting. They may be given with less risk by the rectum. Alcoholic stimulants may be administered by enema or by hypodermic injection. The carbonate of ammonia is an effective heart-stimulant, administered hypodermically. The oil of turpentine given per enema is recommended. All restraints of dress are to be removed. The patient should be kept in as cool and pure an atmosphere as possible. If the surface be hot and dry, sponging the body with spirit and water should be employed. These should

[1] Elements of Medicine, 2d edition, 1859.

constitute measures employed during the attack. Cathartics, emetics, bloodletting, and all depressing agencies are pernicious. The symptoms representing the condition which calls for the treatment just stated are, frequency and feebleness of the pulse, weakness of the heart-sounds, with absence of stertor and the embarrassment of breathing indicative of cerebral compression.

In well-marked apoplectic cases I believe bloodletting to be the measure especially indicated. The treatment called for is the same as in congestive apoplexy. The life of the patient may depend on the prompt employment of bloodletting. The bowels should be freely opened with croton oil. Cold should be applied to the head, either by means of the ice-cap or the douche. The head should be elevated, and everything constricting the chest or neck removed. Revulsive applications should be made to the extremities. The symptoms representing the condition calling for these measures are, fulness of the pulse, slowness of the respiration, with perhaps stertor, heat of the surface, congestion of the face, and throbbing of the carotids and of the temporal arteries.

The question as to the propriety of bloodletting in cases of insolation has given rise to much discussion and difference of opinion. The doctrine which I would inculcate is, that to abstract blood is vastly important in some, and destructive in other, cases. Never to employ bloodletting, and to employ it in all cases, would be alike injudicious. It is, of course, for the judgment of the practitioner to discriminate between the cases in which bloodletting is called for, and the cases in which it will do harm. I have noted several cases which apparently exemplify the importance of bloodletting; and I am led to introduce a brief notice of two cases in view of the fact that, at the present time, some, and perhaps most, practitioners consider this measure improper in all cases of insolation.

On the 9th of August, 1862, eight cases of coma from sunstroke were admitted into Bellevue Hospital. Of these cases, 7 proved fatal. Bloodletting was employed in only one case, and in this case the patient recovered. This was the last case admitted on that day, and bloodletting was resorted to in that case by the house-physician, Dr. Martin, mainly in view of the fatal termination of the seven cases under other measures of treatment. In the case which recovered, the coma was as profound, and the symptoms, in general, apparently as unfavorable as in the other cases. The breathing was stertorous, the pupils contracted, the skin hot and dry, and the pulse frequent, but full. Sixteen ounces of blood were taken from the arm, and the temples freely leeched. The patient came under my observation on the following day. He was then quite comfortable, and complained only of debility. He recovered his strength rapidly, and was discharged in a few days, well.

On the 13th of August, 1864, a patient was admitted into one of my wards at Bellevue Hospital, who had been found in a state of insensibility in the street. The pulse was 100 per minute, and had considerable force; the breathing was stertorous, the skin hot, the pupils neither contracted nor dilated, but not responding to light. Eighteen ounces of blood were taken from the arm, and the cold douche applied to the head. These measures constituted the treatment. He recovered his consciousness in an hour and a half after the bleeding. On the following day he reported himself to be quite comfortable, and was discharged in the afternoon of that day.[1]

In the majority of the cases of insolation, symptoms denoting congestive apoplexy are combined, in variable proportions, with those denoting exhaustion. The importance of bloodletting in these cases is to be measured by the

[1] The case of Dr. S. Weir Mitchell affords a striking example of the benefit of bloodletting. *Vide* Prize Essay by Prof. H. C. Wood, Jr.

predominance of the apoplectic phenomena, and it is contra-indicated if predominance of exhaustion be denoted by the frequency or the feebleness of the pulse. The success of the treatment will depend on the judgment of the practitioner in deciding whether bloodletting be called for, or otherwise, and, if indicated, in determining the amount of blood to be taken. Discrimination is also important in prescribing the croton oil. If the danger be from exhaustion, an active purgative is not indicated. Cold to the head is important in proportion as the symptoms of cerebral congestion predominate. On the other hand, in the cases in which the circulation is notably feeble, stimulant remedies by the mouth or rectum are called for. In all cases quietude is important. In the cases in which convulsions occur, these may be excited by movements of the body. The most efficient measure having reference to convulsions is the inhalation of chloroform.

The bromide of potassium has been employed freely in the treatment of cases at Bellevue Hospital, but without apparent benefit. For several years past considerable reliance, in that hospital, has been placed on sponging the body freely with cold water, in addition to ice to the head. In 1872, the application of cold water to the surface was carried out, under my direction, more efficiently than heretofore, in the following manner: The patient was enveloped in a sheet wet with cold water, and placed on blankets covered with India-rubber cloth. With a sprinkling pot the cold water was applied over the whole body at intervals of a few moments. This was kept up for a period ranging from half an hour to several hours, the continuance being determined by the effect on the temperature, pulse and other symptoms. The temperature of the body was reduced more or less, and sometimes several degrees. The measure was repeated as often as the temperature again rose. If the pulse were feeble, stimulants were given, more or less freely, during the application of the water. The good effect of this plan of treatment has been marked in some cases. A patient admitted at 2 P. M., unconscious, pupils contracted, pulse 150, breathing stertorous, the axillary temperature $110\frac{1}{2}°$, and the body cyanosed, was at once placed in the wet sheet and sprinkled. At half past 4 P. M., the temperature in the axilla had fallen to $104\frac{3}{4}°$, the frequency of the pulse and the cyanosis persisting. He was taken out of the sheet, dry cups were applied to the chest, and at 5 o'clock the wet sheet was again applied and continued until 15 minutes after 7 P. M. The temperature then was $101\frac{1}{8}°$, and the pulse 120. At 9.45 P. M. the temperature fell to $100\frac{3}{4}°$. At midnight he became conscious. Progressive improvement followed, ending in recovery. The only additional measures employed up to the restoration of consciousness, were an enema containing castor oil, with a few drops of croton oil, and the hypodermic injection of ten minims of the tincture of digitalis, the latter having reference to the frequency and feebleness of the action of the heart.

The employment of cold water in the manner just described, was resorted to only in the cases in which there was a considerable increase of axillary temperature—104° and upward. When the temperature was less, sponging the body with cold water was employed. Observations since 1872 have confirmed the efficacy of this plan of treatment in cases characterized by notable increase of temperature. The same method of applying cold has also been found efficient in other affections in which antipyretic treatment is indicated.

Dry cups to the chest relieve symptoms dependent on pulmonary congestion, namely, embarrassed breathing and cyanosis; applied over the spine, they are useful in relieving convulsions and muscular rigidity.

In some cases treated at Bellevue Hospital, the Calibar bean has been given in doses of one grain by hypodermic injection, and repeated two or

three times after intervals of from half an hour to an hour. This remedy was tried with reference to muscular rigidity and convulsive movements. It seemed to be useful, but the observations are too few to warrant any positive conclusions. Given in the dose just stated, it produced no marked effect upon the pupils.[1]

Hyperæmia and Anæmia of the Spinal Cord and its Meninges.

In respect of hyperæmia and anæmia, the spinal cord and its meninges must be considered collectively. These pathological conditions are, probably, never limited to either the meninges or the cord separately. In treating of spinal paralysis occurring without symptoms which denote either inflammation or lesions of structure, that is, functional paralysis, the question will arise as to the existence of one or the other of these conditions. Exclusive of this connection, it is difficult, with our present knowledge, to form an opinion as to the importance of these conditions. It is customary to refer certain symptoms to hyperæmia or anæmia of the cord on conjectural grounds. Our present knowledge does not lead us far beyond conjecture as regards the frequency of these affections, their causation, and their symptomatic phenomena. Both conditions are probably not infrequent; they are attributable to various causes, and it is not irrational to refer to these certain symptoms.

Hyperæmia, here, as in other situations, may be active or passive (*vide* page 26). Active hyperæmia may be caused by prolonged muscular exercise and sexual abuse or excess. Collateral fluxion is supposed to be causative in certain cases of suppression of the menses, the cessation of bleeding from hemorrhoids, and prolonged exposure to cold. Passive hyperæmia is incident to stasis of the systemic venous or the portal system.

The symptoms referred to active hyperæmia are, lumbar pain and pain in the limbs, increased cutaneous sensibility, formications, muscular twitchings, and paresis of the muscles. On the other hand, numbness of the extremities and anæsthesia point to passive hyperæmia.

The diagnosis requires absence of fever and of the local symptoms which denote either spinal meningitis or myelitis. The existence of causative agencies is to be taken into account.

The condition is without danger, except that it may be a factor in the causation of hemorrhage.

Cupping over the spine, using dry or hot cups according to the local symptoms and the general condition of the patient, stimulating foot-baths, the application of cold to the back, and cathartics, are the therapeutical measures indicated. Ergot and belladonna are considered to be useful by causing contraction of the arteries. The patient should lie, as much as possible, on the side or face, and not on the back.

Spinal anæmia (ischæmia) is an effect of aortic obstruction above the point at which the lumbar arteries are given off. Temporary paraplegia is produced by compression of the aorta above that point. Spasm of the intra-spinal arteries has been supposed to be a cause of anæmia of the cord, continuing long enough to lead to impairment of nutrition, and giving rise to paraplegia. Doubtless the cord, like the brain and other organs, suffers, functionally, whenever the blood is notably impoverished. This local anæmic condition, which is incident to general anæmia, probably, has a causative connection with neuralgia affecting the intercostal and other nerves, together with other

[1] For a report of 55 cases treated in Bellevue Hospital, July and August, 1872, prepared, at my request, by Dr. Katzenbach, at that time house-physician, *vide* New York Journal of Medicine, Jan. 1873.

effects pertaining to the so-called "spinal irritation." Exclusive of a conjectured causative connection with functional or so-called reflex paralysis, and of the participation of the spinal cord in the effects of anæmia as a blood-lesion, the diagnosis of spinal anæmia is not warrantable in the present state of knowledge.

Spinal Hemorrhage.

Hemorrhage within the spinal canal, not dependent on injuries of the spine, is an exceedingly rare event. Its infrequency is in striking contrast to intra-cranial hemorrhage. Spinal hemorrhage may be meningeal (hæmatorrhachis), or it may be in the substance of the cord (hæmato-myelus). In cases of meningeal hemorrhage the extravasation may be between the periosteum and the dura mater, between the latter and the pia mater (in the so-called arachnoid cavity), or in the meshes of the pia mater. In cases of intra-cranial meningeal hemorrhage the blood may flow down into the spinal canal. Hemorrhage into the substance of the cord may be either punctate or in the form of a larger focus. It is most frequently situated in the gray matter, in which it may extend for some distance in a longitudinal direction. The same changes occur in the extravasated blood as in cerebral hemorrhage. Both medullary and meningeal hemorrhage may result from traumatism, such as fractures and dislocations of the vertebræ, blows upon the back, etc. Most of the cases formerly considered as spontaneous spinal apoplexies, are those of hemorrhage resulting from a previous myelitis, the vessels sharing in the softening process (hæmato-myelitis); but there are very rare cases which can hardly be interpreted otherwise than as primary hemorrhage into the cord. Aneurisms of the aorta, after having occasioned erosion of the vertebræ, sometimes burst into the spinal canal.

Meningeal spinal hemorrhage causes paralysis, as a rule, so suddenly that the patient falls. Consciousness is retained. Severe pain may be felt at or near the site of the hemorrhage. Pain is also felt in the extremities; the cutaneous sensibility becomes impaired, and abnormal sensations are referred to the skin. The paralysis and anæsthesia are rarely complete. If the hemorrhage take place in the lumbar region, the lower limbs are paralyzed, together with the bladder and rectum. If the hemorrhage be in the upper part of the spinal canal, in addition to paralysis of the lower extremities, paralysis and anæsthesia are present in the upper limbs, and these symptoms may be accompanied by difficulty in breathing and swallowing. Cramps, spasms, and tremor often occur in the upper or lower extremities according to the situation at which the hemorrhage takes place.

The symptoms are due to excitation of the spinal cord and the paralyzing effect of pressure. According to the rapidity of the hemorrhage, they occur abruptly or are developed more or less slowly. Their degree is determined by the amount and situation of the hemorrhage.

If the symptoms follow an injury of the spinal column, violent muscular exertions, or severe convulsive movements, these etiological relations render the diagnosis probable. The diagnosis is substantiated by the exclusion of spinal meningitis and myelitis. These diseases are excluded by the sudden or rapid development of the symptoms, and by the absence of fever. Secondary fever may be developed after the lapse of several days.

If the hemorrhage take place at the upper part of the spinal canal, and the amount be considerable, it may cause speedy death by disturbance of respiration (apnœa). A large extravasation in a lower situation, giving rise to complete paraplegia with cystitis and bed-sores, is often fatal after a duration more or less protracted. Recovery may be expected, except in cases of injury of the spinal cord by fracture or dislocation of vertebræ. The removal

of the coagulated blood by absorption is, however, a slow process, and recovery takes place after a considerable period, the improvement being very gradual.

The treatment at the time of the attack has for its object the arrest of the hemorrhage. Absolute rest and cold applied to the spine are the most important of the measures for this object. Bloodletting is to be employed under the conditions which render this measure advisable in other connections.

The subsequent treatment has reference to the relief of symptoms, the absorption of the extravasated blood, the prevention of muscular atrophy, and the restoration of functional capability of the paralyzed muscles. Iodine, mercury, and electricity are recommended as sorbefacients, but their usefulness in this way is open to skepticism. The treatment to be addressed to the muscles is the same as in cases of paralysis caused by other spinal affections.

Hemorrhage into the substance of the cord is preceded by symptoms denoting myelitis in a certain proportion of cases. These are wanting if the hemorrhage be occasioned by injury of the spine or violent muscular exertions; in either case, there is sudden paralysis without loss of consciousness, accompanied by a localized pain in the spine. The paralysis will involve only the lower, or, in addition, the upper extremities and muscles of the trunk, according to the seat of the extravasation. The pain is temporary; and the symptoms of excitation—spasms, cramps, etc.—which characterize meningeal hemorrhage are wanting. Sensory paralysis below the seat of the hemorrhage is more or less marked and often complete, as regards the sensibility to both tact and pain. The paralysis involves the bladder and rectum. Atrophy of the paralyzed muscles takes place rapidly. Bed-sores are produced speedily. Death may take place quickly by apnœa if the hemorrhage be into the upper portion of the cord. If the seat of the hemorrhage be in the lumbar region, the termination is generally fatal, after a shorter or longer duration, in consequence of sloughing of soft parts exposed to pressure, cystitis, etc.

A small clot in a lateral half of the upper portion of the cord, gives rise to spinal hemiplegia characterized by motor paralysis on the side of the lesion and sensory paralysis on the opposite side. This is very rare.

The points involved in the differentiation from meningeal hemorrhage have been mentioned. Myelitis with softening gives rise to paralysis more or less slowly. This affection is excluded if the paralysis occur suddenly without having been preceded by any symptoms of spinal disease. In hæmato-myelitis, however, the paralysis may develop with great rapidity. But myelitis generally precedes the hemorrhage if the latter be not produced traumatically. Sudden paralysis preceded by symptoms of myelitis renders probable hemorrhage. The affection generally known as the acute spinal paralysis of children (sometimes occurring in adults) is excluded by the absence of fever. The following case is typical of hemorrhage within the cord, although the autopsical proof could not be obtained:—

A girl, aged 14 years, after running a distance of a quarter of a mile and back, complained, on reaching home, of pain in one lower limb, and shortly fell upon the floor bereft of all power over the lower extremities. The pain in the limb recurred, at short intervals, for two hours after the paralytic stroke. She came under my observation a fortnight afterward. There was complete loss of sensation and motion in the lower limbs. Ulceration of the nates had taken place. There was sometimes retention of urine; oftener the urine, as well as the feces, was passed involuntarily. Trismus and opisthotonos preceded the fatal termination.

The objects of the treatment are essentially the same as in cases of meningeal spinal hemorrhage.

CHAPTER II.

INFLAMMATORY DISEASES OF THE MENINGES OF THE BRAIN AND OF THE SPINAL CORD. HYDROCEPHALUS. HYDRORRHACHIS.

Pachymeningitis and Hematoma of the Dura Mater—Acute Cerebral Meningitis—Anatomical Characters — Clinical History — Causation — Diagnosis — Prognosis — Treatment. Chronic Meningitis. Tuberculous Meningitis. Spinal Meningitis. Cerebro-spinal Meningitis—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Hydrocephalus. Hydrorrhachis.

THE dura mater, which is composed of fibrous tissue, is the most external of the three membranes enveloping the brain, and consists of an external lamella which serves as the internal periosteum of the cranium, and an internal lamella, the inner surface of which is lined with flat, polygonal endothelial cells. Most recent writers, discarding a parietal layer of the arachnoid, confine the name arachnoid membrane to that which was formerly described as its visceral layer. This is a thin connective-tissue membrane, whose outer surface is smooth and lined with endothelium. The pia mater is the vascular membrane of the brain, the convolutions of which it follows, and to which it closely adheres. It is connected with the arachnoid by interlacing bundles of connective tissue. The space between the arachnoid and the pia mater is known as the subarachnoid space, or, sometimes, as the meshes of the pia mater. In it is contained the cerebro-spinal fluid. The space between the dura mater and the arachnoid, which is usually found empty at autopsies, is called the subdural space, or according to the former nomenclature, the arachnoid cavity. The subdural and the subarachnoid cavities are to be regarded as lymph spaces.

By the term meningitis is usually understood inflammation of the pia mater or of the pia mater and arachnoid, it being impracticable to distinguish the inflammation of one of these membranes from that of the other. In fact, both are generally involved in meningitis. Sometimes inflammation of the pia mater is denominated *leptomeningitis*, in distinction from *pachymeningitis* which is inflammation of the dura mater.

Pachymeningitis. Hematoma of the Dura Mater.

Pachymeningitis is divided into *pachymeningitis externa* and *pachymeningitis interna.*

External pachymeningitis may be either acute or chronic. Acute pachymeningitis is always suppurative, and is chiefly of surgical interest. It follows injury and disease of the cranial bones. Purulent inflammation of the dura mater follows suppurative disease of the internal or middle ear (otitis interna or media), with consecutive caries of the petrous portion of the temporal bone. It is often combined with purulent thrombosis of the lateral or other sinuses of the dura mater. The purulent inflammation may extend to the pia mater and to the substance of the brain.

By chronic external pachymeningitis is understood the fibrous thickening

of the dura mater, often combined with the formation of osteophytes, which occurs especially in old age. The thickened dura becomes adherent to the skull. This form of pachymeningitis is analogous to the ossifying periostitis of the long bones.

Internal hemorrhagic pachymeningitis is of greater medical interest. This affection is characterized by the formation of an adventitious membrane upon the inner surface of the dura mater, usually in circumscribed patches over the convexity, either limited to one side or extending to both sides of the median line. At first, the membrane is extremely thin, delicate, and hardly to be recognized, except as a reddish, yellow, or brown stain. If one of these membranes be stripped off, and examined under the microscope, it is found to consist chiefly of capillary bloodvessels, with wide lumina, often provided with varicosities and with thin embryonic walls. Between the vessels are a few round, stellate, or fusiform cells, but there is very little fibrillated connective tissue. A considerable number of extravasated red blood-corpuscles, which have escaped either by diapedesis or by rupture of the vessel-walls, and a greater or less quantity of blood-pigment in the form of reddish-brown granules or of ruby-red crystals of hæmatoidin, will also be found in these membranes. The newly formed bloodvessels are in organic connection with the pre-existing vessels of the dura mater. In more advanced cases the new membrane is thicker and composed of several layers, of which the deeper, that is, those nearest the dura-mater, resemble ordinary fibrillated connective tissue. In some cases extensive extravasations of blood occur from rupture of some of the thin-walled, newly formed vessels, and then give rise to the symptoms of meningeal apoplexy. To the bloody tumors thus formed upon the inner surface of the dura mater, the name hematoma is applied. Hemorrhages confined to the subdural space and not of traumatic origin, in the great majority of cases, are due to hemorrhagic pachymeningitis. This fact was first established by Virchow. Some recent writers (Sperling, Huguenin) advocate the view which prevailed before Virchow's investigations, namely, that the first stage in hemorrhagic pachymeningitis is an extravasation of blood upon the inner surface of the dura mater, and that the development of bloodvessels and of new connective tissue is secondary. Huguenin, however, admits that when the extravasation is abundant (hematoma, properly speaking), an organized membrane has, in the majority of cases, already been formed. The more usually accepted view is that in all cases the development of new bloodvessels upon the inner surface of the dura mater antedates the extravasation.

The symptomatic phenomena embrace those proceeding from the inflammation of the dura mater, and those caused by pressure upon the surface of the brain. Cerebral symptoms denoting inflammation are, cephalalgia, which is often notably intense, vertigo, tinnitus aurium, vigilance, and disturbed sleep. Other symptoms are sensitiveness to light, and, in a marked degree, contraction of the pupils. Fever may co-exist, which, in its degree, continuance, and exacerbations is variable in different cases. The foregoing symptoms, in certain cases, are measurably referable to antecedent cerebral disease. The hemorrhage may occur either rapidly or slowly. If rapid and considerable, it causes an apoplectic attack which may prove speedily fatal, but in most cases the patient recovers from the attack. Successive apoplectic attacks occur after variable intervals. If the hemorrhage take place slowly, it causes somnolence which continues for twenty-four or thirty hours, the mind, on awaking, being more or less disordered. Successive periods of somnolence mark repeated, slow and small or moderate hemorrhages. Contraction of the pupils persists, and if the hematoma be limited to one hemisphere, the contraction is greater on that side. At a later period, however, the contraction of the pupils may cease. The pulse is slow and irregular, becoming frequent

in fatal cases before death. Paralysis of the facial muscles and hemiplegia may occur, limited to one side, or occurring first on one, and afterwards on the other, side. Muscular contractions, twitchings, and convulsive movements, more or less marked, are apt to occur on one side or on both sides. The convulsions sometimes have an epileptiform character. Strabismus and ptosis are wanting. The mental faculties are impaired in a greater or less degree.

The clinical history has so much diversity in respect of the events which occur, the order of their occurrence, their duration, etc., that there are few reliable typical characteristics. In respect of its course, the affection may be either acute or chronic. Moreover, its phenomena are often obscured by those of various other diseases with which it is often associated.

If death take place in a primary attack of apoplectic coma, a diagnostic guess may be based on the antecedent cerebral symptoms and certain etiological points. In the cases which have not this termination, the diagnostic points pertaining to the clinical history are, the occurrence of successive attacks of coma or sopor, lasting for many hours or even for days, and the occurrence of more or less of the symptoms which have been mentioned, these occurring in a way not significant of other cerebral affections. Diseases to be excluded are, simple cerebral meningitis, tuberculous meningitis, cerebral hemorrhage, embolism or thrombosis, and general cerebral paralysis. There are cases in which the affection gives rise to no morbid symptoms. The morbid condition is sometimes found after death when it had not been suspected during life.

Points relating to the etiology are of much account in the diagnosis. The affection rarely occurs under 40 years of age, and, of the different decades, the largest proportion of cases is between 70 and 80. It is rare in early life, but the percentage of cases is larger prior to 10 than from 10 to 20 years of age.[1] Men much oftener than women are affected. Persons in health are never affected, if traumatism be excepted. Of the various affections in connection with which it occurs, intercurrently, those caused by alcoholism take precedence. Clinical observations show that it is especially a disease to which drunkards are liable, whatever may be the pathological explanation. It is incident to different chronic lesions of the brain, more particularly to those belonging to general cerebral paralysis. In a considerable proportion of cases it is referable to injuries from blows, falls, etc.

The course of the disease varies from a day to a year or longer. Huguenin gives the following as the results of an analysis of all the carefully recorded cases which he could collect: The duration was from 1 day to 5 days in 34 per cent.;[2] from 5 to 30 days in 40 per cent.; from 1 month to 6 months in 18 per cent.; from 6 months to 1 year in 4 per cent.; and over a year in 4 per cent.

The prognosis will depend on the extent of the hemorrhage, if hæmatoma form. Patients have recovered who had presented symptoms supposed to be a sufficient warrant for the diagnosis. Co-existing diseases often contribute to a fatal ending.

Recovery is not to be expected as a result of any special medication. Impending danger from hemorrhage may be perhaps averted, and death postponed by therapeutical measures. Measures are to be addressed to the inflammatory condition in proportion to the symptoms. Generally, cold

[1] *Vide* Huguenin, in Ziemssen's Cyc., Am. ed., vol. xii.

[2] Of course, in these short durations the affection is not a hemorrhagic pachymeningitis, which is necessarily chronic, but it must be a simple hemorrhage on the inner surface of the dura mater, it being Huguenin's view that this hemorrhage precedes the pachymeningitis.

applications to the head, counter-irritation to the neck, cathartics, and stimulating foot-baths suffice. Venesection or topical bleeding is rarely indicated. With reference to the limitation of hemorrhage, the bromides and ergot may be prescribed. It is doubtful if the iodide of potassium or mercury promote absorption of the effused blood. Palliative remedies, according to symptomatic indications, and the analeptica, form part of the treatment.

Simple Acute Cerebral Meningitis.

The name acute cerebral meningitis denotes, conventionally, inflammation of the meninges of the brain exclusive of the dura mater, that is, inflammation affecting the arachnoid membrane and the pia mater. It is also called *leptomeningitis*. To distinguish it from tuberculous meningitis, it is designated simple meningitis. It is sometimes called acute meningitis of the convexity in consequence of its localization by preference upon this part.

Anatomical Characters.—Inflammation here, as in other situations, is preceded and usually accompanied by hyperæmia. The inflammatory products are serum, fibrin, and pus in varying amount, and in varying proportions. These products of inflammation are chiefly in the meshes of the pia mater (subarachnoid space), but in severe cases they may be present, to a certain extent, also, upon the outer surface of the arachnoid (subdural space), and may extend into the cortical substance of the brain. The inflammation in the highest degree affects usually the pia mater covering the convexity of the hemispheres, but it may extend to the meninges of the base, or, in rare instances, be chiefly confined to the base. When death takes place soon after the onset of the inflammation, the exudation is found to consist chiefly of serum rendered somewhat turbid by the admixture of pus-cells. When death occurs later, as in the majority of cases, the exudation is more distinctly purulent. The greenish-yellow, opaque streaks of pus are found in greatest abundance in the furrows between the convolutions, especially in the track of the large veins of the pia mater. In severe cases of some duration, a greenish-yellow layer may be found spread nearly uniformly over the convex surface of the brain. The exudation, examined microscopically, is found to consist of serum, pus-cells, fibrillated fibrin sometimes in great, sometimes in small, amount, together with a certain number of red blood-corpuscles. The amount of serum varies considerably in different cases. The pus-cells are doubtless emigrated white blood-corpuscles. Pus-cells are also found, sometimes in sufficient number to be visible to the naked eye, in the cortex cerebri, especially around the bloodvessels. Punctate hemorrhages are sometimes found both in the pia mater and in the cortex. The ventricles may contain a moderate quantity of serum, usually turbid, or they may be empty. It is to be borne in mind in examinations after death, that increase in the amount of serum in the subarachnoid space is not evidence of inflammation. Nor is mere opacity of the arachnoid to be mistaken for acute inflammation.

Clinical History.—Simple acute meningitis may be abrupt or gradual in its development. The premonitions are the symptoms of determination of blood or active hyperæmia. There is a marked variation in symptoms at different periods of the disease, namely, prior to, and after, a certain amount of sero-fibrinous exudation. The course is divisible into two stages, the division being based on the amount of the products of inflammation. The first stage extends to the period when, owing to the pressure of these products, a notable change in the symptoms occurs.

The first stage is called the stage of excitement. It is characterized by

pain, usually intense, referred to the entire head, sometimes greatest in the anterior, and sometimes in the posterior, portion. The pain is the same as in active cerebral hyperæmia. Delirium frequently occurs; and the delirium, in this stage, is generally active or maniacal, or in some cases hilarious. Owing to the prominence of the delirium, patients are sometimes carried to insane institutions, the affection being mistaken for acute functional mania. Convulsions may occur, especially in young subjects. The senses of sight and hearing are abnormally acute; light and sounds occasion distress, and increase the cerebral excitement. There is photophobia and the eyebrows are corrugated to shield the eyes from the light. The pupils are generally contracted. The face is flushed. The carotids and temporal arteries pulsate strongly. The head is hot. Vomiting generally occurs in this stage, and is often prominent as a symptom. The bowels are constipated. The abdominal walls are depressed. Fever is more or less intense; the pulse is accelerated, strong, and full, and the axillary temperature may rise to, or above, 104° F. Exacerbations occur in which the delirium and cephalalgia are notably increased. The duration of this stage is short. It may continue but a few hours, and rarely beyond two or three days.

The second stage is called the stage of oppression. The symptoms distinctive of this stage are those denoting pressure by the inflammatory products. The pain in the head is diminished. The morbid sensitiveness to light and sounds is lessened. The pupils may be dilated or contracted, and their responsiveness to light is diminished or lost. Strabismus and loss of vision may occur. Drowsiness succeeds the state of mental excitation. The pulse is diminished in frequency, and often irregular in force and rhythm. It becomes rapid and thready a few hours before death. The respirations are disordered in rhythm or suspirious. The Cheyne-Stokes respiration may be present. Paralysis may occur, limited to the face, or extending over one side of the body. If the progress of the disease be unfavorable, coma is at length induced, and continues until death. Convulsions may occur in the second, as well as the first, stage.

Causation.—Several cases have been reported in which simple meningitis had evidently been developed before birth.[1] It is rarely developed during the first year of life. The number of cases, according to Gintrac's analysis, is about the same between 1 year and 10 years and between 10 and 20 years. After 20 years of age the cases are extremely few of general and basilar meningitis. The vast majority of the cases of these two forms occur prior to the latter period of life. It is otherwise with meningitis of the convexity. This form is more frequent after than before 20 years of age; the proportion of cases is not small after 74 years, and cases occur at a still older age. Males much oftener than females are affected.

The disease is sometimes referable to injuries of the head. In not a few instances it proceeds from caries of the petrous portion of the temporal bone, in connection with diseases of the middle ear (oto-meningitis). In these instances circumscribed inflammation of the dura mater (pachymeningitis) precedes the affection of the pia mater. Inflammation of the latter, however, sometimes occurs in connection with internal otitis without disease of the bones and without pachymeningitis. Caries of the cranium in any situation may give rise to meningitis, either circumscribed or more or less diffused. An excessive abuse of alcohol is an occasional cause. The disease, in rare instances, is developed in connection with various infectious diseases—the

[1] *Vide* Cours théorique et clinique de Pathologie interne, etc., par Gintrac, tome 8, Paris, 1869.

eruptive fevers, pneumonia, ulcerative endocarditis, Bright's disease, pyæmia, typhus fever, etc. The nature of the etiological relations in these various connections, our present knowledge does not enable us to explain.

It is sometimes developed in connection with acute articular rheumatism. Occurring in this connection, it is considered as a variety of the disease under the names *rheumatic meningitis* and *cerebral rheumatism*. The clinical history differs from that of acute meningitis not associated with rheumatism, in either the absence, or a much less prominence, of cephalalgia and vomiting. In some cases the progress from the first to the second stage is notably rapid. Hallucinations are sometimes a marked feature, with tremulousness of the tongue and lips, as in cases of delirium tremens. Tremor of the muscles of the limbs is sometimes a marked feature. This, with pains in the back, points to inflammation of the spinal, as well as of the cerebral, meninges; and autopsical examinations have shown, in some cases, the existence of cerebro-spinal meningitis. Taking into account these distinguishing characters, it is perhaps fair to conclude that the causation involves the essential pathological condition in rheumatism; in other words, that the meningitis or cerebro-spinal meningitis is due to the same internal cause which determines the arthritic manifestations. The occurrence, however, of inflammation of the meninges of the brain, or of the brain and cord, in connection with acute articular rheumatism, is so rare that, judging from this point of view, the concurrence might be considered purely accidental.[1] Severe cerebral symptoms may occur in rheumatism without the development of meningitis.

Diagnosis.—Acute meningitis may be confounded with active cerebral congestion. If the inflammation go off by delitescence, that is, without passing into the second stage, it may be impossible to say, after recovery, whether the affection was meningitis or merely active congestion. In other words, more or less of the symptoms belonging to the second stage are required for a positive diagnosis.

Cases of typhoid fever characterized by early and active delirium, have, heretofore, not infrequently been considered as cases of acute meningitis. The points involved in this differential diagnosis are: The access or slow development of the fever; the distinctive events belonging to it, namely, diarrhœa, meteorism or tympanites, tenderness in the iliac regions, together with absence of morbid acuteness of the senses, and continuance of the delirium without the supervention of the phenomena of the second stage of meningitis; also, the eruption and the characteristic rise of temperature during the first week. These points show the disease to be a fever, and not meningitis. In the somnolence of typhoid or typhus fever, patients manifest no opposition to being aroused, to having their position changed, etc.; whereas, in meningitis, the patient is irritable when disturbed, and resists, perhaps with violence, efforts to give nourishment, to examine the pupils by raising the eyelids, or to interrupt in any way the somnolent condition.

Functional mania may be considered as denoting acute meningitis. The discrimination is to be based on the absence of morbid acuteness of the senses, together with the absence of febrile movement, and the continuance of the mania without the symptoms of compression.

Other symptoms are more likely to be considered acute meningitis than this to be mistaken for other affections. In view of its infrequency, the ability of a practitioner to discriminate it from other affections may be suspected, if he believes that he has met with many cases of it.

[1] For an analysis of 31 cases, *vide* Pathologie Interne, par E. Gintrac, tome 8.

Prognosis.—Acute meningitis involves much danger. It may destroy life quickly. Cases have terminated fatally in 36 hours. As a rule, the duration, in fatal cases, does not extend beyond eight or nine days. The symptoms denoting an unfavorable prognosis are, profound coma, notable disorder of respiration, difficulty of deglutition, general immobility and anæsthesia, feebleness of the pulse, etc. Strabismus, hemiplegia, and convulsions may be present in cases which recover. A few well-marked cases, presenting these symptoms, which have fallen under my observation, have ended in recovery. Data are wanting for determining the ratio of cases which end fatally, but it is certain that the fatal cases greatly preponderate. The association with acute articular rheumatism is considered as rendering the prognosis extremely unfavorable. I have, however, observed a well-marked case, the symptoms denoting spinal, as well as cerebral, meningitis, which ended in recovery.

In cases which prove rapidly fatal, death may be due chiefly to apnœa, but, if life be prolonged for several days, the mode of dying is by apnœa and asthenia combined.

Treatment.—The treatment must have reference to the stage of the disease. The objects in the first stage are to lessen the determination of blood to the head, and to limit the amount of exudation. If the heart act with abnormal power, bloodletting, in this stage, is to be employed. As a measure of depletion and revulsion, active purgation is indicated. Cold is to be applied to the head, either by means of the ice-cap, the cold douche, or constant ablution. Cutting the hair close to the head renders these applications more efficient.

Bloodletting, in this disease, is indicated in view of the promptness of its operation and the short duration, frequently, of the first stage. Bearing in mind that the chief source of danger is from the products of inflammation, it is important that the measures employed with the hope of limiting these, should be resorted to more promptly and vigorously than in other acute inflammations, for example pneumonitis, in which the products of inflammation generally do not give rise to serious results. Moreover, there is not the same necessity for guarding the vital forces as in other acute inflammations; for in this disease there is danger that life may be quickly destroyed by apnœa, caused by the pressure of effused serum and lymph, whereas in most other acute inflammations the danger is that they will destroy life by asthenia. It is not, however, to be forgotten that asthenia enters into the mode of dying in cases of meningitis which do not pursue a rapid career, and, hence, bloodletting and other measures of depletion may be pushed too far. These measures are only indicated in the first stage of the disease. Perfect quietness, exclusion of light, elevation of the head, and the avoidance of everything which may tend to increase cerebral excitement by acting on the senses or the mind, form an important part of the treatment of this stage. The bromides are useful for tranquillizing intense cerebral excitation. If these do not prove effective, codeia may be given, or a salt of morphia, the latter administered hypodermically. Sinapisms to the neck and stimulating pediluvia have a certain measure of utility. Vomiting calls for palliative measures. The diet, in this stage, should be restricted to the blandest articles taken cold.

In the second stage, the great object of treatment is to promote absorption of the morbid products, serum and lymph. Depletion is no longer admissible. Mercurialization is advised for this object, and, although the efficiency of mercury as a sorbefacient has doubtless been much exaggerated, we are not warranted in saying that it has no effect in that way. If it exert ever so

small an effect, it is indicated in a disease like this, in which the object to be effected is of so much importance. Iodine is another remedy supposed to be useful as a sorbefacient. I have witnessed, as I think, the good effect of the iodide of potassium in several cases. Patients under my observation have recovered under the use of this remedy, mercury not having been employed. It may be given in doses of from five to ten grains four or five times daily, increasing the doses, if improvement do not take place, up to the limit of tolerance. A blister may be applied over the nucha. The propriety of blistering the scalp is questionable.

Another object of treatment in the second stage, if death do not take place by apnœa, is to support the powers of the system. Measures for this object are indicated in proportion as the tendency to death is by asthenia.

Attention to the bladder is important in the second stage.

Chronic Cerebral Meningitis.

Simple chronic cerebral meningitis, that is, meningitis not incident to a tuberculous or any prior cerebral affection, is infrequent, although less rare than the acute form of the disease. This statement has reference to periods of life after infancy, but it holds good also with respect to the latter period. In a great majority of cases, it is a subacute affection *ab initio*.

The anatomical characters are thickening and opacity of the pia mater and arachnoid, caused by a new formation of connective tissue. The inflammation is usually circumscribed. The thickened and opaque membranes are abnormally adherent to the brain, and frequently adhesions of fibrous tissue are formed between the dura mater and the arachnoid. There may be considerable effusion into the ventricles. A certain degree of opacity of the pia-arachnoid, especially marked along the longitudinal fissure, combined with increase in the number of Pacchionian granulations, is to be regarded as the normal condition in old age.

This affection may be ranked among the "insidious diseases." The symptoms may not point to any cerebral affection, or they are not distinctive of this form of disease. The diagnosis is difficult. Pain in the head is usually more or less prominent as a symptom, but this is a symptom common to many affections. There may be little or no fever. Vomiting may be a prominent symptom, but this, too, occurs in various pathological connections. Mental apathy, amounting sometimes to stupidity, indisposition to either mental or physical exertion, and a notable change in disposition, characterize certain cases. Paralysis of the face and hemiplegia sometimes occur, but they are effects of other forms of disease. This statement also applies to epileptiform convulsions.

I have known a case of chronic meningitis to be considered a case of chronic gastritis, vomiting being a prominent and persistent symptom. The patient fell into coma before death, but this was attributed to exhaustion. Meningitis was not suspected prior to the autopsy. In another case in which an ante-mortem diagnosis was not made, the patient dying suddenly with apoplexy from extravasation, the case had been considered one of latent or irregular intermittent fever, chills occurring from time to time. A hospital patient had no symptoms referable to the head excepting mental inertia bordering on imbecility. He gradually fell into coma, and, after death, the case was ascertained to be one of chronic meningitis.

As regards diagnosis, close observation ought to lead to the conclusion that there exists a chronic cerebral affection. Paralysis is less likely to occur than in cases of tumors within the skull. The absence of paralysis is, therefore, of some account in the diagnosis. This statement will measurably apply

to convulsions. If cephalalgia, impairment of the mental faculties, and gradually developed coma follow an injury of the head, chronic meningitis is probable; a traumatic cause is likely to give rise to inflammation. Chronic meningitis is developed in a small proportion of cases of the affections of the kidneys embraced under the name Bright's disease. The existence of renal disease is, therefore, of some account in the diagnosis. But, in cases of renal disease, cerebral symptoms referable to uræmia, namely, epileptiform convulsions and coma, are not to be considered as evidence of meningitis. The existence of syphilis is to be ascertained, inasmuch as this is a cause of chronic meningitis.

Intermittency of cerebral functions may render the diagnosis difficult. The following facts, in a case which came under my observation, will serve to illustrate this: A lad, 15 years of age, had vomiting and chills with pain in the head and face. He became somnolent to a degree almost amounting to coma. He emerged from this condition and appeared convalescent. A return of the cephalalgia, vomiting, and somnolency occurred. In a few days these symptoms again disappeared, and he again seemed to be convalescing. The head symptoms, however, returned a third time, he became comatose, respiration and deglutition were notably affected, and death took place 48 hours after the last attack, a month after the commencement of his illness. The autopsy showed cerebral hyperæmia, a little lymph at the base of the brain, without tubercles, and the ventricles distended with liquid which was nearly transparent. The fourth ventricle was dilated. There were no tubercles in the lungs. Variations in the amount of effusion within the ventricles, probably, will account for the intermittency of the symptoms, and the pressure on the medulla oblongata by the liquid in the fourth ventricle explains the disturbance of respiration and deglutition, and the speedy death, in the last relapse. The case was an example of simple subacute or chronic basilar meningitis.

The treatment consists of moderate counter-irritation, the iodide of potassium, and perhaps mercurialization, quietude of mind and body, and the hygienic regulations appropriate to chronic affections generally.

Tuberculous Meningitis.

The distinctive feature of this variety is the presence of miliary tubercles in the pia mater, in connection with meningeal inflammation. Hence the name *tuberculous* or *tubercular meningitis*. As the inflammation, in the majority of cases, is chiefly at the base of the brain, it is called by some authors basilar meningitis; but this name is not to be recommended, inasmuch as meningitis at the base is not necessarily tuberculous. An old name for this affection is *acute hydrocephalus*, as there is usually found a considerable fluid accumulation in the ventricles. Tuberculous meningitis affects chiefly children, and is treated of fully in works devoted to infantile diseases. It is of rare occurrence in the first year of life, occurring especially after two, and under seven years of age. It is not, however, confined to childhood.

Tuberculous meningitis attacks by preference the pia mater covering the fossa Sylvii, the optic chiasm, the interpeduncular space, and the under surface of the cerebellum, but it is by no means confined to these situations, being often found on the convexity of the brain, although, as a rule, in a less degree than at the base. Tubercles may be present also in the choroid plexuses, and even in the substance of the brain. The tubercles appear as grayish-white or yellowish granulations in the course of the small arteries of the pia mater. They are usually of about the size of a millet-seed, but nodules the size of a pea may be formed by the confluence of numerous granulations.

Some of the tubercles are so small as to be recognizable only by the aid of the microscope. While usually found without difficulty, they may be present in such a small number as to require careful search for their detection; and, on the other hand, their number may amount to thousands. A fibrino-purulent exudation, similar to that present in simple meningitis, is found, as a rule, at the base, and may be present upon the convexity of the brain. The amount of exudation varies much in different cases. Although there is reason to believe that tubercles precede the inflammatory exudation, there seems to be no necessary connection between the number of tubercles and the degree and extent of inflammation. Tubercles may be present in large number without any apparent inflammation, and, on the other hand, the inflammatory exudation may be abundant without the coincidence of many tubercles. It can serve, however, no useful purpose, from a clinical standpoint, to distinguish between miliary tuberculosis of the meninges (without apparent inflammation) and tuberculous meningitis, inasmuch as the former usually produces the same symptoms as the latter and, in fact, is accompanied not infrequently by the microscopical evidences of inflammation. In the majority of cases of tuberculous meningitis (in seventy-five per cent., according to Seitz), the ventricles are found dilated and containing a large quantity of serous effusion, either clear or moderately turbid from pus-cells. When the ventricular effusion is abundant, the surrounding brain-substance is often found greatly softened and sometimes almost diffluent. It is probable that this softening is cadaveric and without clinical significance. In proportion to the amount of fluid effusion in the ventricles, the convolutions are flattened, and the sulci shallow. Minute extravasations of blood are frequently found in the pia mater, and sometimes in the substance of the brain.

The microscopical examination of the tubercles shows that they consist usually of a nodular accumulation, not always distinctly circumscribed, of lymphoid cells in the walls and perivascular sheaths of the small arteries of the pia mater, especially where they divide. Giant cells are less common in the tubercles of the pia than in tubercles elsewhere. Caseous metamorphosis of the centre of the tubercles occurs with less frequency than in tubercles in other situations. The lumen of the artery will often be found compressed and thrombosed at the seat of tuberculous infiltration. The inflammatory products are the same in character as those found in simple meningitis.

Evidences of tuberculous inflammation are found, almost without exception, in other parts of the body, most frequently in the form of phthisis, or of caseous lymphatic glands, or of other cheesy foci. Acute miliary tuberculosis may co-exist. Tuberculosis of the pia mater of the spinal cord has been found in many instances, and, probably, is the rule. There may be also tuberculous spinal meningitis. Of diagnostic value is the presence, in some cases, of tubercles in the choroid coat of the eye, which can be recognized during life by ophthalmoscopic examination. Neuro-retinitis and serous infiltration of the sheath of the optic nerve, which have been sometimes observed, are probably the result of the increase of intracranial pressure.

In the progress of this disease, as in simple meningitis, the symptoms undergo a marked change due to the pressure of the exudation and effused liquid; and this change will serve as the basis of a division into two stages. The development of the meningitis may be preceded by the symptoms and signs of pulmonary tuberculosis. Probably the latter always exists as an antecedent affection after infancy and childhood. The meningeal affection, even when it does not distinctly supervene upon tuberculous disease of the lungs, is usually preceded by pallor, loss of weight, impaired appetite, irritability of temper, muscular debility, indisposition to exertion, and other gene-

ral symptoms for a variable period. But, in a certain proportion of cases, the symptoms denoting the head-affection appear suddenly, the previous health having been apparently good. When the meningitis occurs after a prodromic period extending, as it does in some cases, over several weeks and even months, during which the general health becomes considerably impaired, an antecedent tuberculous affection in other organs is to be inferred; or, it may be that the miliary granulations within the skull existed for some time prior to the development of meningeal inflammation. The latter is probable if the prodromic period have been marked by cerebral symptoms. On the other hand, the meningitis, when it is developed abruptly, that is, without a prodromic period, the previous health having been apparently good, is incident to a primary local expression of the tuberculous cachexia within the skull, or, at least, occurring simultaneously with manifestations in the lungs and other organs.

The development of meningitis, as a rule, is denoted by pain in the head, referred generally to the forehead. Convulsions are less likely to occur at the onset than in simple acute meningitis. Vomiting, in most cases, is an early, and sometimes a prominent symptom. More or less fever occurs. The axillary temperature is raised, but the rise is less than in simple acute meningitis. Notable diurnal remissions are apt to occur, the exacerbations taking place at night. These symptoms continue for several days. The cephalalgia is frequently severe. Lancinating pains occur from time to time, causing infants to give a sudden, sharp, and short cry, which has been known as the *cephalic cry*. A common exclamation is, "Oh! my head." The hands are often carried to the head. There is increased sensibility to light and sound. The expression is frowning. In children, raising the lids and exposing the eyes to the light occasion crying. The conjunctiva is often suffused. The pupils in this stage are frequently contracted. The face may be flushed, and, in some cases, paroxysmal flushing of the face is a notable symptom. I have observed this to precede convulsions. During this stage, vigilance is frequently a prominent symptom, and the sleep obtained is disturbed by dreams causing patients to awake suddenly in terror. It is important to note that vomiting and increased sensibility to light, although generally marked, may be wanting.

Drowsiness and somnolence mark the supervention of the second stage. There is now less suffering from cephalalgia, but occasional lancinating pains may still occur. The pulse may fall below the average frequency of health. It is not infrequently faltering; it fluctuates in frequency, and may be irregular in rhythm. The respirations which in the first stage may have been accompanied by sighing, are now often irregular in rhythm. In young children, masticatory movements are common, and after dentition grinding of the teeth. Rolling the head, or boring the pillow, is a symptom in infants. The somnolency increases. The patients are reluctant to be aroused. If able to speak, they reply to questions slowly or in monosyllables, like a person half awakened from profound sleep. When aroused, they have an expression of stupidity. Incoherence is common, and occasionally drowsiness alternates with paroxysms of delirium. The pupils become dilated, and not infrequently present disparity as regards size. They respond sluggishly to light. As the somnolency deepens, the movements of the eyeballs are not in unison, strabismus frequently occurs, and oscillations of the balls are occasionally observed. The eyelids are but partially closed, the eyeballs being raised so that the cornea is partially covered by the upper lid, and in some cases the patients lie with the lids widely opened. Vision is gradually impaired, and frequently lost. Subsultus, carphologia, and fumbling with the bed-clothes are frequent symptoms. Convulsions are apt to occur, especially in children.

They are either limited or general, and may be either severe or slight. Paralysis of one side of the face and incomplete hemiplegia are occasionally observed. Not infrequently the muscles of the posterior part of the neck become rigid, and the patient lies with the head drawn backward. Contraction of certain of the muscles of the limbs occurs in some cases. This is sometimes observed on one side, while the muscles of the opposite side are relaxed. Occasional vomiting is a symptom of the second stage. As a rule, there is complete anorexia, but, in some cases which I have observed, food has been taken with apparent relish. The teeth and lips often become covered with sordes. Constipation is the rule. In young children the dejections are sometimes greenish, and resemble spinach in appearance. The abdomen is retracted. Retention of urine is not uncommon.

Sooner or later the patient becomes comatose. But, in some cases, before the occurrence of coma, remissions occur, in which the improvement, as regards intelligence and in other respects, is such as to appear to the friends to afford ground for much encouragement in hoping for recovery. The occurrence of profound coma is followed by impairment and loss of deglutition, with more or less embarrassment of respiration. The pulse becomes frequent and feeble, and the mode of dying is by apnœa and asthenia combined.

The duration is variable. It rarely falls short of a week. In the majority of cases, it does not exceed two weeks. It rarely extends beyond three weeks, but, exceptionally, it may be prolonged considerably beyond this period. The termination is almost invariably fatal. In some of the cases of supposed recovery, it is probable that the affection was simple meningitis.

The diagnosis involves the discrimination from an essential fever. With the latter it is not infrequently confounded. In making this differential diagnosis, meningitis is to be excluded by the absence of sensibility to light, of the characteristic lancinating pains which belong to the first stage, and of the strabismus, affection of the pupils, and other symptoms belonging to the second stage. In fever, drowsiness and delirium are not preceded and accompanied by the symptoms just referred to. Moreover, in typhoid fever, diarrhœa, abdominal tympanites, and iliac tenderness are likely to be present, symptoms not belonging to the clinical history of tuberculous meningitis.

It is to be discriminated from the so-called *hydrencephaloid affection* incident, in children, to exhaustion from diarrhœa. With this affection it was formerly confounded. In this affection the symptoms denoting inflammation are wanting, and the drowsiness or stupor is not accompanied by strabismus, inequality of the pupils, embarrassment of respiration, irregularity of the pulse, and other symptoms, exclusive of the somnolence, which belong to the second stage of tuberculous meningitis.

To discriminate tuberculous from simple meningitis, is by no means always easy. The gradual development of the former, the prodromic symptoms, the longer duration of the first stage, and the co-existence of pulmonary tuberculosis, in a certain proportion of cases, must serve as a basis of this differential diagnosis. The meningitis is probably simple if it can be distinctly traced to a traumatic origin. It is, however, to be borne in mind that, in most cases, it is possible to recall some injury of the head within a period of weeks or months prior to the occurrence of any disease in childhood; and it is customary to refer the affection to an injury often when there is not sufficient ground for such an opinion. Tubercles in the choroid coat are sometimes discovered by ophthalmoscopic examination. Their presence decides the differential diagnosis; but, inasmuch as they are not always present in cases of tuberculous meningitis, their absence is not sufficient to exclude this affection.

If the diagnosis be positive, the encouragement for successful treatment is

small. It is difficult, of course, to decide upon measures which will be likely to be useful in a disease tending intrinsically, like this, to a fatal issue, and when, in cases of apparent recovery, we are obliged to distrust the correctness of the diagnosis. The chief source of encouragement for successful treatment, in fact, in a case which the practitioner supposes to be one of this disease, is the possibility that the diagnosis may be incorrect. With reference to this liability to error in diagnosis, the measures indicated in simple meningitis are admissible. If, however, the practitioner be thoroughly convinced of the correctness of the diagnosis, he is hardly justified in resorting to blood-letting, or measures which occasion suffering, such as blisters and frequent cathartics. Under these circumstances, measures to palliate distress and prolong life are alone indicated. In this country the iodide of potassium is generally given largely in the second stage of the disease. Cases have been reported in which this remedy was apparently successful; but there is room for the supposition that in these cases either meningitis did not exist, or that the disease was simple meningitis. It is certain that in the immense majority of cases the remedy is unsuccessful. I do not, however, concur in the opinion held by most writers, that tuberculous meningitis is necessarily fatal; at least, there seems to me ground for considering as probable recovery in some instances. I have reported an instance of apparent recovery in another work.[1] Recovery in no instance can be demonstrated, since it can always be said that the diagnosis may have been incorrect. Of course if recovery invalidate the diagnosis, the disease must be considered as always ending fatally.

Spinal Meningitis.

In this affection the spinal membranes corresponding to those affected in cerebral meningitis, namely, the arachnoid and the pia mater of the cord, are the seat of an inflammation which may be either acute, or subacute and chronic. In the majority of cases spinal meningitis is caused by traumatism. The inflammation follows concussions, wounds, and fracture or luxation of vertebræ. It is sometimes attributable to prolonged exposure to cold, as in sleeping upon the damp ground or long immersion in water. Spinal meningitis due to a special cause and associated generally with cerebral meningitis, will be considered under a distinct heading (Cerebro-spinal Meningitis). The anatomical characters of acute inflammation of the meninges of the cord, are essentially the same as in cerebral meningitis. The inflammatory products are within the inner sac, that is, between the spinal arachnoid membrane and the pia mater. The products are fibrinous exudation, pus, and more or less serous effusion. The latter is sometimes sanguinolent. The inflammation often extends to the substance of the cord, causing meningo-myelitis. In chronic meningeal inflammation, the appearances are less marked, consisting of an increase of the subarachnoidean liquid, which is sometimes opaque and sometimes bloody, with newly formed connective tissue which may occasion adhesion of the membranes, or bridles of attachment. In acute spinal meningitis the inflammation, as a rule, extends over the whole or a greater part of the meninges of the cord. In chronic spinal meningitis the inflammation is not infrequently limited to a portion of the meninges. Calcified plates are often found in the pia-arachnoid membrane, especially in old persons, without having given rise to any appreciable symptoms during life.

The local symptoms of acute spinal meningitis, are chiefly referable to effects manifested through the spinal nerves; and they correspond to the functions of the posterior and anterior roots of these nerves. More or less

[1] *Vide* Clinical Medicine by the Author.

pain is felt in the spine, radiating therefrom to the extremities. The pain is increased, not so much by pressure over the spinal column, as by movements of the body. The sensibility of the surface is morbidly increased (hyperæsthesia). These effects are manifested through the posterior roots of the spinal nerves. Other effects are manifested through the anterior roots, or by reflex action through the posterior, namely, tonic contraction of the muscles of the extremities, clonic in some cases, spasm of the muscles of the back so as to give rise to opisthotonos, and sometimes rigidity of the thoracic muscles causing dyspnœa. As regards the muscular contractions or spasms, there are exacerbations and remissions. These symptomatic phenomena are attributable to a morbid excitation of the spinal nerves, and they belong to the early part of the affection. Subsequently, paralysis occurs as the effect of pressure upon the cord by the products of the inflammation. The paralysis may be limited to the lower extremities (paraplegia), or it may be general, that is, affecting both the upper and lower extremities. The paralysis is rarely complete. It is usually limited to motion, and with it, indeed, exaggerated sensibility or hyperæsthesia may persist, as well as tonic contraction of muscles. With these local symptoms there is more or less fever, together with anorexia and prostration. The pulse is sometimes abnormally infrequent, and this may be found in striking contrast with the temperature of the body as determined by the thermometer. In the course of the disease, however, the pulse becomes frequent and feeble. Profuse perspirations are apt to occur. Reflex and electrical excitability are generally preserved.

The diagnostic features point to the spinal cord as the seat of the disease, and denote an inflammatory and a grave affection. Hysterical opisthotonos lacks the evidences both of inflammation and of gravity. Moreover, various antecedent and concomitant phenomena betoken the existence of hysteria. It is to be differentiated from tetanus which is a very grave disease. The latter, however, is distinguished by the early occurrence of trismus and tonic spasms; by the absence of local and general symptoms denoting inflammation, and by the traumatic origin of the affection in the majority of cases. The diagnostic points involved in discriminating acute spinal meningitis from acute myelitis, will be noticed in treating of the latter in the next chapter. It may, however, be remarked here that acute spinal meningitis and acute myelitis very rarely occur independently of each other. The two affections are generally associated; but the inflammation may be primarily seated in either situation, and it may predominate in one or the other.

Acute spinal meningitis often runs a rapid course, its duration not extending beyond a week. It ends fatally in a large proportion of cases. Life is destroyed by apnœa in some cases in which the respiratory function is notably compromised by either spasm or paralysis of the muscles concerned in respiration, or by an extension of the inflammation to the medulla oblongata. If the latter occur, dysphagia is likely to be a symptom. In either case death is preceded by intense dyspnœa, which, on a physical examination of the chest, is found not to proceed from any adequate pulmonary or cardiac complication. In other cases, asthenia predominates in the mode of dying.

The danger is to be estimated by the extent of the diffusion of the inflammation and the severity of the symptoms. The immediate danger depends on the extension of the inflammation upward so as to interfere with respiration. In cases of a moderate intensity of the disease, recovery may take place rapidly and completely. The disease may continue and become chronic, or recovery may take place, leaving, as sequelæ, more or less atrophy and paresis of the muscles which had been affected.

The indications for treatment are essentially the same as in acute cerebral meningitis. Considering the rapid course of the disease in severe cases, and

the danger in the direction of apnœa, bloodletting, general or local, or both, may be employed if contra-indicating circumstances, relating to the pulse, the blood, and the constitutional strength, be not present. Mercurialization is warrantable, if not desirable. If employed, it should be rapidly induced; and, for this end, inunction may be added to the administration of calomel at short intervals. Ergot and belladonna are supposed to diminish hyperæmia, by causing contraction of the small arteries, and, in this way, to be useful. When the symptoms denote the presence of the products of inflammation, the vesication, successively, of different sections of the spine, and the iodide of potassium in large doses are indicated. Sustaining treatment is, of course, indicated in proportion as the duration of the disease is prolonged, and the symptoms show a tendency to death by asthenia. Retention of urine is to be prevented, and cystitis may claim appropriate treatment.

Chronic spinal meningitis is less rare than the acute affection. Hence, taking into view the fact that the latter often ends fatally after a rapid course, in most cases of the chronic affection the inflammation is subacute from the first. In the chronic affection the inflammation rarely extends over the whole of the meninges, but is more or less limited.

Chronic spinal meningitis gives rise to bilateral paralysis which, in the great majority of cases, is confined to the lower limbs (paraplegia). It sometimes gives rise to paralysis of the four extremities (general spinal paralysis), the facial muscles not being involved. If the paralysis be general, either the inflammation extends over the whole length of the cord, or it is limited to the cervical portion. The paralysis is generally incomplete, that is, more or less voluntary power over the paralyzed muscles is retained (paresis). The muscles of respiration may, or may not, be affected. In the chronic, as in the acute, form of the disease, the cord, together with the roots of the nerves, is implicated in the meningeal inflammation. The term meningo-myelitis is appropriate, it being understood that the inflammation has its primary seat in the meninges.

Chronic meningitis, like the acute form, is attributable generally to either traumatic causes or exposure to cold. Excessive abuse of the sexual function, either naturally or unnaturally, is probably causative in some instances.

The symptoms, as in the acute affection, are referable, *first*, to excitation of the cord and, *second*, to pressure, or, at length, to atrophy or softening of the cord. They are the same in character as in the acute affection, the difference being in degree. More or less pain is referred to the spine, and the muscles of the back are somewhat rigid. If the affection do not extend above the lumbar or dorsal section, the patient has a sensation as if the trunk were encircled by a tight belt. Pain, a sense of weight, and other abnormal sensations are felt in the paralyzed limbs. The paralysis varies in degree in different cases, but is rarely complete. It is apt to differ in degree on different days. The sensibility of the skin may be more or less diminished, but is rarely lost. Sometimes there is hyperæsthesia. The paralysis is developed gradually, and slowly increases. It may remain stationary at a certain point for a long period, or permanently. Incontinence or retention of urine is liable to occur, and cystitis is a frequent concomitant. Reflex and electrical excitability are retained for a time, but, at length, may cease.

Paraplegia from meningitis is to be discriminated from that caused by myelitis. The following are the points of distinction: The latter is accompanied by less pain in the spine, limbs, and extremities; the paralysis is developed more rapidly, and is greater in degree; cutaneous anæsthesia and analgesia occur earlier and are more marked; the muscles sooner become atrophied.

From locomotor ataxia, paraplegia differs in the fact that the motor difficulty is in the lack of voluntary power over the muscles, not in a want of coördinating ability (*vide* Sclerosis of the Posterior Columns of the Cord). In ataxia the muscular power under the control of the will may not be diminished. It is, however, important to bear in mind that paralysis and ataxia are not infrequently combined, and in proportion as the former predominates, the characteristics of the latter are less conspicuous.

Tumors within the spinal cord produce paralysis more slowly than meningitis, and the symptoms of the latter are not present at the oustet.

In a considerable proportion of the cases of paraplegia and general paralysis dependent on chronic spinal meningitis, the progress and termination are unfavorable. The duration in different cases is very variable. Progressive increase of the paralysis, loss of reflex and electrical excitability, cystitis, bed-sores, atrophy of the paralyzed muscles, impaired appetite and digestion, emaciation, etc., point to a fatal ending sooner or later. On the other hand, patients sometimes recover even when the paralysis has been of long duration, and circumstances have seemed unpropitious.

The following case of general spinal paralysis, probably dependent on meningitis, is instructive in the way of prognosis:—

An unmarried woman, aged 27, began to lose power over the limbs shortly after an attack of acute articular rheumatism which had confined her to the bed for about four weeks. The paralysis progressively increased for two months, when she was admitted into hospital. The paralysis of the limbs was incomplete, but was sufficient to render her helpless. There were no cerebral symptoms, and the intelligence was unaffected. The breathing was exclusively costal, and, at times, the suffering from dyspnœa was extreme. Scotch snuff introduced into the nostrils caused an intense desire to sneeze and grimaces, but there was no sneezing act. There were no signs of pulmonary or cardiac disease. She could speak only in a feeble voice, and with jerking efforts. At one time the want of power to carry on respiration was so great that apparently she was almost moribund. After a fortnight there was marked improvement under treatment by dry cupping over the spine, tonics, alcoholics, and good alimentation. She was then attacked with pneumonia affecting the lower lobe of the right lung. She passed safely through this disease. The ability to sneeze soon returned, and, after remaining in hospital several months, she was discharged well.

I have met with several cases of paraplegia referable to spinal meningitis, in which recovery took place after a long duration of the paralysis. A German immigrant became paralytic shortly after his arrival in this country, and was sent to the Ward's Island Hospital, where he remained five years, and during three of these years he kept the bed. He came under my observation at Bellevue Hospital at the end of five years, and after a few months was discharged, having perfectly recovered.

Cases like these show that the spinal cord may tolerate the pressure of morbid products for a long period without disorganizing lesions which render complete recovery impossible. In general, however, if the paralysis have existed for a series of months or years without improvement, and, still more, if it have progressively increased, the probability is that it will be permanent.

In the treatment of chronic spinal meningitis, the indications for blood-letting, local or general, are rarely present. Dry cupping, blisters, sinapisms, and irritating liniments applied to the back are considered highly useful while the inflammation continues. The application of the hot iron is recommended as an efficient method of counter-irritation. During this period the avoidance of exercise and of exposure to cold is important. When there is reason to think that inflammation no longer continues, it is an object of

treatment to promote absorption of the inflammatory products. The iodide of potassium is supposed to be of use in this way. Mercury may be tried, with proper precautions to avoid ptyalism. Nothing should be done to impair the general condition, and, if impaired, restorative remedies and hygienic measures are indicated. Tepid baths seem to be of use. The improvement sometimes derived from mineral waters, used either internally or externally, probably does not depend on any special efficacy, but, to a greater or less extent, on the hygienic advantages which are associated with their use.

As regards treatment addressed directly to the paralysis, the measures are the same as in all paralytic affections, whenever the measures are not contra-indicated by conditions standing in a causative relation to the paralysis, the object being to maintain the nutrition and functional capacity of the affected muscles.

Cerebro-Spinal Meningitis.

The name cerebro-spinal meningitis denotes an inflammatory affection of the arachnoid and pia mater of both the brain and the spinal cord. As a sporadic and purely local affection, it is extremely rare. A few cases only have fallen under my observation.[1] The name is generally understood as designating an epidemic disease characterized by cerebral and spinal meningeal inflammation. In the latter application it denotes an infectious disease, in the sense in which the term infectious is at present defined (*vide* page 89). Epidemic cerebro-spinal meningitis is a general, not a local, disease. Its appropriate nosological place is among the essential fevers. It is with propriety called by some writers cerebro-spinal fever. The evidence of its having existed prior to the present century is not clearly apparent in medical literature. Since the beginning of the nineteenth century, epidemics have occurred, at different periods, in various parts of the old world and in this country. It prevailed in New England between the years 1807 and 1816, and was then known as *spotted fever*. For a quarter of a century after that period, this country was exempt from its visitations; but within the last forty years, it has prevailed, from time to time, in different districts of the United States and in Canada. This article will have reference to the cerebro-spinal meningitis as an epidemic disease, or to cerebro-spinal fever.

Anatomical Characters.—In the majority of cases, an exudation of a purulent character, and similar to that in simple meningitis, is found in the meshes of the pia mater both of the brain and cord. The extent and the abundance of the exudation vary much in different cases. The inflammation affects the pia-arachnoid membrane both of the convexity and of the base of the brain, but is usually most intense at the base, and it may be limited to this situation. Within the spinal canal the inflammatory exudation is limited mostly to the posterior surface of the cord, and to the membranous envelopes of the posterior nerve roots. The purulent exudation, however, is rarely uniformly distributed over the posterior surface, but is most abundant in the lumbar, lower dorsal, and lower cervical regions of the cord, while it may fail in the rest of the cervical region, or be present there only in scattered patches. The exudation consists predominantly of pus, together with serum and fibrin mixed usually with a considerable number of extravasated red blood-corpuscles. In recent cases mucin may be present in considerable amount, so as to render the exudation gelatinous. The membranes, as well as the substance

[1] For an analysis of 48 cases of sporadic cerebro-spinal meningitis, *vide* Pathologie Interne, par E. Gintrac, tome 7.

of the brain and cord, are generally hyperæmic, and frequently the seat of small hemorrhagic extravasations. The substance of the brain and cord has usually an abnormally soft consistence which may be particularly marked at certain points. The ventricles commonly contain an increased amount of fluid, somewhat turbid in appearance, or, rarely, decidedly purulent. The central canal of the spinal cord may be dilated with purulent fluid.

In cases terminating within a few hours (fulminant cerebro-spinal meningitis), the anatomical evidences of the disease may be very slight or entirely absent. In such cases the exudation is mainly serous, although the microscope may show that emigration of white blood-corpuscles has already actively begun. In these fulminating cases the brain-substance will be found, as a rule, œdematous and anæmic. In cases of prolonged duration, the ventricles are usually found greatly dilated with serum. The previously creamy, purulent exudation is, perhaps, now desiccated and caseous, or, more frequently, has nearly disappeared.

The following embrace the most important of the morbid changes existing in other parts of the body: The skin often presents herpetic vesicles and petechiæ. The voluntary muscles, especially of the neck and back, are dark red in color, and often the seat of granular degeneration. As in other infectious diseases, parenchymatous degeneration of the heart, liver, and kidneys is usually found. The lungs present no constant changes, but are frequently the seat of bronchitis, atelectasis, lobular pneumonia, and hypostatic congestion. The spleen, in the majority of cases, is not enlarged, but is of lax consistence. Sometimes the spleen is found greatly swollen and softened. A moderate enlargement of Peyer's patches and the solitary follicles is common. Abscesses in the joints and elsewhere have been occasionally observed. Endocarditis and inflammation of serous membranes are rarer complications. Suppurative inflammation of the middle and internal ear, choroiditis, and iritis are to be mentioned as occasional sequelæ.

Clinical History.—The characteristic features of epidemic cerebro-spinal meningitis are remarkably distinctive. In many cases the disease commences with a sudden attack, the patient being at once stricken down with grave symptoms, but the access may be more or less gradual, the development occupying from one to eleven days. The prodromic symptoms, enumerated in the order of their relative frequency, are, cephalalgia, chills, without rigor, or chilliness, nausea and vomiting, pain in the spine and limbs, vertigo, and diarrhœa. Cephalalgia is usually the most prominent symptom when the disease is developed. The pain is intense, lancinating, and accompanied with a sense of tension; it is referred either to the frontal region, the occiput, or the whole head. The pain persists without intermissions. It is increased by light, sounds, and movements of the body. Pain referable to the spine, or rachialgia, is generally added to the cephalalgia. The pain may extend over the whole of the spine, or it may be referred to either the lumbar, dorsal, or cervical portion. The extent and situation of the spinal pain probably correspond with the extent and situation of the spinal meningitis. The rachialgia is wanting if the disease prove fatal without the inflammation extending to the spinal membrane. The spinal pain is not always increased by pressure over the vertebral column, but notably by movements of the body. Pain is frequently felt in different parts of the body, and especially in the lower extremities. The pain in other situations than the head and spine is often intense. Hyperæsthesia of the surface of the body is often a marked symptom, rendering the slightest contact a source of suffering. Not infrequently vomiting accompanies the cephalalgia at the outset of the disease.

Delirium in some cases quickly supervenes, but in other cases after a variable period. Sooner or later it occurs in a large proportion of the cases which are not quickly fatal. It varies much in character and intensity. At first there is simply difficulty in collecting ideas, but after a time the patient either remains taciturn, making no response to questions, or replies incoherently, or becomes actively delirious, shouting and struggling against restraint. The latter form of delirium occurs in paroxysms, with calm intervals. The paroxysms occur especially at night. They are accompanied by hallucinations, in some cases, and insane delusions. Occasionally the delirium is hilarious. The mind is usually desponding and apprehensive, if the intelligence be preserved. Loquacity and erotic desires with priapism have been observed. Repeated seminal emissions occurred in a case which came under my observation. In a certain proportion of cases, the patient becomes quickly somnolent and falls into coma which may be of temporary duration, or continue until the disease ends fatally. More or less stupor, frequently amounting to coma, occurs not infrequently on the first day of the disease. The vision is rarely lost; double vision sometimes occurs; the pupils are frequently dilated, but sometimes contracted; the conjunctiva is often injected; temporary deafness is an occasional symptom. In one of the cases of sporadic cerebro-spinal meningitis which I have observed, lateral and vertical oscillation of the eyeballs was a notable symptom. The coma in some cases is without stertor, and resembles that of hysteria; the patients seem to be in a quiet sleep, crying out if any attempt be made to alter the position of the body. A patient in one case which came under my observation had remained in precisely the same position for 48 hours, and, in another case, for three days. Mobility of the iris may remain, although the patient is in this comatose or deeply somnolent state.

Important symptoms relate to the muscles. Tonic contraction of the muscles of the neck and back is of frequent occurrence, giving rise to retraction of the head and opisthotonos in a greater or less degree. Trismus sometimes occurs, and, in rare instances, pleurosthotonos. Contractions of muscles of the extremities are not infrequently observed. Pain in the muscles of the legs and thighs, the spinal muscles, and those of the neck, is a source of suffering if the patient be conscious. Muscular tremor is an occasional, and strabismus not an infrequent, symptom. Subsultus and carphologia occur in cases in which the disease is protracted. Convulsions are not of frequent occurrence. Paralysis is also infrequent. Hemiplegic paresis and ptosis have been observed.

Nausea and vomiting are more or less prominent throughout the disease in a minority of cases. Constipation is the rule. The appetite is generally lost: however, a desire for food is sometimes expressed, although convalescence is not near at hand. The tongue is frequently large and flabby, showing indentations made by the pressure of the teeth. It becomes coated, and, in the progress of the disease, dry and dark. The teeth and lips frequently present sordes.

The respirations are sometimes suspirious. They are usually increased in frequency even when no pulmonary complication exists, and they are sometimes irregular. Stertor is rare. The pulse at the commencement of the disease is generally not more frequent, and is often less frequent, than in health. In the progress of the disease it becomes moderately accelerated, rarely exceeding 100 per minute, until toward a fatal termination, when it is frequent and small. Fluctuations in frequency at different periods of the day constitute a striking feature in some cases. Palpitations are occasionally observed. The quantity of urine is greater than in health, and the urates are deposited in abundance. In a fatal case among those which I have observed, there was

hematuria, the hemorrhage being abundant, and not occurring in any other situation.

The temperature of the skin varies in different cases and at different periods in the progress of the disease. At the beginning the temperature rarely exceeds, and often falls below, that of health. Notable heat of the surface is very rarely observed; the thermometer, however, shows the heat of the body to be more or less raised. Thermometric examinations in the axilla were made by Githens in 44 cases at 6 A. M., at 12 M., and at 6 P. M., daily, with the following results: The maximum of increase was 105° Fahr.; in only two cases was this height reached. The maximum in 15 cases was between 104° and 105°; in 7 cases between 102° and 103°; in 6 cases between 101° and 102°; and in 2 cases it was below 100°. The difference between the morning and evening temperature was less than in most of the essential fevers. "A rapid fall was the sure precursor of collapse."[1] As regards dryness and moisture, cases vary on different days and at different periods of the same day. Sweating is rare except in some cases shortly before death. The face is often suffused and of a dusky hue.

Petechial spots are frequently observed, but they are by no means constant. They appear to be of more frequent occurrence in some epidemics than in others. They vary in size from that of a pin's head to spaces a quarter of an inch in breadth or even larger. They are evidently due to an extravasation of blood or of blood-coloring matter, such as occurs in scorbutus, purpura, in some cases of continued fever, and occasionally in various affections. They are hardly entitled to be called an eruption. A rose-colored papular eruption, resembling that of typhoid fever, has been occasionally observed. Herpes of the face occurs often in some, and rarely in other, epidemics. Urticaria, erythema, and bullæ have been observed, but their occurrence is evidently accidental; that is, they do not belong to the clinical history of the disease. In some of the cases which I have observed, sudamina were abundant.

A survey of the clinical history of this affection, exclusive of the cases in which death quickly ensues in apoplectic coma, shows a correspondence with the symptoms of acute cerebral meningitis, and the addition of those due to inflammation of the meninges of the spinal cord. The duration of the disease is very variable. Of fatal cases, the minimum duration is stated by Tourdes to be twenty hours. Ames states the minimum to be fifteen hours. The maximum duration in fatal cases is stated by Tourdes to be 100 days, and by Ames over forty days. Of the cases analyzed by Ames, 16 terminated fatally on the second or third, and 19 on the fourth day.[2] Of 160 cases analyzed by Dr. S. B. Hunt, 12, or one in 13, died within the first twenty-four hours; 92, or more than half, died before the close of the fifth day; 14, or one in 11, died before the close of the tenth day; 4, or one in 40, before the close of the fifteenth day, and 18 survived for various periods thereafter.[3] In Upham's cases the duration varied from thirty-six hours to six weeks.[4] Thus, in the majority of fatal cases, the disease runs a rapid course, ending prior to the fifth day. In cases which end in recovery, the convalescence is generally tedious, and the patient remains for a long period in feeble health. Relapses have not been observed.

It is not easy to divide the career of the disease into well-marked stages. And the arrangement of cases into different classes, such as inflammatory,

[1] *Vide* Am. Journ. of Med. Sciences, July, 1867.
[2] *Vide* New Orleans Med. and Surg. Journal, 1848.
[3] Article by Dr. Hunt in the medical volume of the Sanitary Memoirs of the War.
[4] Epidemic Cerebro-spinal Meningitis in the Camps in and around Newbern, in 1862–63, by J. Baxter Upham, M.D., Boston, 1863.

congestive, malignant, etc., is not attended by any practical advantage. Remissions are stated to occur by different observers. They vary as regards the time of their occurrence, their duration, and the degree of amelioration of the symptoms. Not infrequently the improvement for a few hours, and sometimes for a day or so, is so marked as to give encouragement to hope that convalescence is about to take place. These remissions are most apt to occur on the second or third day. In a case under my observation the temperature and pulse became normal, the intelligence returned, and for twenty hours the patient seemed convalescent; the symptoms, however, returned and the case ended fatally.

Pathological Character.—All at present known of the pathological character of epidemic cerebro-spinal meningitis is embraced in the statement that it is an infectious disease, and belongs among the essential fevers. The inflammation of the pia mater of the brain and cord is a local manifestation or an effect of an underlying general morbid condition. Of the nature of this general condition, and the rationale of the connection between it and the inflammatory affection, we have no positive knowledge; but we are not more in the dark than as regards the pathological character of most diseases which are embraced in the same category. It must be admitted that the phenomena of the disease are largely symptomatic of the cerebro-spinal inflammation.

Causation.—The prevalence of the disease as an epidemic implies the existence of a special cause. With respect to the source of the special cause, and the circumstances concerned in its production, we have no positive knowledge. Nearly all who have observed the disease concur in the belief that the causation does not involve a contagium. That the special cause is a germ derived from the body, but becoming a morbific agent only when a development has taken place under circumstances which are exterior to the body, is an opinion held by some, but resting wholly on conjecture. The disease has prevailed in situations in which periodical fevers rarely occur. It is, however, not improbable that in malarial districts the special course may be combined with that giving rise to periodical fevers, and that the phenomena of the latter are sometimes associated with those of cerebro-spinal meningitis.

In France, the disease has been observed to prevail especially among soldiers, and more particularly among new recruits. In this country it has prevailed among troops stationed at several different points. It attacks persons in all conditions, and at all periods of life. Infants are not exempt, but the liability is increased after seven years of age. In a series of cases, the larger number are between the ages of 20 and 30 years. Of the persons attacked, the larger proportion are males. The difference, however, is not great. The statistics of Sanderson, cited by Hunt, show 164 cases among males, and 154 among females.

Epidemics occur much oftener in the winter and spring than during the summer months. Of the epidemics which have occurred in this country, nearly all were in the spring and winter months. Of 52 epidemics in Europe, analyzed with reference to this point by Dr. John Simon, 10 were in August and September; 24 were in October and November; 46 were in December and January; 48 were in February and March; 30 were in April and May, and 24 were in June and July. The disease, as stated by Hunt, who cites the foregoing statistics, "has its favorite habitat in prisons and barracks." "The four or five years following 1837 it invaded nearly all the crowded barracks in France. It has appeared frequently among the galley slaves of Toulon."

Facts pertaining to the localization of epidemics, and the occasional occur-

rence of sporadic cases, show conclusively that auxiliary causes which pertain to overcrowding, defective ventilation of dwellings, poisoning of the atmosphere by sewer emanations, etc., have a potential causative influence, in association with the special cause; and it is an important fact that these auxiliary causes are by no means always confined to the habitations of the poor.

Diagnosis.—Difficulty in making the diagnosis of cerebro-spinal meningitis relates chiefly to sporadic cases, and to those in which the disease aborts or is unusually mild. Abortive cases sometimes occur, and the disease is sometimes so mild that its usual diagnostic features are not marked.

The disease need never be confounded with typhoid fever. The suddenness of the attack in many cases, the intensity of the cephalalgia, and the occurrence of symptoms denoting inflammation of the meninges of the brain and cord, distinguish it alike from typhoid and typhus fever. The characteristic abdominal symptoms of typhoid fever are wanting, namely, diarrhœa, meteorism, and iliac tenderness. Absence of the latter symptoms does not exclude typhus; but other diagnostic points belonging to the latter disease are wanting. The characteristic eruption of typhus, often copious, appearing on the third or fourth day after taking to the bed, does not occur in cerebro-spinal meningitis. The spots of ecchymosis on which the name spotted fever is based, cannot be confounded with the eruption of typhus. Tonic contraction of the muscles of the neck and back, rachialgia, convulsions, and furious delirium, which occur in cases of cerebro-spinal meningitis, are very rare in cases of either typhoid or typhus fever.

In the cases in which the patient falls quickly into coma and dies after the lapse of a few hours, the affection resembles, in this fact, a paroxysm of pernicious intermittent fever. In general, however, the latter does not destroy life in the first paroxysm, and the occurrence of a paroxysm from which the patient has emerged, suffices to establish the diagnosis. It is of course only in districts in which periodical fevers exist, that the practitioner is called upon to make this differential diagnosis.

The occurrence of trismus and opisthotonos may suggest tetanus. But in tetanus the cerebral symptoms which belong to cerebro-spinal meningitis are wanting. Moreover, tetanus, in other than tropical climates, is exceedingly rare save as a traumatic affection, and never prevails as an epidemic.

Prognosis.—There are few epidemic diseases so destructive to life as cerebro-spinal meningitis. In the epidemic observed by Tourdes, the proportion of deaths was 60 per cent. Ames gives the same proportion of fatal cases in the epidemic which prevailed in Alabama in 1848. In an epidemic observed by Lefèvre, four-fifths died at the commencement, and two-thirds toward the end of the epidemic. Of 366 cases analyzed by Dr. S. B. Hunt, the deaths were 243, and the recoveries 123, making the percentage of fatal cases 70. Stillé states that ten epidemics between 1838 and 1848 gave an average mortality of 70 per cent., and a similar number of epidemics between 1855 and 1865 gave an average of about 36 per cent. He cites these statistics as showing a gradual decline of power in the epidemic cause. All observers agree as respects a large death-rate in cases of this disease. The prognosis in all cases in which severe symptoms occur—such as notable delirium, coma, convulsions, and muscular contraction—is exceedingly grave. The disease is most apt to prove fatal in infants, and in persons in middle and advanced life. It is stated that the proportion of fatal cases is greater among females than males. The mode of dying, in the cases in which coma and death take place speedily, may be by apnœa, but in the majority of cases it is chiefly by asthenia.

Deafness and blindness are not very rare sequels of this disease. In the large majority of cases, the deafness is bilateral. The blindness may be in both eyes, but oftener it is unilateral. The blindness is due to purulent choroiditis, and the deafness to purulent inflammation of the labyrinth of the ear.[1]

TREATMENT.—As might be expected in a disease so severe and fatal as this, various potential therapeutical agents have been employed. No reliable abortive or curative treatment has as yet been discovered. Experience has, however, shown the utility of certain measures, in the employment of which the physician is to be governed by the rational and symptomatic indications present in individual cases.

Great severity of symptoms, the patient having been attacked in full health, and the pulse being strong or hard, renders bloodletting appropriate. Wet cups may be applied to the neck, or leeches behind the ears, in lieu of venesection, when the indications for bloodletting are less clear. The abstraction of blood is contra-indicated if the cerebro-spinal symptoms be not severe, if the pulse be readily compressed, and if the patient were anæmic or feeble when attacked.

Quinia in large doses has appeared in some cases to be useful. Its apparent success is, perhaps, in a measure to be accounted for by supposing that pernicious intermittent fever may have been mistaken for the disease, and by the fact that malarial effects may be associated with the latter. The utility of this remedy may sometimes be due to its antipyretic operation. For the reduction of a high temperature, in this disease, sponging the body and the wet sheet are preferable. These measures are indicated by intensity of fever.

The testimony in behalf of opium in large doses is discrepant. As regards its utility, however, there is very general agreement among physicians of large experience. Prof. Stillé recommends one grain of opium every hour in severe cases, and every two hours in cases of moderate severity. This recommendation is based on the study of about 120 hospital cases. He has not known any approach to narcotism in the cases thus treated. The hypodermic administration of morphia is to be preferred. It is important to avoid narcotism. The bromides, given in large doses, are regarded with favor by many physicians with whose practice I have become acquainted through professional intercourse.

The utility of cold applications to the head and back is conceded by all physicians. The extent to which this measure is to be carried, is to be determined by the sensations of the patient and the effect upon the symptoms.

The foregoing remarks relate to the treatment when the symptoms denote cerebro-spinal excitation. When the symptoms are those of oppression, the objects of treatment are the same as in cases of simple cerebral and spinal meningitis, namely, limitation of morbid products and their removal by absorption. The iodide of potassium, given in doses as large as are well tolerated, is indicated. Mercury, internally and by inunction, may do something toward effecting the objects just stated, and, if so, it is desirable to secure its usefulness, however small it may be.

Support by alcoholics and nutritious alimentation is indicated in proportion as the symptoms denote asthenia.

Whenever an epidemic of this disease occurs, or a sporadic case, local auxiliary causes should be sought after and removed. Removal of residents without the area of the infected situation, if practicable, is to be recommended.

[1] *Vide* Article by Dr. H. Knapp in the N. Y. Medical Record, Aug. 15, 1872.

Hydrocephalus. Hydrorrachis.

By the term hydrocephalus or hydrocephalus internus is understood an excessive accumulation of serous fluid in the ventricles of the brain, particularly the lateral ventricles. The name hydrocephalus externus is sometimes applied to great increase of fluid in the subarachnoid space. The serous effusion of hydrocephalus may be due to a variety of different processes, such as venous congestion, atrophy of the brain, changes in the walls of the blood-vessels, and inflammation of the lining membrane of the ventricles or of the pia mater. In some, especially the congenital, forms of hydrocephalus, we are unable to determine the cause of the disease. There is but little tendency to dropsical effusions within the cranium in cases of general dropsy. Hydrocephalus occurs as a congenital affection, or in early infancy, leading in some cases to an enormous enlargement of the cranium, and giving rise to a characteristic deformity of the head. The reader is referred to works on the diseases of children for an account of this affection.

The name hydrocephalus *ex vacuo* is given to an effusion of serum into the ventricles as a result of wasting or atrophy of the brain-substance, as in old age. Under these circumstances, as the effused serum simply fills an unoccupied space, the brain does not suffer from compression. An abundant serous effusion is an important element in certain cases of tuberculous meningitis (acute hydrocephalus), and sometimes in other forms of meningitis. The exudation of fibrin and pus in some cases is very small and the amount of effused serum large; but these are not properly cases of hydrocephalus. It was formerly thought that serous effusion sometimes occurs suddenly in sufficient quantity to occasion apoplexy (serous apoplexy). This was the explanation of certain cases which are now explained by our knowledge of thrombosis, embolism, and uræmia.

Serous effusion into the lateral ventricles may occur in consequence of pressure upon the veins carrying the blood from the ventricles into the sinuses (venæ Galeni), as from a tumor of the pineal gland, solitary tubercles of the cerebellum, etc. A chronic accumulation of serum in the lateral ventricles, combined with a granular condition of the ependyma, has been described under the names *granular ependymitis* and *chronic ependymitis*. It occurs especially in cases of chronic alcoholismus and in old age. A similar serous accumulation may be present in chronic cerebral meningitis with or without a granular ependyma. The growth and coalescence of the granulations may cause obliteration of portions of the ventricles, for example, the anterior horns of the lateral ventricles, or may lead to the formation of bands of adhesion between the ventricular walls.

Extensive serous accumulation within the spinal canal is called *hydrorrachis*. The effusion may be in the central canal of the spinal cord (hydrorrachis interna or hydromyelus), or in the subarachnoid or subdural space (hydrorrachis externa). These affections, when congenital, are often combined with deficiency of portions of the vertebral column, constituting the affection commonly known as *spina bifida*. In this affection a tumor, consisting of the serous accumulation with its enveloping membranes (hydromyelocele), protrudes through the fissure, most frequently in the sacral or dorsal regions. The affection is treated of in works on the diseases of children and on surgery. An accumulation of fluid in the central canal of the cord attends some cases of myelitis.

CHAPTER III.

INFLAMMATORY AND STRUCTURAL DISEASES OF THE BRAIN.

Encephalitis. Inflammatory Softening and Abscess of the Brain. Sclerosis of the Brain. Non-inflammatory Softening of the Brain. Intra-cranial Tumors. Chronic Bulbar Paralysis. General Cerebral Paralysis of the Insane.

Encephalitis. Inflammatory Softening and Abscess of the Brain.

THE terms encephalitis and cerebritis denote inflammation of the substance of the brain. It has already been mentioned that in cerebral meningitis the inflammation frequently extends more or less from the pia mater into the brain-substance. With this exception, encephalitis is localized either in one situation, or in a greater or less number of foci. The inflammation presents itself, 1, as softening, 2, as abscesses, and, 3, as sclerosis or induration of the brain. Much confusion has existed, and still exists, as to inflammatory softening of the brain. Formerly nearly all varieties of cerebral softening were considered to be inflammatory in their origin. We now know that the majority of cases of softening are not inflammatory, but the result of suspended nutrition (necrobiosis), attributable to either embolism or thrombosis. There remain, however, rare cases of primary softening, the cause of which cannot be found in changes in the bloodvessels, and which are still classified as inflammatory, although our knowledge is very imperfect as to their genesis and their distinctive pathological characters. This encephalitic softening is generally red in color, and hence is called inflammatory red softening. It may form the first stage of abscess, but it does not necessarily lead to suppuration, nor is abscess necessarily preceded by red softening. The affected portion of brain, which may be either the white or gray matter, is softened, somewhat swollen, of a diffuse reddish-yellow color, frequently dotted with red points of capillary blood-extravasations. The region of inflammatory softening is not distinctly circumscribed, but is surrounded by a zone of œdematous brain-tissue. The microscopical examination reveals hyperæmia, extravasations of blood, the latter, when small, perhaps confined to the perivascular sheaths, broken-up nerve-fibres, fatty and disintegrating ganglion-cells, pus-cells in greater or less number, some granular corpuscles, and sometimes pigment-granules. It is difficult from the histological characters to differentiate inflammatory from non-inflammatory softening. This inflammatory softening is often present around tumors, infarctions, hemorrhages, and abscesses, but as a primary affection, independent of suppurative inflammation, it is very infrequent. The patches of yellow softening (plaques jaunes) which are occasionally met with in the cortex cerebri in a variety of conditions, especially old age, chronic alcoholism, and insanity, are also considered by many writers as centres of chronic circumscribed encephalitis. It is stated by Rokitansky, Huguenin, and others that inflammatory red softening may terminate in yellow softening, and in cysts and cicatrices not to be distinguished by their structure alone from those resulting from hemorrhage. We

possess no accurate information as to the termination of encephalitis in resolution or complete restitution of the normal structure.

Suppurative encephalitis or abscess of the brain, on the other hand, is better understood. Cerebral abscess may develop in any part of the brain. When recent, the abscess does not possess an enveloping capsule of connective tissue, and some abscesses of long duration are devoid of it. Non-encapsulated abscesses have a shaggy wall of cerebral tissue. Other abscesses have a cyst-wall of fibrous tissue. In the majority of cases, abscess of the brain is single, but sometimes there are several distinct abscesses which are then usually small in size. Abscesses have been described which involve nearly a whole cerebral hemisphere, but in the majority of cases the size varies between that of a pigeon's egg and a hen's egg. Abscesses may perforate into one of the ventricles, or may burst upon the base, or the convexity of the brain. Circumscribed or diffuse meningitis is apt to complicate abscesses seated near the surface of the brain. The pus is sometimes fetid, especially when the abscess is secondary to putrid affections of the lungs, such as gangrene, and bronchiectasis with stagnating secretion. The pus may be gelatinous in consistence from admixture with mucin, and is sometimes acid in reaction.

In a large proportion of cases, suppurative inflammation of the brain is secondary to caries of the cranial bones, generally connected with disease of the internal ear, the orbit, or the nose. It is oftener a result of injury of the head than of any other cause. As a purely primary affection, that is, occurring independently of these causes, excluding also the cases in which it is due to the presence of a clot or a tumor, and those in which it is secondary to pyæmia, it is one of the rarest of rare diseases. Of the causation, when it is primary, we have no knowledge.

Encephalitis is accompanied by pain and a sense of fulness in the head, vertigo, tinnitus aurium, disturbances of vision, unilateral contractions and convulsive movements of the muscles of the limbs, hesitancy or uncertainty of gait, and embarrassment in speech. The pulse is more or less accelerated, and the axillary temperature rises, but the increase rarely exceeds 103°. Vomiting occurs at intervals; the bowels are constipated; the cephalalgia usually continues and is more or less marked. Epileptiform convulsions are apt to occur. These symptoms represent a stage of the disease corresponding to the "period of excitement," or the first stage, in meningeal inflammation. This stage continues rarely beyond a week. Softening, or the formation of pus, gives rise to paralysis, mental dulness, somnolency, coma. This stage may be of brief duration, or life may be prolonged for many weeks and even months, death being perhaps caused by some intercurrent affection.

Coma, in connection with encephalitis, is sometimes sudden, and, hence, authors have reckoned this disease among the several morbid conditions giving rise to apoplexy. Doubtless, in some of the cases of so-called apoplectic encephalitis, the sudden coma was due to embolism. Softening from inflammation, however, may occasion cerebral hemorrhage which may take place with sufficient rapidity and in sufficient amount to cause apoplexy. Another event giving rise to sudden coma and death, is the rupture of an abscess, the pus being discharged into one of the ventricles, or upon the surface of the brain. In some cases of cerebral abscess connected with disease of the ear, orbit, or nose, the pus from the abscess is discharged externally in these situations. Irregular chills may occur with cerebral abscess, but they are rare in this connection.

Aphasia may be caused by inflammatory softening or abscess of the brain, as well as by other cerebral lesions, especially when the seat of the morbid changes is in the left anterior lobe of the cerebrum, near the island of Reil.

The foregoing clinical history applies to the large number of cases. But cases are not extremely rare in which abscesses of the brain, even of considerable size, give rise to no marked cerebral symptoms, and they may remain latent for an indefinite period. Of course, in these cases, the motor portions of the cortex and other motor tracts of the brain cannot be involved.

For the points which bear upon the localization or the topical diagnosis of inflammatory softening and abscess, the reader is referred to page 675 *et seq.* The diagnosis involves the exclusion of embolism and thrombosis, acute cerebral meningitis, cerebral hemorrhage, and tumor of the brain. The existence of symptoms pointing to some affection within the skull prior to paralysis or coma, will exclude embolism and thrombosis, these accidents occurring without prodromic symptoms. Cerebral meningitis is attended by more intense local symptoms—cephalalgia, delirium, etc., and it gives rise to greater intensity of fever, together with other evidence of general disturbance. Moreover, muscular contractions and convulsive movements in encephalitis are generally unilateral, whereas in meningitis they are bilateral. Hemorrhage into the substance of the brain, when not a sequel of encephalitis, usually occurs without prodromes, and the symptoms denoting inflammation around the clot occur several days after the apoplectic seizure. The differentiation from tumors is the most difficult. Tumor may be excluded if the encephalitis pursue a regular course, the first stage well marked, continuing for a week or somewhat longer, and followed by the symptoms denoting softening or suppuration. The course of encephalitis, however, is not always regular, but it is subject to great variations, and, as already stated, abscess of the brain is sometimes notably latent, being found after death when it had not been suspected during life. As regards the differential diagnosis of abscess and tumor, much weight belongs to the following points: If the cerebral affection be connected with disease of the internal or middle ear, orbit, or nose, or if it have a traumatic cause, it is abscess rather than tumor. If there be room for doubt, the probabilities are in favor of tumor, inasmuch as abscess is much less frequent than tumor.

Encephalitis leading to softening or suppuration, ends fatally, sooner or later. The duration varies from a few days to several weeks or months. Recovery is perhaps possible if suppuration have not occurred. An abscess may become encapsulated. Cases have been reported in which the symptoms and progress seemed to denote inflammatory softening, and the patients recovered, save that more or less paralysis remained. But in these cases there is always room for doubt as to the correctness of the diagnosis. It is by no means improbable that circumscribed encephalitis may occur and end in recovery without having eventuated in notable softening or suppuration; but, in such cases, the symptoms cannot be relied upon for the diagnosis.

A few words will embrace all that is to be said with reference to treatment. At a period when a probable diagnosis may be made, that is, after inflammation has eventuated in softening or suppuration, the possibility of recovery involves sufficient prolongation of life for the absorption of the destroyed cerebral tissue with the inflammatory products, and for cicatrization. The great object, then, of the management, is the prolongation of life. Keeping in view this object, depletory and debilitating measures are likely to do harm. Mild revulsives, tonic remedies, a nutritious diet, repose of the mental faculties, and stimulants if the patient be in danger from depression of the vital powers, should constitute the treatment. The operation of trephining and making an incision into a cerebral abscess resulting from injury of the skull, has been resorted to with success.

Sclerosis of the Brain.

This structural affection corresponds to the chronic interstitial inflammations of other organs, such as cirrhosis of the liver and of the kidneys. The essential anatomical condition is a morbid production (hyperplasia) of connective tissue. The underlying pathological condition is regarded as a chronic inflammation. Sclerosis of the brain is, therefore, characterized by a hyperplasia of the interstitial nerve-cement, the analogue of the connective tissue in other situations, called by Virchow the neuroglia; and the affection is supposed to be a form of chronic encephalitis.

In rare cases the lesion extends over an entire lobe, or even over an entire hemisphere. The affection is then called diffuse cerebral sclerosis. As a rule, however, it occurs in isolated, disseminated portions which are more or less in number, and it is then distinguished as multiple sclerosis (sclérose en plaques). The indurated or sclerosed nodules vary in size from that of a small pea to an almond. They may be so few that, if small, they are liable to be overlooked, or the number may be great. As regards their number and size, different cases offer great variations. They are found chiefly in the white or medullary substance of the brain, very rarely existing in the cortical substance. The color of the nodules is grayish-white. The consistence is firm, rarely gelatinous. Microscopical examination shows in the fresh gelatinous plaques proliferation of the neuroglia-cells. In the denser patches fibrillated connective tissue predominates. Nerve elements are few or absent. Fatty granules and granular corpuscles may be present especially in the thickened vascular walls. Amyloid corpuscles are often abundant. These appearances denote hyperplasia of the neuroglia and atrophy of the nerve structure, the latter, doubtless, dependent on compression by the former. From the color, the lesion has been called gray degeneration. The nodules may be found in any and in all parts of the medullary substance of the brain. They may be limited to the brain, but they often exist in both the brain and the spinal cord, occurring primarily and predominating sometimes in one and sometimes in the other of these situations. The name cerebro-spinal sclerosis expresses this concurrence of the affection in the brain and cord. This affection will be considered subsequently.

Symptomatic effects of this lesion are pretty constantly manifested in the mental condition. The faculties of the mind, as a whole, may be more or less enfeebled. The impairment may be especially apparent in failure of the memory. Melancholy and a morbid emotional impressibility are the prominent mental manifestations in some cases. Cephalalgia and vertigo enter into the clinical history. Like other lesions of the substance of the brain, this gives rise to paralysis. As to the muscles which are affected with paralysis, this will depend on the situation, the size, and the number of the sclerosed or indurated nodules. A diagnostic feature is, the paralysis affects in an irregular manner different muscles successively, not simultaneously. This is explained by the dissemination of the lesion which causes the paralysis, and by the successive occurrence of sclerosed nodules. Generally, at first, the paralysis is confined to certain of the muscles of one of the lower limbs; then, certain muscles of an upper limb, or of the corresponding member on the opposite side, may become affected. The paralysis may extend to the muscles of the trunk. Strabismus may occur. There may be facial paralysis on one side or on both sides. The muscles involved in speech are often affected, and sometimes those of deglutition and respiration become implicated. This irregularity in the successive paralytic manifestations, corresponding to the multiple character of the lesions, is highly significant of the affection. The cutaneous sensibility may be but little, or not at all, affected. The sense of tact may be

diminished, while the susceptibility to pain is preserved. Defective vision, sometimes even amaurosis, and deafness are occasional effects. Other of the cranial nerves, exclusive of the facial already referred to, may be involved. Muscular tremor is a very constant symptom. It precedes and accompanies the paralytic effects. It is manifested with voluntary movements, and, also, irrespective of these, especially under the influence of emotions or mental excitement. During the progress of the affection, convulsive movements and spasms sometimes occur, but they are rare. Defective co-ordinating power over certain muscles (ataxia) is sometimes observed. The paralyzed parts are susceptible to reflex excitation, and to the electrical current; they also do not show defect of nutrition. The nutrition of the body may be well maintained, and patients may even grow fat. The attitude of the patient when standing, and the manner of progression, are sometimes characteristic. In standing, the body is bent forward, and, instead of walking, the patient has a jog-trot gait. This symptom is called festination. Generally the trotting is forward, but sometimes the patient moves backward for several steps before going in a forward direction. Sclerosed plaques are sometimes found in the brain without any of the symptoms which have been mentioned. They are not very infrequent in the brains of idiots, the insane, and epileptics.

The duration of the affection is long, extending, in the majority of cases, from five to ten years. The duration may exceed considerably the latter period.

As regards treatment, it must, in the first place, have reference to symptomatic indications, together with attention to the general health. In the second place, although medication will not effect a cure nor prevent a fatal ending, certain remedies are useful. The phosphide of zinc, in a case under my observation was unmistakably and decidedly beneficial. Hammond recommends the chloride of barium. S. Weir Mitchell has given the bichloride of mercury with advantage.

Softening of the Brain.

The term softening of the brain is often used in a vague sense popularly, and sometimes by practitioners, to signify a condition of mental weakness. Not only is this clinical use of the term inexact, but we are unable now to attach any definite pathological significance to cerebral softening as such. Cerebral softening may result from a variety of conditions, and represent various morbid processes. Even when the softening is defined as red, white, or yellow, it is not rendered clear what the real nature of the process is. A yellow color may be due to the presence of altered blood-pigment, of granular corpuscles with fatty degeneration, and of pus-cells. Thus yellow softening may follow embolism or thrombosis, with hemorrhage or without hemorrhage; it may be the sequel of primary capillary hemorrhages, and of primary or secondary encephalitis. A red color is due to the presence of blood, and red softening may result from a primary hemorrhage, a hemorrhagic infarction, or an encephalitis. The name white softening is often applied to necrobiotic softening (from embolism or thrombosis) both in its early and in its later stages, to œdema of portions of the brain, and to hydrocephalic softening (see Tuberculous Meningitis). As the term softening simply designates a physical condition which may attend a variety of processes, both inflammatory and non-inflammatory, it has been recommended, in order to avoid confusion, to discard its use altogether as a name for any pathological process. As it has been adopted, however, so generally and for so long a time, it will probably continue to be used. When employed, it is desirable that some other epithet than simply that indicating the color

should be added, such as embolic yellow softening, embolic red softening, inflammatory red softening, hydrocephalic white softening, etc. It may be borne in mind that when the expression yellow or white softening is used without further definition, the form is probably meant which results from alterations in the bloodvessels (embolism, thrombosis, atheroma), as it is the form which is most frequent, the origin of which is best understood, and that in which the morbid changes are most constant. In view of what has been said, it is hardly necessary to add that softening of the brain can no longer be treated as a special disease. Its various forms have received appropriate consideration in preceding portions of this work.

Tumors within the Cranium.

Most of the tumors which have been found in other parts of the body may also develop within the brain. Among the most frequent and characteristic of cerebral tumors is *glioma*. It develops from the cerebral substance, and not from the membranes. It is met with elsewhere only in the spinal cord and retina. It is the sarcoma of the brain, differing from ordinary sarcomata by the presence of that finely fibrillated and molecular connective substance called neuroglia. A peculiarity of glioma is that it often appears more as a diffuse infiltration than as a circumscribed growth. The consistence of the tumor may be either hard or soft. The hard variety may be mistaken for cerebral sclerosis, the soft for cerebral softening. The tumor is often very vascular and may be the seat of hemorrhages. Sometimes the hemorrhage is so great as to destroy the larger part of the tumor, and to present the appearance of a primary cerebral hemorrhage. In such a case the microscopical examination of the tissue immediately surrounding the hemorrhage will usually reveal gliomatous structure. In some cases of glioma can be demonstrated large numbers of the branching cells, called brush-cells and spider-cells, which characterize the normal neuroglia. In other cases the tumor seems to consist chiefly of small round cells imbedded in a finely fibrillated granular matrix. In the latter cases, proper methods of demonstration will often reveal the characteristic branching cells. Glioma is often combined with sarcoma, constituting the so-called *glio-sarcoma*. All varieties of *sarcoma* may develop in the brain, either as primary or as secondary growths. They may originate either in the membranes or in the brain-substance. *Gummata* are among the most important of cerebral tumors. They take their origin almost invariably from the membranes, but not infrequently grow from the pia mater into the brain-substance. They also form in many cases diffused growths. They are usually combined with chronic inflammatory changes (gummatous meningitis). They usually present spots of cheesy degeneration. Other manifestations of cerebral syphilis are syphilitic endarteritis and syphilitic encephalitis. The endarteritis is of the obliterating form. It is not characteristic of syphilis. *Solitary tubercles* consist of nodules, varying in size from a pea to an apple, which present a cheesy centre and a periphery of connective tissue rich in small round cells. In the peripheral zone there are sometimes endothelioid cells and giant-cells. Only in a minority of cases do these solitary tubercles seem to be composed of conglomerated tuberculous granula. Tubercles may be present in other parts of the body. Solitary tubercles may occur in any part of the brain. They are found with especial frequency in the cerebellum. The propriety of calling these nodules tubercles is a matter of dispute. The brain and its meninges are a rare seat of secondary *carcinoma*. Tumors presenting a structure very similar to carcinoma may develop primarily in the membranes. They are considered by some writers to take their origin from endothelium in the

periarterial sheaths. The tumor called *cholesteatoma* is misnamed, as it by no means always contains cholesterin. The appearance of cholesterin is afforded by the presence of flat epithelial-like cells, often arranged in concentric masses. *Psammoma* derives its name from the presence of little calcareous granules resembling particles of sand. The calcareous masses often present a concentric arrangement. They appear to be connected with the bloodvessels. The two latter varieties of tumor grow from the membranes, especially from the dura mater. Of other intra-cranial tumors, may simply be mentioned fibroma, myxoma, lipoma, lymphoma, osteoma, angioma, neuroma, papilloma. The reader is referred to Part First, page 43 *et seq.*, for a brief consideration of most of the tumors found in this situation. In this connection may be mentioned the occurrence in the brain of the parasites, cysticercus cellulosæ and echinococcus. The cerebral arteries are occasionally the seat of aneurism, aside from those distinguished as miliary. Aneurismal tumors are generally connected with arteries at the base of the brain, the basilar, the internal carotid, the middle cerebral, and the circle of Willis. Generally the tumors are small, but they are sometimes of the size of a pullet's egg.

The different tumors produce morbid effects by pressure on the brain, and their effects, thus produced, other things being equal, are proportionate to the size of the tumor and the rapidity of its growth. Special morbid effects depend on the situation of the tumor. But they cause additional injury to the brain either by exciting circumscribed cerebritis and thereby inducing softening of the brain-substance surrounding them, or by interfering with nutrition and thus leading to non-inflammatory softening; and as a result of the softening, hemorrhagic extravasation is not uncommon. These morbid effects are produced alike by different tumors; that is to say, the morbid effects have no relation to the particular kind of tumor. Hence, the kind of tumor in any case cannot be determined by the symptoms which it occasions. For this reason the several tumors are considered collectively, instead of receiving each a separate consideration.

Of the symptoms which accompany tumors within the skull, cephalalgia is usually a prominent symptom. The pain is frequently limited to a circumscribed space which sometimes, but not always, corresponds to the site of the tumor. Pain is prominent as a symptom in proportion as the tumor gives rise to circumscribed meningitis. Other cerebral symptoms, more or less prominent, are, vertigo, difficulty in preserving an equilibrium in walking, momentary loss of consciousness, tinnitus aurium, the feeling of formication, numbness in different parts of the body, and scintillations, hyperæsthesia of the surface followed by blunted sensibility, mental irritability, to which succeed dulness and progressive impairment of the faculties of the mind; sometimes active delirium, and, frequently, epileptiform convulsions. The so-called compelled movements, either backward, forward, or rotatory, or in a circle (circus movements), are sometimes, although rarely, observed. Vomiting may be a prominent symptom, occurring irrespective of the ingesta, and not accompanied by symptoms denoting gastritis. This symptom is apt to be prominent in the cases in which cephalalgia and vertigo are unusually marked.

Paralysis, more or less extensive, affecting the special senses and voluntary muscles, occurs sooner or later. Hemiplegia, generally incomplete, is a frequent form of the paralysis. In some cases the two sides are successively affected, constituting double hemiplegia. The hemiplegia may have been preceded by facial paralysis, and if the latter do not precede, it may either accompany or follow the hemiplegia. The tumor may be so situated

as to press upon certain of the cranial nerves exterior to the brain; the paralysis of the parts supplied by these nerves will then be on the same side as the tumor and opposite to the hemiplegia, whereas, if the paralysis be due to pressure of the tumor within the substance of the brain, the cranial nerves affected are those on the same side as the hemiplegia and the side opposite to the hemisphere in which the tumor is situated. The paralysis caused by pressure upon nerves beyond their central connections, have the distinctive characteristics of a peripheral paralysis. The affected muscles speedily lose electrical excitability. The paralyses may be limited to the seventh or *portio dura* nerve, or other of the cranial nerves may be involved. Loss or impairment of vision in one eye or both eyes occurs when the tumor either involves destruction of the optic nerve or interrupts its function by pressure. Paralysis of sensation on one side of the face results from similar effects upon the fifth nerve. The third and the fourth nerves may be involved; and not infrequently the paralysis affects, separately or collectively, the sense of hearing, of smell, and of taste.

The differences in different cases, as regards the parts affected with paralysis, of course depend on the seat of tumors, their size, and the direction in which they extend. With reference to the differential diagnosis of tumors and inflammatory softening or other lesions, the extension of the paralysis to different parts in succession, after variable intervals, is a highly significant fact. The paralysis affecting successively parts supplied by different cranial nerves, the members in some cases becoming affected first on one side and then on the other side, and the continued increase of the degree of the paralysis of different parts, point with significance to tumors, because such a history is in correspondence with their continued growth, and the progressively increasing amount of pressure and of destruction of cerebral substance. Aphasia, in some cases, is an effect of tumors, and this effect renders it probable that they affect the posterior portion of the third convolution of the left anterior cerebral lobe. The ophthalmoscope is useful in determining the existence of intra-cranial tumors. Morbid changes in the optic disks, either congestive, inflammatory or atrophic, are found in a very large proportion of cases, even although the vision be not appreciably affected. The ophthalmoscope may be therefore of much value in the diagnosis even before there are any subjective symptoms referable to the eye. Swelling of the optic papilla, producing the appearance called choked disk, is a result of intra-cranial pressure, and may occur wherever be the seat of the tumor. Choked disk is an important aid in diagnosis. There may be descending optic neuritis. Atrophy of the optic nerve may be either secondary to the foregoing, or a direct effect of the pressure of the tumor on the optic tract. The pupils are often dilated, and not infrequently they differ in size. With reference to the localization of tumors, the reader is referred to the article on the localization of cerebral lesions (*vide* page 675). It cannot be claimed, on the basis of clinical experience, that, by means of the so-called topical symptoms, tumors or other lesions can be always accurately localized. Aside from the imperfections of our present knowledge of the functions of the different parts of the brain, their relations with each other are such that a lesion in a particular situation may affect other situations more or less remote, and the parts thus secondarily affected may give rise to prominent symptoms. Nevertheless, experimental physiology and clinical observations have furnished facts which have led to some approximation to accuracy in localization.

The clinical history of abscess of the brain may present a series of events which render it difficult thereby to differentiate this affection from tumor. If the affection have followed speedily injury of the head, if it be connected with otitis, or if there be caries of the skull in any situation, the affection is pro-

bably abscess. If these etiological relations be wanting, tumor is more probable than abscess. Cerebral hemorrhage and softening from thrombosis or embolism, are distinguished by this fact, namely, paralysis with or without an apoplectic seizure, occurs suddenly without prodromes, whereas, paralytic and other marked effects of tumor occur in succession and after prodromic symptoms which have existed for a longer or shorter period. In cases of hemiplegia from the affections just named, nerves of the special senses, and other cranial nerves are rarely involved as they often are in cases of hemiplegic paralysis from tumor. Paralysis of the face on one side, and of the limbs on the other side (alternate paralysis) is far more likely to occur from tumor than from hemorrhage or softening.

With respect to the character of the tumor in individual cases, carcinoma is probable if the patient be of middle or advanced age, if cancer be hereditary, and if it exist elsewhere. The evidence afforded by the symptoms of a rapid growth of the tumor is in favor of the conclusion that it is carcinomatous. The tuberculous character of the tumor is to be inferred from the existence of tuberculous disease in the lungs and other organs, and from the youth of the patient. Tumors of this kind rarely occur after puberty or under three years of age. The syphilitic character of the tumor is rendered probable by the fact that the patient has had syphilis, and by the absence of evidence of carcinoma and tubercle. Aneurismal tumors rarely occur except in persons between fifty and sixty years of age.

As regards digestion, nutrition, and the functions of the body in general, cases differ. Patients may retain their weight and an aspect of health for a considerable period after the occurrence of paralysis and other symptoms referable to the brain. In other cases debility and emaciation occur early. The general condition will be likely to deteriorate speedily in the cases in which the tumor is either carcinomatous or tuberculous, other parts than the brain being the seat of the disease. It is to be added, that the tumors within the skull may remain latent, as regards both local and general symptoms, until they have attained to a considerable size. The slowness of their growth favors their latency. On the other hand, local morbid conditions incident to the growth of the tumors, namely, inflammation and softening of the surrounding brain-substance, congestions, circumscribed meningitis, and extravasation of blood, give rise, not only to paralysis affecting different parts in succession and progressively increasing in degree, but to exacerbations of pain and other cerebral symptoms, varying much in frequency and intensity in different cases; to somnolency or coma, in some cases, either of transient duration, or lasting for several days, and occasionally to active delirium.

The termination, in most cases of tumor within the skull, is, sooner or later, fatal, the duration of life varying much in different cases, according to the nature of the tumor, the rapidity of its growth, and the incidental local morbid conditions; in some cases, death takes place after a few months, and in other cases not until after many years. An exception to this statement is to be made in behalf of syphilitic tumors. These are amenable to curative treatment, if they have not attained to much size, and have not led to damage of the cerebral substance in proximity to them. Death may take place after gradual exhaustion; it may take place suddenly from cerebral hemorrhage; epileptiform convulsions sometimes determine the fatal termination; and patients sometimes die from secondary meningitis.

Syphilitic tumors offer much encouragement in the way of successful medicinal treatment. Cases in which are presented hemiplegia, paralysis of cranial nerves, aphasia, epileptiform convulsions, and delirium, are by no means hopeless, if the affection be traced to syphilis. I have met with instances success-

fully treated, in which these symptoms were present. It is vastly important to resort to anti-syphilitic treatment in all cases in which there is any ground for suspecting the previous existence of syphilitic disease.

The indications for the treatment of non-syphilitic tumors, relate to the palliation of symptoms and the prolongation of life by analeptic and supporting measures. It is not certain that any known remedies have a special influence upon the tumors themselves or the brain-lesions which they produce. It is, however, claimed that certain remedies, namely, the iodide of potassium, the bichloride of mercury, and arsenic do have such an influence in some cases. Trial may be made of these remedies, taking proper precautions as regards a deleterious effect upon the general condition of the patient.

In this connection may be introduced an account of a case which, from its being extremely rare, if not unique, and in view of the striking features of the clinical history, is of much interest. The case occurred in the practice of Prof. William H. Thomson. I saw the patient in consultation. The brain was exhibited at a meeting of the New York Pathological Society, June 12th, 1872. The white substance of the entire brain, more especially of the cerebellum, was infiltrated with bodies like grains of sand, generally of the size of a pin's head, but a few as large as a pea. They were composed of the carbonate and phosphate of lime. There were no appearances denoting meningitis, except that the arachnoid membrane of the superior part of the cerebrum was slightly opaque. There was no morbid effusion into the ventricles. The arteries were not atheromatous. The brain was notably anæmic. Other organs than the brain were not examined. The patient was a merchant aged about 40 years. Except that he was subject to attacks of gout, he had had good health up to Dec. 1871. He then became melancholic, and had delusions, fancying that he was financially ruined and that he had committed frauds. These passed away in about a month; he was afterwards taciturn, and the mind acted slowly, but he gave no evidence of mental derangement. A remarkable feature of the case was a tendency to extraordinary movements, and positions of the body. He often sat in bed with his head between the knees, and sometimes with his knees on the bed and his head on the floor. When not in these positions, much of the time he performed saltatory movements, not infrequently throwing himself out of bed, so that constant watching to prevent this became necessary. Sometimes he performed a somersault on the bed. These movements were voluntary, not convulsive or automatic, but under an uncontrollable impulse (compelled movements). He never complained of pain either in the head or elsewhere. He ate well, and the digestion was good, until near the end of life. There was no paralysis except of the bladder. The urine was withdrawn by the catheter twice daily for five months; but, towards the close of life, he recovered the ability to expel it by his own efforts. Examinations of the urine for the evidence of renal disease were negative. A few days before his death he became comatose, and died in that condition. The duration of his illness was about six months.[1]

Chronic Bulbar Paralysis. Glosso-labio-laryngeal Paralysis.

This form of paralysis was described first by Duchenne in 1860 under the name "progressive muscular paralysis of the tongue, the palate, and the lips." Since that date a variety of names have been proposed, among which may be mentioned chronic progressive bulbar paralysis, progressive bulbo-nuclear

[1] For a fuller report of this case, *vide* New York Medical Record, Aug. 15, 1872.

paralysis, progressive atrophic bulbar paralysis, glosso-labio-laryngeal paralysis. The disease is characterized by progressive paralysis and atrophy of the muscles of the lips, tongue, soft palate, pharynx, and larynx. The symptoms and the anatomical lesions are analogous to those of progressive muscular atrophy, with which, in fact, chronic bulbar paralysis is not infrequently combined. The anatomical basis of chronic bulbar paralysis is to be found in an atrophy of ganglion-cells belonging to the nuclei of origin of certain motor nerves of the medulla oblongata. The topographical distribution of the anatomical lesions has been recently described with accuracy by Duval and Raymond.[1] While there is no doubt that the essential change is an atrophy and disappearance of motor ganglion-cells, it is not certain whether the morbid process consists in a primary atrophy of these cells, or in a primary interstitial myelitis with secondary degeneration of the nerve-cells. The medulla oblongata may present no distinct alterations to the naked eye, or, perhaps, there may be detected a few ill-defined gray and atrophic spots near the floor of the fourth ventricle. Microscopical examination is required for an accurate localization and study of the lesions. Atrophy and disappearance of the ganglion-cells have been found in the main and accessory nuclei of the hypoglossal nerves, in the motor (anterior) nuclei of the pneumogastric, spinal accessory, and glosso-pharyngeal nerves (called the mixed nerves), in the inferior (anterior or proper) nucleus of the facial, and in the motor (masticatory) nucleus of the trigeminal nerves. The changes are bilateral. Of these nuclei the main nucleus of the hypoglossus seems to be earliest and most extensively involved. Sometimes it possesses not a single ganglion-cell. Some of the above-named nuclei may escape—for example, the motor nucleus of the fifth nerve. In the process of atrophy the ganglion-cells become rounded, devoid of processes, filled with pigment, diminished in size, and finally they disappear. In the nuclei of origin, some increase of the neuroglia (interstitial myelitis), corpora amylacea, and granular corpuscles usually attend the degenerative changes in the ganglion-cells. The degenerated spots are most readily recognized on microscopical sections stained with carmine by their red color which is deeper than that of the normal parts. The nerve-fibres in the roots and trunks of the nerves, whose centres of origin are affected, undergo, to a greater or less extent, degeneration and atrophy. Although the muscular fibres in the tongue are atrophied, the organ may preserve nearly its normal dimensions in consequence of a formation of fat-cells in the interstitial tissue, a change recognized by the yellow color on section. The atrophy which takes place in the muscular fibres in this affection, is of the same nature as that to be described for progressive muscular atrophy.

Clinically, the disease is characterized by progressive diminution of voluntary power over the tongue, the muscles of the palate, and the lips. The disease commences insidiously. The paralytic effects are bilateral and symmetrical. The loss of power, at first slight, gradually increases. After a time there is much difficulty in articulation; the patient is unable to pronounce words and the letters of the alphabet, more especially the consonants requiring for their enunciation movements of the tongue and lips. Speech at length is impossible, and the only means of communication is by signs or writing. The paralysis of the orbicularis oris renders the lips immovable during emotions of grief or mirthfulness; the mouth is elongated and gives to the face an expression as if about to weep. The saliva is increased and dribbles over the lips. Food collects between the teeth and cheeks, and the fingers are

[1] Duval et Raymond, Paralysie labio-glosso-laryngée, Arch. de Phys. norm. et path., 1879, p. 735.

required to dislodge it. The ability to protrude the tongue or to curl the tip upward is lost. When the paralysis of the tongue and orbicular muscles of the mouth has increased to a certain extent, or even from the outset, and before the paralysis has extended to the lips, the muscles of the palate are affected. Deglutition then is more or less difficult, food and drink being often returned through the nostrils. The laryngeal muscles become paralyzed, causing aphonia, and either diminution or cessation of the respiratory movements of the glottis. Paresis of the muscles of respiration may follow; the acts of respiration are feeble, and the power of coughing is impaired.

Portions of food and drink, and the salivary fluids, are apt to be drawn into the larynx, and are with difficulty expelled owing to the inability to cough effectively. For this reason, if the patient be attacked with bronchitis, there is danger from the accumulation of mucus in the bronchial tubes. Paralysis may occur in other parts of the body, and may extend, more or less, over the voluntary muscles. The progress of the affection is unattended by fever. The affection advances steadily, but more or less gradually, toward a fatal termination. Death may be caused by apnœa from impaired ability to carry on respiration, and accumulations in the bronchial tubes; or the mode of dying is by asthenia, or starvation, in consequence of inability to ingest a sufficient amount of aliment to sustain life. At an advanced period the action of the heart may be notably disturbed. Paroxysms of feeble, irregular action, together with cyanosis, sometimes occur, and death may take place by syncope.

The intelligence remains unaffected. The paralyzed muscles, in most cases, until an advanced period of the disease, retain electrical excitability. Reflex excitability is generally lost, but in some instances it is retained, and in rare instances increased. The paralyzed muscles become more or less atrophied. The general sensibility of the mouth, tongue, and pharynx is not affected; the gustatory sense and the other special senses are preserved; the appetite and digestion may be unimpaired.

The affection is readily distinguished from double facial paralysis (*diplegia facialis*), by the fact that the orbicular muscles of the eye and the muscles of the face, other than the orbicularis oris, are not affected. In its progressive character and the occurrence of paralysis in other situations, it bears a resemblance to general cerebral paralysis, in which the muscles concerned in speech are apt to be first affected. It differs from the latter affection in the fact that the intellect remains unaffected; and paralysis of other muscles than those of the tongue, mouth, pharynx, and larynx, occurs incidentally in only a certain proportion of cases. The group of symptoms which characterize bulbar paralysis may occur in the course of progressive muscular atrophy. In the latter disease, however, the muscles of the extremities or trunk are first affected. In other words, spinal disease precedes that of the medulla oblongata. Chronic bulbar paralysis may be followed by progressive muscular atrophy. In like manner the spinal diseases, called *amyotrophic lateral sclerosis* and *disseminated sclerosis of the cord*, may involve by extension the medulla oblongata, and give rise secondarily to the symptoms which belong to the history of bulbar paralysis. Embolism or thrombosis of the vertebral arteries, occluding the branches going to the medulla oblongata, and hemorrhage limited to the latter, have been known to cause the same group of phenomena which characterizes bulbar paralysis. The differential points pertaining to thrombosis and hemorrhage are, the sudden occurrence of the paralysis of the tongue, lips, and pharynx, and the occurrence simultaneously of paralysis either unilateral or bilateral of the limbs. The name acute bulbar paralysis has been applied to these cases. (Page 678.) Tumors in the medulla oblongata, in connection with the symptoms of bulbar paralysis, give

rise to those denoting cerebral disturbance and to ophthalmoscopic appearances which are wanting in the latter disease.

With reference to causation, the fairest statement is a confession of ignorance. The disease very rarely occurs before 40 years of age, and the male is more liable to it than the female sex. Occupation and station in life have no causative influence. Beyond these facts nothing can be positively affirmed in regard to the etiology. It is, however, reasonable to suppose that exposure to cold, excesses of all kinds, over-exertion, either physical or mental, and, perhaps, syphilis, have more or less agency in the development and progress of the disease.

In chronic bulbar paralysis involving irrecoverable anatomical changes in the medulla oblongata, all that can be hoped for is that the disease will cease to be progressive, or, next to this, if the progress continue, that it will be slow. The extreme limit of the duration of the disease is five years. The prognostics which show the fatal termination to be not far distant are, complete dysphagia, great debility from inanition, embarrassment of respiration, and syncopal disturbances of the heart's action.

The objects of treatment are, *first*, the arrest of the progress of the disease, and, *second*, if this object be unattainable, retardation of its progress. With reference to these objects, the patient should, as far as possible, be withdrawn from every agency which may be supposed to have a causative operation. All unsanitary influences pertaining to body and mind are to be removed. The system should be well nourished, and measures employed for restoration of the general health, if this be in any way impaired. These injunctions embody, perhaps, the most important part of the treatment, with our present knowledge. It is not certain that any remedies have a special influence on the disease. An able observer (Erb) warns against the administration of strychnia and phosphorus. Yet the latter is undoubtedly useful in some cases of a similar disease seated in the spinal cord, namely, progressive muscular atrophy, and also, in multiple sclerosis. It is doubtful if much benefit be derived from the nitrate of silver, the iodide of potassium, ergot, and belladonna, but it is proper to make trial of these remedies. There is very little ground for expecting benefit from counter-irritation. Most neurologists attach importance *par excellence* to electricity, but it does not seem, thus far, to have effected great results. Persistent trial of this agent, however, is not to be omitted.

When deglutition becomes extremely difficult, nourishment should be introduced into the stomach by means of the œsophageal tube, and rectal alimentation may be resorted to.

Acute bulbar paralysis, so called in cases of embolism or thrombosis of branches of the vertebral arteries going to the medulla oblongata, or of hemorrhage in this situation not sufficient to cause death, offers a better prospect of improvement and recovery than the chronic affection which is generally understood when the term bulbar paralysis is used. For an account of the acute affection, *vide* "Localization of Cerebral Diseases," page 678.

General Cerebral Paralysis of the Insane. Dementia Paralytica. Diffused Interstitial Cerebritis.

The characteristics of the disease designated by these names are, mental derangement and gradual impairment of motion. The mental disturbance is characterized by extravagant delusions, terminating in more or less complete dementia; the motor disturbance by incomplete paralysis (paresis) of the

face and extremities often combined with ataxic phenomena. Various lesions have been found after death both in the brain and spinal cord. From the frequency with which chronic diffuse inflammation of the pia mater and the convolutions of the frontal and parietal lobes of the brain have been found, the disease has been called chronic interstitial cerebritis, diffused meningo-encephalitis, or meningo-periencephalitis.

The pathological changes which have been most frequently observed are, hemorrhagic pachymeningitis, opacity and adherence of the pia mater over the anterior portion of the cerebrum, atrophy of the cortical substance of the frontal and parietal lobes, dilatation of the ventricles with granular ependymitis, chronic spinal meningitis, and degeneration of one or more of the columns of the spinal cord, most frequently of the posterior columns. In exceptional cases other lesions have been found, such as extension of the chronic encephalitis to other parts of the cerebrum and to the cerebellum, and insular sclerosis of the brain and spinal cord. Most attention has been paid to the changes in the cortex of the anterior part of the cerebrum. According to L. Meyer,[1] in the early stages the convolutions in this region are swollen, congested, and softened in certain spots. He found evidence of inflammation in the presence of large numbers of emigrated cells, especially around the bloodvessels. In chronic cases the frontal and parietal convolutions are found in many instances, though not constantly, atrophied and firm, and the pia adherent. Sometimes little holes and depressions filled with serum are present in the convolutions. The microscopical examination reveals increase of the neuroglia, pigmentary atrophy of the ganglion-cells, hyaline transformation of the coats of the bloodvessels, and the presence of round and granular cells, especially in the neighborhood of the vessels. These changes are more marked in certain places than in others. They may extend to the medullary substance, and may involve the lenticular nucleus. The changes in the spinal cord may resemble those of locomotor ataxia, those of the secondary degenerations of Türck, or may be irregularly distributed. According to some writers the alterations in the spinal cord are to be regarded as complications, and the essential process is to be ranked as a diffuse interstitial encephalitis.

The development of this affection is generally very gradual. As a rule, the primary symptoms are those which denote mental disorder. Motor disturbances follow after a variable period; or they may be coincident with the symptoms referable to the mind, and they occasionally precede the latter.

The evidence of mental aberration in the incipiency of the affection is generally extravagance in ideas and actions, which, for a time, may pass simply for eccentricities. Persons talk and act in a manner inconsistent with their previous character. Memory of recent events is impaired. Tremulousness of the tongue when protruded, and of the muscles of the face in speaking are early symptoms. The articulation is thick, as in partial intoxication, and is characterized often by dropping of syllables.

Sooner or later, insanity is evident. The insane delusions are generally characterized by egotistical exaltation. The patient, in imagination, has become enormously rich, or is some distinguished personage, or the recipient of some extraordinary good fortune (*délire des grandeurs*). The delusions are not fixed but constantly shifting. Paroxysms of mania are not infrequent, and they may lead to homicide. Melancholia may at times take the place of the ideas of grandeur, and, in rare instances, is the prevailing character of the insanity.

The paralysis is general, and progresses more or less slowly. It is mani-

[1] L. Meyer, Virchow's Archiv, Bd. 58.

fested by a shambling, tottering gait in walking, by the body, in standing, being poised on the legs widely separated. The patient is apt to stumble in walking, and, after falling, is unable to rise without assistance. Paralysis of the upper limbs is shown by defective power of grasp and by clumsy movements of the fingers. The muscles of the face are affected, so that the facial expression is lost. Tremor of the lips and dribbling of saliva are among the characteristic symptoms. General sensibility is often more or less blunted. The special senses, as a rule, are not notably affected. The pupils are usually dilated. They are unequal in size, and their reaction is sluggish. The ophthalmoscope shows, at an early period, hyperæmia of the optic disk, and, afterward, neuro-retinitis.

The functions of the body, irrespective of mental disorder and paralysis, may be for a considerable period but little, or not at all, disturbed. The appetite and digestion are frequently unaffected. The pulse is regular. The temperature has been observed to fall below the normal range. The paralyzed muscles respond to the electrical current.

In the advanced stage of the disease, the paralysis increases to such a degree that there is inability to walk or stand, and there is mental imbecility. This is the stage of dementia. The patient passes the evacuations in bed, and is insensible to ideas of cleanliness and decency. The limbs, in some cases, become contracted. Difficulty of deglutition now becomes a feature more or less prominent, and sudden death has repeatedly been caused by the impaction of food in the pharynx. Death, if not caused by this accident or some intercurrent affection, is a result of either extreme exhaustion gradually induced, or of inability to carry on respiration from paralysis of the respiratory muscles.

During the progress of the disease, sudden attacks of coma are liable to occur, from which the patient may emerge and nearly regain his condition prior to the attack, but, in the majority of cases, the coma is the forerunner of death. Epileptoid seizures are common. The convulsions are less marked than in epilepsy. An aura, epileptic cry, and biting of the tongue are wanting. Sudden hemiplegia is another event which is apt to occur. From this not infrequently the patient recovers after free purgation, and in some cases frequent hemiplegic attacks take place, which may affect alternately the two sides. Another form of sudden attack consists of a notable increase of the general paralysis, without unconsciousness. Remissions, in the course of the affection, as regards the mental derangement and the paralysis, either or both, have been observed. The improvement manifested in these remissions is sometimes such as affords a delusive hope of recovery.

The prognosis is extremely unfavorable. A few cases of recovery are on record, and in these cases the affection had not progressed far. There is scarcely any ground for holding out encouragement as regards recovery. In a large proportion of cases death is due to some intercurrent affection. If the muscles of the chest have become notably affected, any pulmonary affection is likely to prove fatal. Even ordinary bronchitis, under these circumstances, occasions much embarrassment of respiration from the accumulation of mucous secretion within the bronchial tubes, and it may prove fatal.

The duration of this affection is extremely variable. Patients sometimes live for many years in a condition of either incomplete or complete dementia. In the great majority of cases, however, death takes place within the space of three years, and the affection sometimes proves fatal within a few months or even weeks. Death may occur, of course, at any time from intercurrent affections.

General paralysis of the insane occurs much oftener in males than in females. In the great majority of cases the age is between thirty and fifty;

but the affection occurs at all periods of life. There seems to be ground for imputing the affection, in a considerable proportion of cases, to painful moral shocks arising from loss of friends, disappointment, bankruptcy, remorse, etc. In a certain proportion of cases it has been attributed to intemperance.

This disease is to be discriminated from general spinal paralysis. The former is dependent on cerebral lesions; hence, differential points are mental disorder in connection with the latter, and paralysis of muscles supplied by cranial nerves, whereas in spinal paralysis insanity does not occur except by accidental association, and the facial muscles are not affected. The affection known as progressive locomotor ataxia presents some analogous features. As will presently be seen, however, the latter is not a paralysis, but its distinctive feature is deficiency of the power of co-ordinating voluntary movements. Moreover, insanity does not belong to the natural history of this affection, and groups of the voluntary muscles are affected, not simultaneously, but successively. The affection which will presently be noticed under the name progressive muscular atrophy, differs essentially in the fact that the loss of muscular power is due to an atrophic lesion of the affected muscles. It is only, however, within late years, that the form of paralysis under consideration has been clearly separated from the three affections just named, and the latter distinguished from each other.

The great majority of patients affected with paralysis of the insane, sooner or later are received into hospitals for the insane. Not only is there scarcely any ground for curative treatment, but permanent improvement is hardly to be hoped for. The treatment consists of palliative measures, together with the regulation of diet, regimen, etc., with a view to retarding the progress of the affection and contributing, as far as practicable, to the comfort of patients during its progress.

CHAPTER IV.

INFLAMMATORY AND STRUCTURAL DISEASES OF THE SPINAL CORD.

Myelitis—Acute and Chronic. Cerebro-spinal Sclerosis. Locomotor Ataxia or Posterior Spinal Sclerosis. Anterior Poliomyelitis. Spinal Amyotrophic Affections. Acute Anterior Poliomyelitis. Acute Anterior Poliomyelitis in the Adult. Chronic Anterior Poliomyelitis. Progressive Muscular Atrophy. Progressive Unilateral Facial Atrophy. Spasmodic Spinal Paralysis. Amyotrophic Lateral Sclerosis. Compression of the Spinal Cord. Intra-spinal Tumors. Pseudo-hypertrophic or Myo-sclerotic Paralysis. Scleroderma.

Myelitis.

INFLAMMATION of the substance of the cord is called *myelitis*. Myelitis appears as an *acute* and as a *chronic* affection. These two forms, however, cannot be sharply discriminated in all cases, since acute myelitis often passes into the chronic form. Other divisions are based upon the extent of the inflammation and the part of the cord involved. Thus the inflammatory changes may be either circumscribed, diffuse, or disseminated; the white matter, the gray matter, or both, may be affected; the disease may tend to extend transversely or in a longitudinal direction. When both white and

gray matter of the greater portion of the cord are inflamed, the process is called *diffuse myelitis;* when the inflammation affects only or chiefly the gray matter, the disease is *central myelitis;* and, when confined to the anterior horns of gray matter, it is *anterior poliomyelitis* or *anterior cornual myelitis.* In *transverse myelitis* the whole thickness of the cord over a circumscribed space is involved; *cortical myelitis* or *meningo-myelitis* is the name given to inflammation of the peripheral portion of the cord, the inflammation being consecutive to spinal meningitis. When a number of separate foci of inflammation exist in the cord, the change is designated as *disseminated* myelitis. Myelitis extending from below upward is denominated *ascending,* extending from above downward *descending.*

As regards the tissue primarily affected, Charcot, following Virchow's classification, distinguishes two varieties of myelitis, namely, *interstitial* and *parenchymatous myelitis.* In *interstitial myelitis* the connective tissue or neuroglia is first inflamed, and the nerve elements suffer secondarily; in the parenchymatous form the ganglion-cells and nerve-fibres are primarily involved, and the interstitial changes are secondary. The final result in both cases is the same. Leyden and other writers do not recognize the parenchymatous form, but consider most of the so-called parenchymatous myelitides as degenerative at the outset.

The gray substance of the cord, on account of its greater vascularity and functional importance, is more frequently the seat of primary myelitis than the white matter. Inflammation of the gray matter is particularly prone to extend in the vertical direction (central myelitis).

Acute myelitis, in the majority of cases, appears under the form of softening of the cord; chronic myelitis, on the other hand, as induration or sclerosis. The changes which characterize acute myelitis will be described first, and then those of the chronic form. Softening and acute myelitis are not to be regarded as synonymous, since there exists non-inflammatory as well as inflammatory softening of the cord. Exceptionally, the consistence of the acutely inflamed cord is found to be normal or even increased. The color also varies. It may be that of the normal cord, in which case, if the consistence be unchanged, the existence of inflammation can be determined only by microscopical examination. Most frequently the color is reddish or yellow; in cases of more prolonged duration, it may be grayish or white. The red color is due to the presence of blood. In very acute cases of central myelitis, the softened part may contain so much extravasated blood as to present the appearance of a primary hemorrhage into the cord. The name *hemato-myelitis* is given by Hayem to cases of acute myelitis attended by extensive hemorrhage. From the sudden development of the symptoms it is also called *apoplectiform myelitis.* The stage of red softening gradually gives place to that of yellow softening. The yellow color is due to alterations in the blood-pigment, to fatty degeneration, and to the presence of pus-cells and granular corpuscles. The affected portion of the cord is usually, but not always, swollen. The pia-arachnoid membrane is, as a rule, involved to some extent in the inflammatory process. The dorsal and the lumbar regions of the cord are the favorite seats of the disease.

The microscopical examination, in cases of acute myelitis, reveals dilatation of the bloodvessels, extravasated red blood-corpuscles, granular corpuscles, fat granules, pus-cells, disintegrated nerve-fibres and nerve-cells, swollen and apparently proliferating neuroglia cells, granular material, especially around the vessels (regarded by Lockhart Clarke as coagulated albuminous exudation, and called by him "granular disintegration"), blood-pigment, and corpora amylacea. In the early stage, and in the neighborhood of softened foci in the later stages, the axis-cylinders of some of the nerve-fibres are

much swollen, presenting the appearance called varicose or fusiform hypertrophy. The ganglion-cells also may be found swollen, spherical, pigmented, and devoid of processes. They finally undergo atrophy and disappear. The recognition of the granular corpuscles (also called fat-granule bodies, inflammatory corpuscles of Gluge) is of great assistance in distinguishing ante-mortem softening from the softening so often produced artificially in removing the cord. These corpuscles are usually spherical or oval in shape, vary greatly in size, and are so densely filled with small fat-globules as to appear opaque by transmitted, and bright by reflected, light. They may be formed from emigrated white blood-corpuscles, from neuroglia-cells, from cells in the walls of the bloodvessels, and, perhaps, in other ways. They are not distinctive of inflammation, but may be present in simple degenerative processes.

If acute myelitis pass into the chronic stage, the red and the yellow give place to white softening. Cysts filled with a whitish, milky fluid may be formed as in cerebral softening. By absorption of the inflammatory exudation, by atrophy of the nerve-elements and the production of fibrillated connective tissue, acute myelitis may terminate in sclerosis, as has been demonstrated by Leyden. It is probable that very mild cases of myelitis may be followed by complete restoration to the normal condition. Certain observations tend to show that nerve-fibres in the cord, which have been destroyed by the myelitic process, may be regenerated. Suppuration or abscess is an extremely rare form or termination of acute myelitis, and, when present, is either pyæmic or consecutive to suppurative processes in the membranes, vertebræ, or surrounding parts.

Transverse myelitis of sufficient duration (probably at least a month) is followed by the secondary degenerations of Türck. These degenerations affect both centripetal and centrifugal fibres, and are therefore ascending and, when the myelitic focus does not reach the lower extremity of the cord, descending. The ascending degeneration occupies the columns of Goll, and the direct cerebellar fasciculi (situated in the periphery of the posterior part of the lateral columns); the descending degeneration follows the course of the pyramidal fasciculi of the anterior and of the lateral columns (the former in the median part of the anterior, the latter in the posterior part of the lateral columns). These tracts, when degenerated, appear gray, and finally atrophied, the process consisting in a gradual atrophy of the nerve-fibres combined with increase of the neuroglia and the appearance of granular corpuscles. When the myelitis occupies the whole thickness of the cord, the degenerations are bilateral. Myelitis confined to one half of the cord is very rare.

Chronic myelitis includes, according to common usage, the processes also called sclerosis and gray degeneration. It is characterized by proliferation of the neuroglia-elements, resulting in the production of fibrillated connective tissue and the atrophy of nerve elements. Granular corpuscles and corpora amylacea may also be present. The consistence of the affected part is usually firm, its size diminished rather than swollen, its color gray. Sometimes there are no morbid changes visible to the naked eye. As regards their clinical history, certain cases of slowly developing softening of the cord are to be referred to chronic myelitis, although Leyden considers all instances of inflammatory softening of the cord as acute in their origin.

Chronic myelitis embraces affections of the cord which vary greatly as to localization, extent, and nature of the pathological process. Certain forms have an exact localization, and follow the course of certain definite groups of nerve-fibres and of nerve-cells, others are characterized by irregularity in distribution and extent. Of the forms which have more or less of an exact localization, may be mentioned posterior spinal sclerosis or locomotor ataxia,

primary lateral sclerosis, and chronic anterior poliomyelitis (embracing spinal paralysis of infants and adults, and progressive muscular atrophy). These will receive separate consideration. The secondary degenerations of Türck are also regarded by many writers as the result of chronic myelitis. The name *funicular sclerosis* is given to sclerosis following certain definite columns of the cord, such as lateral and posterior spinal sclerosis. It is probable that in these cases the primary change is in the nerve-fibres, whether of the nature of parenchymatous inflammation or of degeneration is uncertain. Otherwise it would be difficult to understand why inflammation should be confined to the course of definite nerve-tracts. The most important examples of chronic myelitis with irregular distribution are, chronic transverse myelitis, circumscribed sclerosis, and disseminated or multiple sclerosis. Multiple sclerosis will be considered separately, as it has a well-defined clinical history. Myelitis resulting from slow compression (angular curvature resulting from Pott's disease, cancer of the vertebræ, intraspinal tumors) is usually of the ordinary transverse variety and accompanied by secondary degenerations.

The clinical history of *acute myelitis* presents variations corresponding to those which belong to the anatomical characters of the disease. The latter furnish the interpretation of the former, and, from the symptoms, the seat of the inflammation, its extent, and the particular parts of the cord which are involved, may be inferred with considerable accuracy. Certain symptoms belong alike to acute spinal meningitis and to acute myelitis. In many, if not in most, cases, these two affections are associated. In meningitis, the inflammation extends from the membranes to the cord, and in myelitis the membranes are likely to be secondarily involved. Practically, at the bedside, having diagnosticated an acute intra-spinal inflammation, exclusive of intra-cranial inflammatory diseases, the diagnostic problem which remains is to differentiate myelitis from meningitis, that is, to decide that the inflammation has its origin and is predominant in the cord. The symptoms, therefore, which distinguish myelitis from spinal meningitis especially claim attention.

Disorders of sensation are apt to be the first local symptoms. These are, pain in the back, the sensation of a girdle around the trunk and tenderness over certain of the vertebræ. Preceding paralysis, the muscles which are to be paralyzed are sometimes affected with tremor or spasms.

The early occurrence of paralysis is a distinguishing feature. It occurs within a day or two, and sometimes within a few hours, after the symptoms have pointed to a spinal affection. In most instances the form of the paralysis is paraplegic, showing the seat of the affection to be in the dorsal or the lumbar portion of the cord. According to the seat at the outset or the subsequent extension of the inflammation upward (ascending myelitis), the muscles of respiration may be affected and the upper extremities. The speedy occurrence of paralysis is evidence of the cord being primarily affected. Sudden and complete paralysis denotes that the myelitis is central and accompanied by hemorrhage (hæmato-myelitis).

Paralysis affecting the bladder and rectum is more constant and occurs earlier in myelitis than in spinal meningitis. Loss of cutaneous sensibility is more frequent in the former than in the latter. It is rare for sensory paralysis to be wanting. Its absence shows that the myelitis does not involve the posterior columns of the cord. Sensation may not be lost, but more or less diminished, and it may be characterized by retarded transmission of sensory impressions. Exceptionally there is cutaneous hyperæsthesia, this being attributable to complicating meningitis. Priapism is a symptom of not in-

frequent occurrence. Symptoms relating to reflex movements are of significance as regards the localization and the extent of the lesions. The continuance or increase of the reflex movements shows either that disorganizing changes have not taken place, or that the disorganization has not extended to the lower end of the spinal cord. On the other hand, loss of reflex excitability is an effect of destruction of the gray matter in the lower part of the cord. This extension is shown by the loss of reflex excitability after the occurrence of the motor paralysis.

Spasm of the muscles of the lower extremities, constituting the so-called spinal epilepsy of Brown-Séquard, is a prominent symptom in some cases of transverse myelitis not involving the lower lumbar region.

If life be sufficiently prolonged for wasting of the paralyzed muscles to take place, this is proportionate to the destruction of the gray matter of the cord, and in proportion as wasting occurs, the electric excitability of the muscles is lessened.

In myelitis earlier and in a greater degree than in spinal meningitis, the parts exposed to pressure—sacrum and trochanter—take on gangrenous inflammation. Not infrequently this occurs within a few days after the attack. The urine is retained and within a short period becomes alkaline. The presence of muco-pus shows the existence of cystitis.

Fever, in cases of acute myelitis, is rarely high, and generally of a low grade. The propriety of the term acute, in this connection, has reference to the rapid development of grave symptoms, rather than to the elevation of temperature and other evidence of constitutional disturbance. Fever symptomatic of gangrenous inflammation (septic fever) and of cystitis, occurs in the progress of the disease.

Acute myelitis may run a rapid course, destroying life in a few days; or death may take place as a result, in part, of gangrenous inflammation and cystitis after the lapse of several weeks. Complete recovery is rare. In a certain proportion of cases the disease becomes chronic. It may end in more or less complete atrophy of the cord, and patients may live indefinitely with a permanent paraplegia, the general health being good.

In the foregoing account of the symptomatology of acute myelitis, reference has been had especially to the parts involved in the differentiation from acute spinal meningitis. These points have been already referred to in the account given of the latter disease (*vide* page 705). The affection to be noticed in connection with the functional affections of the spinal cord, called acute ascending paralysis (*vide* Chapter V.), closely resembles acute ascending myelitis, and the differentiation is not easily made prior to the autopsy. The symptoms which relate to reflex and electrical excitability, the paralysis of the bladder and rectum, the occurrence of cystitis and of bed-sores at an early period, are sufficiently characteristic of acute myelitis as contrasted with so-called systemic reflex and functional paralysis. Acute myelitis, the inflammation limited to the anterior horns of the gray matter of the cord (anterior poliomyelitis) constituting the affection known as infantile paralysis, and an analogous affection in adults, will be considered separately in this chapter.

Acute myelitis is an exceedingly rare disease, especially if cases of traumatic origin be excluded. Aside from injuries of the cord from fractures, contusions, penetrating wounds, etc., prolonged exposure to cold, as in sleeping upon damp ground, seems to be the only cause clearly apparent. The adequateness of other agencies supposed to be causative, such as muscular efforts, excessive venery, and exposure to a high temperature, is promblematical. The disease occurs when it cannot be traced to any causative agency.

The treatment in the early stage of acute myelitis has for its objects diminution of the intensity of inflammation, and the prevention of disorganization

therefrom resulting. Dry cupping over the spine, and, in full-blooded subjects, the local abstraction of blood by cups or leeches are indicated. The application of the ice-bag to the spine is recommended. Ergot and belladonna have been supposed to be useful by causing contraction of the arteries of the cord. Mercurialization, by giving calomel and also by inunction, is to be advocated in view of the danger and often rapid progress of this disease, on the ground that the notions formerly held in regard to the antiphlogistic effect of mercury are not without some foundation, and that the evils of the remedy are of little moment, provided it has a favorable influence upon the inflammatory process, however small this influence may be.

It will often happen that the acute stage is too brief to afford much time for treatment with reference to the objects just stated. This may be inferred when complete paralysis has taken place. Revulsive applications to the spine may be employed; but, considering the liability to gangrenous inflammation, they should not be made in situations exposed to pressure. To obviate the effects of pressure is an important part of the treatment. Relieving the bladder of an accumulation of urine is important, and, also, proper attention to the early symptoms of cystitis.

Absolute rest is an important part of the treatment. Brown-Séquard advises recumbency on the abdomen, but the continuance of this decubitus is hardly practicable. There is no difference of opinion as to the impropriety of the employment of electricity in acute myelitis. Strychnia is contra-indicated.

Chronic myelitis, in the most comprehensive sense of the term, includes several distinct affections, among which are, sclerosis of the posterior column of the cord, multiple cerebro-spinal sclerosis, sclerosis of the lateral columns, anterior poliomyelitis, and progressive muscular atrophy. These will be considered in this chapter under separate headings. Exclusive of these affections, the term chronic myelitis denotes an inflammatory affection localized in a segment, or sometimes in more than one segment, and extending transversely, more or less, throughout the cord (transverse myelitis). The form of paralysis resulting therefrom is generally paraplegia, but, if the cervical portion of the cord be the seat of the affection, general spinal paralysis is the result. In cases of the disease as thus restricted, the clinical problem is similar to that in cases of the acute form, namely, to differentiate chronic myelitis from chronic spinal meningitis. Here, too, it is to be considered that, in the latter affection, the inflammation extends more or less from the meninges to the cord, and that, in the former affection, inflammation of the cord generally involves the meninges. The antecedent history is to be taken into account. Both chronic myelitis and chronic spinal meningitis may have been preceded by an acute form of disease, and, of course, the chronic has the same primary seat as the acute. If, therefore, the previous history show the acute disease to have been acute myelitis, the existing affection is chronic myelitis.

As regards the symptoms, they point to myelitis, instead of meningitis, in proportion as they represent more or less disorganization of the cord. Hence, completeness of the paralysis, sensory as well as motor paralysis, paralysis of the bladder and rectum, cystitis, wasting of the paralyzed muscles, and a tendency to gangrenous ulceration, are diagnostic of myelitis rather than spinal meningitis.

The practical importance of making this discrimination relates chiefly to the prognosis. The prospect of improvement and recovery is far better in cases of spinal meningitis than in cases of myelitis. In proportion as the symptoms denote disorganization of the cord (softening and secondary atrophy),

the prognosis is unfavorable. As already stated, however, destruction of the cord, causing complete motor and sensory paralysis of the lower limbs, is not incompatible with long life and good general health. In the preceding editions of this work, a case is cited in which complete paraplegia followed a fall of forty feet, and, after death there was found atrophy of the cord below the twelfth dorsal vertebra. This patient lived over fifty years after the accident, married, and had six children, amassed a little fortune by his industry, and, finally, died with double pneumonia. In another case, reported by Dr. Purple, in the New York Medical Journal for 1853, there was complete loss of motion and sensation below the fifth dorsal vertebra, following an injury. In this case the patient, finding his lower limbs burthensome, persuaded a surgeon to amputate them near the hip-joint. The operation was wholly without pain, and the stumps healed readily.

The measures of treatment indicated in cases of chronic myelitis are rest, as long as the symptoms denote an inflammatory condition, and moderate counter-irritation over the spine. Remedies given with a view to promote the absorption of morbid products, namely, the iodide of potassium and mercury, are not indicated; severe counter-irritation—moxa, issues, setons, etc.—is of no use. Electricity may be useful in retarding atrophy of the paralyzed muscles. The application of water to the spine by sponging and compresses is to be recommended, but cold affusions and hydropathic packing are hurtful. Experience has shown the hurtfulness of thermal baths. Attention to the bladder is important. Indications pertaining to the general condition of the patient are to be met. If the patient be confined to the bed, precautions are to be taken against the effects of pressure.

Cerebro-spinal Sclerosis. Multiple or Insular Sclerosis.

Among the names for this affection may be mentioned multiple sclerosis, disseminated sclerosis, insular sclerosis of the brain and spinal cord, *sclérose en plaques disseminées*, cerebro-spinal sclerosis, disseminated chronic interstitial encephalo-myelitis. The disease was recognized pathologically by Cruveilhier (1835) and by Türck (1855). From a clinical point of view, it has been studied most thoroughly by Charcot and his pupils.[1] It is characterized anatomically by the development of many or of few nodules of sclerotic tissue in the central nervous system. These nodules are the result of a disseminated chronic interstitial inflammation. Charcot distinguishes, according to the situation of the nodules, three types of the disease, namely, the cerebro-spinal, the cerebral, and the spinal. The cerebro-spinal form is the most common type, its clinical history is best understood, and it is the one most readily diagnosticated. The spinal form, with our present knowledge as regards its symptomatology, is not readily distinguished from the ordinary forms of chronic myelitis.

In the majority of cases, the spots of sclerosis can be recognized by the naked eye. In exceptional cases they may be visible only microscopically. They are distributed irregularly throughout the spinal cord, medulla oblongata, pons Varolii, cerebrum and cerebellum. The sclerotic islands in the pons and medulla are rarely absent, and they give rise to characteristic symptoms. Their number in the cerebrum and cerebellum is greater in the white than in the cortical substance. In the cord, they occupy, unsymmetrically, both white and gray matter. They may be concealed in the interior, or,

[1] Charcot, Gaz. des Hôpiteaux, 1868. Bourneville et Guérard, De la Sclérose en plaques disseminées, Paris, 1869.

reaching the surface, they may be visible from the exterior. It is rare for the sclerosis to extend throughout the entire thickness of the cord. The nodules may be scattered at wide intervals, or several may coalesce. The size of individual nodules may vary from microscopic dimensions to several inches in length. The color of the sclerotic spots is reddish-gray, the consistence, especially in the brain, firmer than normal, the cut surface smooth and somewhat translucent, the borders irregular and in many cases well de-defined. The affected parts may be shrunken, or of normal, or even increased, size. The membranes, especially the pia mater, may be thickened and opaque, or they may be unchanged.

The microscopical examination of the gray, sclerotic nodules reveals, as the essential change, increase of the interstitial tissue, together with atrophy of the nerve-fibres and nerve-cells. The interstitial tissue appears as a finely fibrillated, but dense, connective tissue, mingled with finely granular material. Large stellate cells, called Deiter's cells or spider-cells, are often present. The walls of the bloodvessels are notably thickened, and often infiltrated with fat molecules and lymphoid cells. Granular corpuscles, and corpora amylacea are usually present but not in large number. In the sclerosed patches most of the nerve-fibres have disappeared,[1] those remaining being, for the most part, naked axis-cylinders, sometimes much hypertropied. At the borders of the sclerotic nodules the neuroglia-reticula are swollen, and the cells apparently in proliferation. The ganglion cells, when the gray substance is involved, become filled with yellow pigment, lose their processes, and finally disappear by atrophy. It has been pointed out by Frommann that sometimes a considerable quantity of fat, in the form of free globules and in cells, occupies the sclerotic islands. This he refers to a fatty degeneration of the elements of the neuroglia. Similar gray, translucent spots of sclerosis have been observed also in the cerebral nerves and in the roots of the spinal nerves. Sclerotic nodules have been recognized with especial frequency in the optic nerves.

The individuality of this affection has been recognized only within a few years. Prior to its clinical characteristics having been pointed out by Charcot and others, it was confounded with locomotor ataxia, general paralysis of the insane, senile trembling, and, more especially, paralysis agitans. Typical cases, at the present time, are readily discriminated. This statement will not apply to the rare instances in which the lesions are limited to either the brain or the spinal cord. I have met with an instance, the diagnostic features being extremely well marked, in which there were no symptoms, other than tremor, pointing to a cerebral affection, the duration of the disease extending over many years.

The development of the disease is usually very gradual, and, for a considerable period, its peculiar characters may not be declared. Various indefinite symptoms referable to the brain or spinal cord may have existed for months and even years before a positive diagnosis is practicable. Among these symptoms are, cephalalgia, vertigo, mental disturbance, apoplectiform attacks, abnormal sensations in the limbs, muscular feebleness (paresis), lack of co-ordinating power (ataxia), etc. It is easy to understand that different cases offer a great diversity as regards, not only the initial symptoms, but those associated with the diagnostic characters of the disease, when it is considered how great are the differences as regards the number, size, and situa-

[1] Later observations (Erb, Frommann) do not confirm the opinion of Charcot that insular sclerosis, in distinction from other forms of chronic myelitis, is characterized by the preservation of numerous nerve-fibres in the sclerotic islands.

tions of the sclerotic patches. The interpretation of the diverse sympathetic phenomena is to be sought after in the pathological relations of the different parts of the brain, medulla oblongata, and spinal cord, in which the lesions are liable to be seated. Charcot calls the disease polymorphous, in view of the great variety of the forms of disorder observed in different cases. Notwithstanding these variations, the diagnostic features, when these are present, render the differentiation from the several diseases just named not difficult.

Following incomplete paralysis of one or both of the lower limbs and, perhaps, also of the upper limbs, accompanied often by rigidity of the muscles (spastic paralysis), tremor occurs, and the most diagnostic feature relates to this symptom. The tremor is excited by volition, and is wanting as long as there is no exercise of the will (volitional tremor). The muscles are quiet, or nearly so, if the patient be entirely at rest, but whenever any action is excited by the will, they take on automatic spasmodic movements more or less violent, and the patient's will is powerless for their arrest. These movements may extend from the limbs over the whole body. A hospital patient for a long time under my observation, while sitting quietly was free from tremor, but directly he made any voluntary effort the motions of his limbs and body were so violent and grotesque that it was difficult to regard the spectacle otherwise than as ludicrous. The tremor which is thus characteristic of this disease, is analogous to that of chorea in so far as it is automatic, but excited by the will. In chorea, however, automatic movements take place without, as well as with, the exercise of the will. The tremor differs from the incoördinate movements of ataxia, in that the latter are not automatic. The tremor in cases of senile trembling and paralysis agitans, differs in being independent of volition, taking place when the patient is entirely at rest. Moreover, in both these affections the movements are less violent, have less range, and are more rhythmical in character. The term *shaking tremor* expresses more correctly the movements in multiple sclerosis than the word tremor alone. This symptom is referable to lesions seated in the medulla oblongata.

A peculiar disturbance of speech is diagnostic of this disease. The patient speaks in a slow, monotonous manner, with intervals between syllables, as in scanning. The peculiarity is known as the "scanning speech." The voice is sometimes reduced to a whisper. Aphonia and the feeble, monotonous voice are referable to paresis of the vocal cords. In some cases the lips, tongue, and muscles of the palate become paralyzed, as in cases of bulbar paralysis.

Impaired vision (amblyopia) and double vision (diplopia) occur not infrequently; and oscillation of the eyeballs (nystagmus) is so frequent in this disease and so rare in other diseases, that it has much diagnostic significance. These symptoms represent sclerotic patches affecting the optic tracts or nerves, and nerves going to the muscles of the eyeballs. Inequality of the pupils is a not infrequent symptom.

Sensory paralysis is rarely marked, and is not infrequently wanting. If, however, the sclerotic patches involve the posterior columns of the cord, more or less impairment of sensibility and ataxia are associated. There may be little wasting of the muscles, but in some instances it is otherwise, the inference, in these instances, being that the anterior horns of the gray matter of the cord are involved.

Disturbances referable to the brain are rarely, but sometimes, wanting. The mental faculties generally fail. Patients often alternately weep and laugh irrationally, and progressive deterioration of the mind ends at length in imbecility. Apoplectiform attacks are liable to occur, accompanied by hemiplegia. With these attacks there may be considerable fever, showing

an intercurrent acute inflammatory condition. Patients usually recover from these attacks but they sometimes prove fatal.

The diagnosis is to be based chiefly on the tremor, together with the peculiar disorder of speech, taken in connection with the varied motor, sensory, and mental disturbances. The diagnostic criteria probably proceed from sclerosis of the medulla oblongata and pons Varolii. If these parts escape, which probably is rare, the clinical characteristics of the disease may be wanting. An important point in the diagnosis is the age of the patient. In the great majority of cases the commencement of the disease dates from a period between 20 and 40 years of life.

Aside from the influence of age, nothing has as yet been definitely ascertained respecting the etiology.

The disease is usually progressive, but with a slow march, the duration sometimes extending from ten to twenty years. Long periods, in which the disease appears to be stationary, are not uncommon, and, also, periods in which the symptoms give delusive hopes of real improvement. Often the life of the patient is destroyed by some intercurrent affection. A fatal ending may be due to disturbances of respiration and deglutition, incident to the occurrence of bulbar paralysis. Irrespective of these causes, death is the result of exhaustion from cystitis, bed-sores, and the giving way of the processes involved in nutrition. Clinical experience thus far has furnished no ground for entertaining any hope of recovery from the disease.

The utmost to be hoped for in the way of treatment is that the disease will remain stationary, or, if it be progressive, that the progress may be retarded. Various remedies have seemed to be of use in isolated cases. Among these are the nitrate of silver, arsenic, the chloride of barium, and the phosphide of zinc. The latter remedy, in a case under my observation, was repeatedly followed by distinct, although limited, improvement. Electricity and hydropathic treatment have appeared to be beneficial. More is to be expected from the removal, as far as possible, of all causes of disorder, from measures for the improvement of the general health, and from treatment governed by symptomatic indications, than from any remedies given with a view to a special influence upon the disease.

Locomotor Ataxia. Posterior Spinal Sclerosis.

This affection was described by Duchenne in 1858 and 1859, under the name progressive locomotor ataxia, more fully than by any previous writer; hence Trousseau designated it Duchenne's disease. The principal symptoms of the disease, however, had been recognized previously by Romberg, who applied to it the old name *tabes dorsalis*. The distinctive character and the seat of the affection were clearly defined also by the late Dr. Todd, prior to the researches of Duchenne. Other names of the disease are *gray degeneration of the posterior columns*, *sclerosis of the posterior columns*, *posterior chronic leucomyelitis*.

The anatomical characters of locomotor ataxia consist of sclerosis of the posterior columns of the spinal cord, involving frequently a part of the lateral columns, and of the gray substance. The posterior nerve-roots are atrophic and gray. The pia mater covering the posterior part of the cord is thickened, opaque, and often adherent to the dura mater. In advanced cases, the posterior columns appear shrunken, gray, and somewhat firmer than normal. The observations of Pierret (1872), under Charcot's direction, render it probable that the primary seat of the sclerosis is in two bands, each in the outer part of the posterior columns and lying close to, and parallel with, the posterior horns of gray matter. These bands they call the *external* or *lateral bands*.

This view of Pierret and Charcot is based, on the one hand, on the fact that sclerosis of the columns of Goll, although usually present in locomotor ataxia, does not cause ataxic symptoms, as shown in cases of ascending secondary degeneration and of primary sclerosis of these columns; and, on the other hand, on the observation of a case of locomotor ataxia in which the sclerosis was confined to the external bands, while the columns of Goll were normal. When, as is usual, the symptoms are most marked in the lower extremities, the changes in the posterior columns are most extensive and advanced in the lower dorsal and upper lumbar regions. Here the whole thickness of the posterior columns is involved. In very rare cases the symptoms are chiefly referable to the upper extremities, the sclerosis then being most developed in the cervical enlargement. As a rule, however, while the dorso-lumbar sclerosis occupies the greater part of the posterior columns, it is found that, in the cervical region, the sclerosis is confined either to the columns of Goll or to these together with the external bands. The almost constant involvement of the columns of Goll may be regarded as referable to an ascending secondary degeneration. The sclerosis may be traced continuously to the restiform bodies of the medulla oblongata, where it ceases. There is a tendency in the disease during the later stages to extend to the posterior part of the lateral columns. The posterior horns of gray matter seem to be generally involved. Extension to the anterior horns of gray matter is a rare complication, causing muscular atrophy. Gray degeneration of the optic nerves, and, rarely, of the oculo-motor, hypoglossal, and certain other cranial nerves, has been observed.

Microscopical examination of the sclerosed parts reveals increase of the interstitial tissue, which appears as a dense but finely fibrillated connective tissue, containing, in the early stages, many nuclei and granular corpuscles, and, in the later stages, abundant corpora amylacea. The walls of the blood-vessels are thickened, and the perivascular sheaths inclose a large number of fat globules which have probably been derived from the products of fatty degeneration of the nerve elements. The nerve-fibres lose their medullary sheaths, undergo atrophy, and, for the most part, disappear. The exact localization of the sclerosis as described above can only be determined by microscopical study. The morbid process is regarded by most writers as beginning in the nerve-fibres either as a parenchymatous inflammation (Vulpian, Charcot, Erb) or as a degeneration (Leyden), the chronic interstitial inflammation being a secondary change. The histological appearances are those of chronic interstitial myelitis, but it is difficult to understand why a primary interstitial inflammation should remain confined to the course of definite groups of nerve-fibres.

Locomotor ataxia is not a form of paralysis, although generally associated with diminished sensibility, and not infrequently with more or less diminution of motor power. The distinctive characteristic of the affection is impairment or loss of the ability to combine and direct voluntary muscular movements. The patient may have as much muscular strength as in health, but there is either inability or difficulty in co-ordinating the action of the muscles by the will. A natural division is, into the prodromic period or first stage, the ataxic period or second stage, and the paralytic or third stage.

Lancinating, shooting pains, usually at first in the lower, and later in the upper, limbs often constitute a prominent symptom. The patient often compares the pains to those caused by electric shocks. In consequence of their intensity they have been called fulgurating pains. They are not positively characteristic, inasmuch as they occur in other forms of myelitis, and they are not invariably present in cases of ataxia. The "girdle sensation," which is a symptom in other inflammatory affections of the cord, is sometimes

felt. Other events which may occur in the first stage are, nocturnal incontinence of urine, frequent seminal emissions, anaphrodisia, or, on the other hand, a morbid excitability of the sexual organs, urethral and rectal neuralgic pains, a sense of fatigue in the muscles of the lower limbs after any exertion, attacks of vomiting accompanied by gastralgia (*crises gastriques* of Charcot), paralysis of certain of the nerves of the eyeball—the oculo-motorius, the abducens, and, rarely, the trochlearis—giving rise to strabismus, diplopia, and ptosis. These paralytic symptoms may be transient; they may disappear and return, sometimes remaining permanently. Impairment of vision in some cases occurs early, and it may end in amaurosis. The ophthalmoscope shows an opaque, pearly whiteness of the optic papilla, characteristic of progressive atrophy. Irregularity of the pupils is not infrequent. The pupil on one side may be contracted to a pin's point, showing paralysis of the sympathetic, and with this symptom are sometimes associated dilatation of the vessels and increased heat on the corresponding side of the face. The pupil on one side may be contracted and on the other side dilated. Oftener both pupils are contracted. Difficulty of speech from paralysis of the hypoglossus, and paralysis affecting branches of the trigeminus and facial nerve, are occasional symptoms. The acoustic nerve is sometimes involved. These events are liable to occur in the first stage, that is, they may precede the development of ataxia, or their occurrence may be delayed until the second stage. They may precede for a long period—months and even years—the ataxic characteristics. The latter mark the second stage of the disease.

The ataxia is generally first manifested in the lower extremities. It may appear first in the upper extremities. This was true of a case which I have observed. One lower limb is sometimes affected before the other, and both limbs on the same side may be first affected. When one limb is first affected, whether it be a lower or an upper extremity, it is on the left oftener than on the right side. The defect of co-ordination is apparent when any combined movements are undertaken. In proportion as the affection is marked, the patient's gait in walking is uncertain, irregular, and grotesque. The lower limbs are thrown forward by forcible jerks, without definite direction. The body is sometimes swayed from side to side in the attempt to maintain an equilibrium, and the arms thrown out like those of a person balancing on the tight rope. In cases less marked, the greatest difficulty is experienced in beginning to walk, and, after getting under way, the patient is unable to advance slowly, but walks with precipitation; the legs are thrown forward with a quick, jerking movement, the feet brought to the ground on the heels with force, and liable to strike against each other. Notwithstanding the violence of the exertions, the muscular strength being retained, patients are sometimes able to travel long distances. In an extreme degree of the affection, walking, even with the aid of a cane or assistants, is impossible, and the patient is confined to the chair or bed.

The defect of co-ordinating power over the upper extremities is shown by an inability to execute acts which require the combined movements of the fingers. The patient is unable to button or unbutton clothes; yet the grasp may have not less force than in health. A patient whom I exhibited at a clinic tried in vain to unbutton his vest, but his grip was too strong to be borne. In extreme cases the patient is unable to guide the hand to his mouth, and requires to be fed by others.

In a certain proportion of cases, the affection progressively extends over the voluntary muscular system, and increases in degree more or less slowly. The defective co-ordinating power may be much more marked at some times than at others. A patient for some time under my observation, who had had this affection for five years, habitually walked with a certain amount of un-

certainty and irregularity, and enunciated with labor and slowly, but distinctly. This patient at times, for the space of an hour or so, walked with great difficulty, presenting in a marked degree the characteristic gait, and the embarrassment in speech was such that he was with difficulty understood. These paroxysms recurred on some days repeatedly, and he was sometimes exempt from them for several successive days. This patient had occasionally double vision and night-blindness.

A symptom, even when the affection is slight, is inability to stand with the eyes closed. This symptom is not pathognomic of locomotor ataxia. The patient, with the feet in apposition, and the eyes closed, shortly reels, and would fall if not supported. This has been attributed to the co-existence of more or less anæsthesia of the soles of the feet. Patients, however, with notable loss of sensibility of the soles, but who have not ataxia, are sometimes able to stand without difficulty when the eyes are closed.[1] A moderate amount of ataxia occasions want of confidence in the locomotory powers. A patient of mine has the disease only in a sufficient degree to walk usually with what seems an eccentric gait; but were he to cross a street when it became necessary to hasten in order to get out of the way of carriages, he would scarcely be able to make any headway, and he carefully avoids such a contingency.

In most, if not all, cases, the cutaneous sensibility is more or less impaired. The amount of sensory paralysis varies in different cases. Generally both anæsthesia and analgesia are combined. There is also diminution of the sense of weight and of temperature. The so-called muscular sense is impaired. Retardation in the transmission of sensory impressions to the sensorium is sometimes marked. These symptoms denote that the posterior horns of the gray matter of the cord are implicated. The difficulty in walking is increased by the impairment of sensibility. The patient's eyes are directed to the feet and ground in walking; there may be inability to walk with the eyes closed.

As already stated, although distinct from motor paralysis, the latter may co-exist with the ataxia, and may be either primary or secondary as regards the former. In cases of paralysis from different spinal affections, the difficulty in walking depends often measurably on defective power of co-ordination.

Impotence occurs, as a rule, sooner or later, either before or after the advancement of the disease to the ataxic stage.

Affections of the joints occur in a proportion of cases, small, but sufficient in number to show a pathological connection. These have been described, especially by Charcot, under the name ataxic arthropathies. They may occur before as well as after the development of the ataxic condition. Generally the larger, but sometimes the smaller, joints are affected. Those attacked by preference are the knee and the shoulder. The joints are attacked suddenly, without any traumatic cause; they are swollen from intra-articular effusion; pain and fever are wanting, and recovery often takes place after several weeks or months. On the other hand, permanent structural changes may be the result, leading sometimes to dislocation.[2] The affections of the joints are considered as denoting that the anterior horns of the gray matter have become involved. A corroborative fact is that they are accompanied by wasting of the muscles.

The conditions as regards reflex and electrical excitability, are not uniform in different cases or in different periods of the same case. The so-called reflex action of tendons is generally wanting. Percussion over the ligamentum

[1] *Vide* report of a case by Dr. Pepper in Am. Journ. of Med. Sciences, July, 1871.
[2] Leçons sur les maladies du système nerveux. Paris, 1877.

patellæ or over the tendo Achilles, does not occasion spasmodic movements as in health. This is a point of diagnostic importance. The condition as regards reflex excitability of the tendons has no relation to the cutaneous reflex excitability. As a rule, for a long period the nutrition of the muscles is well maintained.

In the advanced or paralytic stage, notable paralysis is added to the ataxia. The muscles waste; the patient falls into a cachectic state; cystitis and bed-sores occur, and death takes place by exhaustion. Happily the disease progresses to this stage in but a small proportion of cases. It is generally reached, if reached at all, after a long period. When a certain amount of progress has taken place, sometimes the disease remains without further progress, indefinitely or during life. If progressive, the progress may be extremely slow. Notable improvement takes place in some cases. I have known the ataxia to be so great as to compel patients to keep the bed for several months, and such a degree of improvement to follow that they were able to walk without much difficulty. Complete recovery is extremely rare, but if the disease be not far advanced, it is possible. Hence, the name *progressive*, applied by Duchenne, is by no means characteristic of the disease. In the great majority of cases death is owing to some intercurrent affection. The disease may not interfere with the continuance indefinitely of appetite, nutrition, and good general health.

The diagnosis involves a discrimination from paraplegia, and, in some cases, from general paralysis. The differential diagnosis may be easily made. The ataxia is not a paralytic affection; the difficulty in walking, or in using any of the affected muscles, depends, not on deficiency of muscular power, but on the lack of ability to combine and direct the movements of the affected muscles. The difference in this respect is strikingly shown by causing two patients, one affected with paralysis and the other with locomotor ataxia, to walk side by side. The paralytic walks with a feeble tottering or shuffling gait; the patient affected with ataxia throws out his limbs with force, but in an irregular, uncertain manner. The preservation of voluntary motor power, in ataxia, is shown by the resistance which the patient is able to make when the physician tries to bend the limbs, and, also, by the freedom and strength of movements when the patient is recumbent. If there be paralysis, more or less in degree, combined with ataxia, it is not a difficult problem to determine this fact, and to estimate the relative prominence of either. The coexistence of mental aberration with general cerebral paralysis, is a diagnostic feature of the latter. In that disease the voluntary muscles of the limbs, face, etc., are simultaneously affected; in locomotor ataxia different parts of the voluntary muscular system are successively affected, the affection being generally manifested first in the lower extremities.

Affections of the cerebellum giving rise to vertigo, may occasion an embarrassment in walking and standing, suggestive of ataxia. The embarrassment is due to vertigo, and is analogous to that caused by drunkenness. With proper attention this cannot be confounded with the ataxic difficulty. Moreover, the vertigo is usually accompanied by other symptoms pointing to cerebellar disease.

Sclerosis of the lateral columns, or spasmodic spinal paralysis, presents diagnostic characters which, as will be seen, are sufficient for the discrimination of this affection.

The etiology of locomotor ataxia relates to age, sex, over-exertion of the muscles, together with exposure to cold, and sexual excesses. The disease occurs very rarely prior to adult life. In the great majority of cases the ages are between 30 and 50 years. Men are oftener affected than women. The disease has been observed to follow various affections, namely, rheuma-

tism, pellagra, epilepsy, hysteria, etc., but the diversity of these antecedent affections renders it doubtful if the sequence denote any etiological connections. The personal history in many cases gives nothing definite as regards the causation. Erb has recently reported an analysis of 33 cases, of which a syphilitic history existed in 29 cases. The analysis of these cases shows the antecedent syphilis to have been generally mild, and that the ataxia occurs from five to ten years after the syphilitic infection.[1]

The nitrate of silver, the iodide of potassium, arsenic, the chloride of barium, and phosphorus, are remedies recommended in this disease. Each has been found useful by some, and not so by other, observers. None are entitled to be considered as specially curative. Their degree of usefulness is limited in the cases in which they appear to be useful. The nitrate of silver may be given continuously in doses of from a third to a sixth of a grain for several weeks, and it should then be suspended for a season. Phosphorus has seemed to me to be useful in several cases. It may be given in the form of phosphide of zinc, or of the oleaginous solution.

They who have had large experience in electro-therapeutics bear testimony to the usefulness of electricity. Both the faradic and galvanic forms are useful; the latter having the most testimony in its favor.

Thermal baths are generally regarded with disfavor by those who have observed their effects in a considerable number of cases. Sponging the body with cool or tepid water, and the hydropathic packing, the latter employed with care and moderation, are recommended. The usefulness of these measures, as well as of electricity and the other remedies which have been named, is to be explained by their general influence upon the functions of the body, this influence reaching thus indirectly the local disease.

There is general agreement as to the inutility of local depletion and counter-irritation.

The lancinating pains, the attacks of gastralgia with vomiting, seminal emissions, the affections of the joints, the retention or incontinence of urine, and other complications, claim, of course, appropriate measures of treatment.

Measures to improve and maintain nutrition, to invigorate the general health, to remove co-existing disorders, and to palliate symptoms, doubtless do much toward preventing or retarding the progress of the disease.

Inasmuch as measures of treatment appear in not a few cases to prevent or retard the progress of the disease, it is obvious that an early diagnosis is highly important. It is important to recognize the significance of the symptoms which precede the ataxic stage, with the hope that, as a result of judicious management, the disease may not advance to this stage. There seems to be no good reason, *à priori*, why the disease might not become stationary, to say the least, at this, as well as at the second stage.

Anterior Poliomyelitis. Spinal Amyotrophic Affections.

There is a group of diseases, embraced by Charcot under the name spinal amyotrophies (amyotrophies spinales), characterized by the presence of muscular atrophy as a leading symptom, by the absence of marked disturbances of sensation, and by the retention of the functions of the bladder and of the rectum. Paralysis in some of these diseases precedes the muscular atrophy; in others it appears simultaneously with the atrophy and seems to be proportional to the latter. The common anatomical basis of these spinal amyotrophic disturbances is atrophy of the ganglion cells in the anterior horns of the

[1] Wiener med. Blatt., No. 11, 1880.

gray matter of the spinal cord, combined usually with evidences of inflammation in this situation. Hence the name *anterior poliomyelitis*,[1] signifying inflammation of the anterior gray substance, is the pathological designation proposed for this group of diseases.

Anterior poliomyelitis may be conveniently divided into an acute and a chronic form. Acute anterior poliomyelitis includes the spinal paralysis of children, and the acute spinal paralysis of adults; chronic anterior poliomyelitis embraces the subacute general spinal paralysis of Duchenne and certain forms of progressive muscular atrophy. The acute form will be first considered.

Acute Anterior Poliomyelitis. Spinal Paralysis of Children and of Adults.

Infantile spinal paralysis was fully described clinically by Heine in 1840. For our knowledge of its pathological anatomy we are indebted especially to Prévost, Vulpian, Lockhart Clarke, Charcot, Joffroy, Roger and Damaschino. After the clinical and pathological characters of this form of paralysis had been established, it was discovered that the disease in its typical form may occur also in adults, though less frequently than in children. The discovery of this fact is due especially to Meyer and to Duchenne. Among the synonyms for this affection may be mentioned *essential paralysis of infants*, *acute spinal paralysis of adults*, *acute atrophic spinal paralysis*, *spinal paralysis from inflammation of the motor tract*, *acute myelitis of the anterior horns*. Our knowledge of the pathological anatomy of acute anterior poliomyelitis is derived almost entirely from the study of cases of infantile spinal paralysis. Although there is reason to believe that similar anatomical changes are present in the acute spinal paralysis of adults, it is necessary to await more conclusive post-mortem examinations than have as yet been made.

In the early stages of acute anterior poliomyelitis, the spinal cord may present no changes to the naked eye. In some cases, discoloration and a certain degree of softening may be recognized in the anterior horns in certain parts of the cord, but, in general, microscopical examination is necessary to determine the existence of the characteristic lesions. This reveals, according to the observations of Roger and Damaschino, foci of acute interstitial inflammation with degeneration and atrophy of motor ganglion cells in the anterior horns. The changes are most intense in the lumbar and the cervical enlargements, but atrophy of motor ganglion cells is to be found, as a more or less diffuse process, throughout the spinal cord in many cases. Granular corpuscles, proliferating neuroglia-nuclei and lymphoid cells are present. In the later stages, sclerotic fibrous tissue is formed in the place of the softened foci. In this the ganglion cells are much reduced in number and there are many corpora amylacea. In the process of atrophy, the ganglion cells become filled with pigmentary particles, lose their processes and finally appear as small spherical masses of pigment, or entirely disappear. In the later stages, it is often possible to distinguish with the naked eye the atrophy of one or both anterior horns, combined frequently with sclerosis of the adjoining parts of the antero-lateral columns. The anterior nerve-roots undergo atrophic degeneration.

The atrophied muscles present increase of the interstitial tissue with simple atrophy of the muscular fibres. The sarcolemma-nuclei of some of the

[1] Πολιός, gray. Tephromyelitis (Charcot), spodomyelitis (Vulpian), anterior cornual myelitis (Gowers), have been suggested as synonyms.

muscle-fibres may be greatly increased in number. Although fatty degeneration may be present in some of the fibres, this is not the predominant process. A considerable amount of fat may be deposited in the interstitial tissue, so that the volume of the muscular mass may be about normal. The primary changes in the cord are considered by Charcot to be in the ganglion cells, and to be of the nature of a parenchymatous inflammation. On the other hand, the observations of Roger and Damaschino confirm the view that the primary process is an acute interstitial inflammation of the anterior horns.

The clinical characteristics of this disease in children are strikingly distinctive. The initial history of a typical case is as follows: A child is suddenly attacked with fever, perhaps in the night, having been at bedtime apparently perfectly well. The fever has considerable, it may be great, intensity. It is accompanied by cerebral symptoms, namely, vertigo, somnolence, coma, and sometimes convulsions. There is also pain in the spine and extremities. The fever and the concomitant symptoms subside and disappear after a minimum duration of a few hours or a maximum duration of a few days. The patient may have seemed to have had a febricula. As a sequel of the fever, paralysis is discovered, generally quite unexpectedly. The paralysis may be at first confined to one extremity, much oftener a lower than an upper. It may quickly extend to another extremity, and it may involve the four extremities. The extension from one part to other parts takes place quickly, that is, within a few hours, or, at most, a few days, and the paralysis as quickly becomes complete. There is no sensory paralysis. After a few days the liability to an extension of the motor paralysis ceases. As regards the parts paralyzed, different cases differ widely. The paralysis may be confined to one lower extremity; oftener both lower limbs are affected. Cases occur, but they are extremely rare, in which either one or both of the upper limbs are alone affected. More or less of the muscles of the trunk may be involved. Not infrequently the paralysis does not affect all the muscles of the extremities, but is confined to certain groups of muscles.

There are occasional variations from the foregoing history as regards the fever and the concomitant symptoms. The fever may be slight, and, in rare instances, wanting. More or less of the cerebral symptoms may be absent. The latter do not represent any definite cerebral affection, and they are probably incident to the fever. The fever is generally considered as symptomatic of acute spinal inflammation. The intensity of the fever, in some cases, and the short duration, sometimes lasting only a few hours, militate against this view. It is more rational to consider the fever as essential or idiopathic. If the latter view be accepted, the spinal affection is to be regarded as a local manifestation of a general disease, holding to the latter, perhaps, a relation analogous to that of meningeal inflammation to cerebro-spinal fever or epidemic cerebro-spinal meningitis.

The clinical history after the development of paralysis embraces certain diagnostic features.

The susceptibility of the paralyzed muscles to reflex excitation of the skin and percussion of the tendons is quickly lost. Within a few days the susceptibility to the faradic current may be also lost. The muscles, however, for a considerable period respond to the galvanic current. If recovery from the paralysis take place, the muscles often respond to the will before the return of faradic excitability. These are facts characterizing what has been distinguished by the not very happily chosen phrase "reaction of degeneration." Much importance belongs to the employment of the faradic current with reference to the prognosis. All the affected muscles are not paralyzed

in an equal degree, as tested by this current. If the susceptibility to the current be completely extinguished, there is not much probability that the muscles so affected will ever be restored. But if the susceptibility be more or less diminished, without being lost, restoration may be expected. The faradic current, therefore, gives speedy information as regards the muscles which will remain paralyzed, and those which will be restored.

Speedy and notable wasting of the muscles which lose the susceptibility to the faradic current, is a diagnostic feature. This occurs too early and goes on too rapidly to be referable simply to disuse; it denotes trophic disturbance, and is evidence of a connection of nutrition with the ganglion cells in the anterior portion of the gray matter of the cord. The atrophy in some muscles may proceed to such a degree that all trace of the muscular tissue has disappeared. The temperature of surface over the paralyzed parts is lowered, as determined by the thermometer as well as the touch, and the skin has a livid appearance.

Within a few weeks improvement commences either in all, or in a certain number of, the paralyzed muscles. In a small minority of cases, the improvement in all the muscles goes on to complete recovery. In the large majority of cases, the improvement is limited to muscles incompletely paralyzed and retaining more or less susceptibility to the faradic current. The muscles which, after the lapse of several weeks, are without any improvement, as a rule, remain permanently paralyzed. As regards the number and the situation of the muscles so remaining, different cases present great diversities. The permanent paralysis may be confined to one lower limb, to both lower limbs, to an upper limb, to an upper and lower limb, etc. It is rare for all the muscles of a limb to remain paralyzed in an equal degree; often the paralysis is limited to a certain group of muscles, and sometimes even to a single muscle.

The permanent paralysis of a greater or less number of muscles involves no disturbance of the general health. The assimilatory and the nutritive processes (exclusive of those in paralyzed muscles) may go on as completely as possible. In all respects, save the paralysis and its local consequences, the health may be excellent, and the duration of life is not shortened.

The local consequences of the paralysis are, however, by no means trivial. A great variety of deformities are results of this disease. The growth of the bones is arrested. Owing to a want of a proper antagonism of the muscles, distortions of the feet and hands are common; the joints become loose, and often admit of ready dislocations. The painful spectacles so often met with of shortened, flaccid limbs, club-foot, etc., if not congenital, are generally remote consequences of this disease.

The discrimination of this disease from other paralytic affections, after the development of paralysis, is easy. The diagnostic points summarized are as follows: The paralysis following an initial fever, and affecting muscles in rapid succession and in an irregular manner; the paralysis of a certain number of muscles rapidly becoming complete; the rapid loss or notable diminution of electrical susceptibility, and the speedy disappearance of reflex and tendon reaction; early and progressive atrophy of paralyzed muscles; absence of anæsthesia and sometimes hyperæsthesia; coldness and blueness of the skin over the paralyzed limbs; no tendency to gangrenous inflammation of parts exposed to pressure; commencement of improvement within a few weeks in more or less, and sometimes in all, of the paralyzed muscles; permanent paralysis of certain of the affected muscles in the great majority of cases.

We possess no actual knowledge of the etiology of this disease beyond its being especially incident to childhood. Children are attacked when appa-

rently in perfect health, and when nothing is apparent on which suspicion can rest as causing the attack. These facts render probable a special cause, the nature and source of which are unknown.

The disease involves very little danger to life. As regards prognosis, the danger relates to permanent paralysis with atrophy of a greater or less number of muscles, and the deformities arising therefrom. The object of treatment in the early stage of the disease is the prevention of these; in other words, the prevention of the changes in the anterior gray columns of the cord, on which depend the permanent paralysis and atrophy of groups of muscles corresponding to the situation and the extent of the spinal lesions. For this object the treatment indicated in acute myelitis is recommended, namely, active purgation, local bloodletting by cups or leeches, the application of cold to the spine, dry cupping and vesication, rubbing in mercurial ointment, the internal administration of ergot, belladonna, and the iodide of potassium. The physician must use his discretion in the employment of these measures, having due regard to the age and the constitution of the patient. Could the diagnosis be made in the initial febrile stage, perhaps more would be accomplished by antipyretic treatment than by the measures just enumerated. Unfortunately, a positive diagnosis is rarely made in this stage.

The treatment after the occurrence of paralysis, has for its objects the restoration of motor power over the paralyzed muscles and the prevention of atrophy. For these objects the reliance is chiefly on electrical treatment. Neurologists are generally agreed upon the superiority of the galvanic current, but faradic electricity may be combined with advantage. The electrical treatment should be continued steadily for many months. It is claimed by some observers of large experience that muscles which have lost susceptibility to the faradic current are sometimes restored. Hydropathy employed with proper care, and massage, are useful. The system should be well nourished, and invigorated by hygienic measures, together with tonic remedies whenever these are indicated by debility, want of appetite, feeble digestion, etc.

The treatment of the deformities which are apt to follow this disease, falls within the province of surgery.

Acute Anterior Poliomyelitis in the Adult.

This affection in the adult is rare. After childhood, the cerebral symptoms which in children accompany the initial fever, are less marked. The clinical characteristics, however, which relate directly to the spinal affection are the same. The development of the paralysis is rapid. The distribution of the paralyzed muscles is irregular, and, as regards their number and situation, different cases present much diversity. In more or less of the affected muscles, reflex and electrical excitability are soon greatly lessened or lost. There is no impairment of sensation. The bladder and rectum are unaffected. The sexual function is not involved. After the lapse of from one to two weeks, improvement in certain, or, it may be, in all, the paralyzed muscles begins. If improvement begin in all, and progress, the recovery may be complete after several weeks or months. The improvement and recovery, however, may be limited to a certain proportion of the paralyzed muscles, a greater or less number remaining permanently paralyzed. These are rapidly atrophied, and, as remote consequences, distortions occur, but in a less degree than in childhood.

The objects of treatment, and the measures to be pursued, are the same as in the disease occurring in childhood.

Chronic Anterior Poliomyelitis. Chronic Atrophic Spinal Paralysis.

Under the designation chronic anterior poliomyelitis or chronic inflammation of the anterior horns, are included *chronic atrophic spinal paralysis* and *progressive muscular atrophy.* Chronic atrophic spinal paralysis was described first by Duchenne under the name subacute anterior general spinal paralysis. It is characterized by the gradual or by the rapid development of paralysis, first, usually, of the lower and then of the upper extremities, without marked disturbance of sensation, combined with progressive atrophy of the paralyzed muscles, and by loss of reflex and of faradic excitability. The disease usually ceases to progress after a time, and may terminate in recovery. The recorded post-mortem examinations are as yet too few and imperfect to enable us to determine accurately the seat and character of the lesion. Yet they, upon the whole, confirm the view, which is, *à priori*, very probable, that the disease is pathologically a subacute or chronic myelitis of the anterior horns.

The clinical characteristics are analogous to those of the acute affection exclusive of symptoms denoting acuteness. Fever is absent. The development of the paralysis, as a rule, is not rapid but gradual, occupying months or even years. Groups of muscles of the lower extremities are usually first affected, and the paralysis, sooner or later, may extend to groups of the upper extremities and of the trunk. The irregular distribution of the paralyzed muscles is a feature of this, as of the acute affection. The paralyzed muscles become insusceptible to the faradic current, and atropy occurs, evidently from trophic disturbance. Reflex excitability of the paralyzed muscles is extinguished. Sensibility is but little, or not at all, impaired. The bladder and rectum are not involved.

Complete recovery takes place oftener than in the acute affection; but, in a certain proportion of cases, the recovery is limited to a greater or less number of the paralyzed muscles, the others remaining permanently paralyzed. Distortions follow the disturbance of the normal equilibrium of antagonizing muscles. Death is sometimes caused by an extension of the paralysis upward, so that deglutition and respiration become affected.

This paralytic affection is distinguished from progressive muscular atrophy by the fact that paralysis precedes the atrophic degeneration of muscles, whereas, in the latter affection, atrophy of the muscles is the primary event, of which the loss of muscular power is an effect. Moreover, in the latter affection, the atrophy affects portions of the muscles, more or less of the fibres retaining their susceptibility to reflex action and electricity. In chronic antero-poliomyelitis, on the other hand, the loss of motor power, together with reflex and electrical excitability, extends over the whole of the muscles affected. As will be seen, however, in the account to be given of progressive muscular atrophy, this affection is to be considered as having for its anatomical basis morbid changes in the anterior gray matter of the cord.

The objects and measures of treatment are the same as in acute poliomyelitis, after the acute stage has passed. With our present knowledge, the chief reliance is on the judicious and persistent employment of electricity, more especially the galvanic current.

Progressive Muscular Atrophy.

Among the spinal amyotrophic affections, a leading place is to be assigned to the disease known as *progressive muscular atrophy*, which was described first under this name by Aran in 1850. About the same time Cruveilhier

also investigated the disease, particularly from a pathological point of view. The affection has been called by English writers *wasting* or *creeping palsy.* There has been much controversy as to whether the primary seat of the disease is in the muscles (myopathic theory) or in the spinal cord (neuropathic theory). We are indebted especially to Lockhart Clarke and to Charcot and his school, for repeated and careful microscopical examination of the spinal cord in cases of progressive muscular atrophy. These investigators have observed with great uniformity, as the essential lesion, atrophy of the ganglion cells in the anterior horns, combined with chronic interstitial inflammation about the atrophied cells. The view held by Friedreich that these changes in the spinal cord are not primary, but secondary to the muscular atrophy, has not met with favor, and is not in harmony with the fact that muscular atrophy, when undoubtedly primary, may exist for a long time without alterations in the cord, and that the atrophy of ganglion cells which follows amputations, is not to be compared in extent and degree with the atrophic changes in progressive muscular atrophy. The neuropathic origin of typical cases of progressive muscular atrophy (that is of the type of Aran and of Duchenne) may be considered, therefore, as demonstrated. But it is also certain that there are cases even of wide-spread muscular atrophy, which may bear great resemblance to the Aran-Duchenne type, and in which the most searching microscopical examination has failed to reveal any atrophy of ganglion cells or other changes in the spinal cord. A case of this nature, of great similarity to the typical progressive muscular atrophy, but differing from it in certain particulars, has been recently reported by Lichtheim.[1] He failed to discover any diminution in the number or size of ganglion cells in the cord. We must, therefore, admit there are certain forms of progressive muscular atrophy which differ more or less widely from the typical variety, and which are myopathic in their origin. Our information as to the points of distinction between the myopathic and neuropathic forms of progressive muscular atrophy, is as yet so imperfect, that it would not be profitable, within the limits of this work, to attempt to classify and describe separately different forms of the disease. We may hope that in the future their distinctive characters will be better understood. In the present article the ordinary form of progressive muscular atrophy will be described. This may be considered to be neuropathic in origin.

Progressive muscular atrophy may be primary or secondary. In the secondary form (deuteropathic of Charcot) the chronic anterior poliomyelitis is secondary to some other morbid process in the cord, such as primary lateral sclerosis(?), posterior spinal sclerosis, spinal meningitis, and insular sclerosis. Of the secondary form, that consecutive to lateral sclerosis is the most important, and is called amyotrophic lateral sclerosis. It will be referred to under the heading of Lateral Sclerosis. The intimate connection between chronic bulbar paralysis and progressive muscular atrophy in symptomatology, development, and pathology, has already been mentioned while treating of the former affection. The anatomical appearances in the spinal cord in cases of progressive muscular atrophy, are essentially the same as those met with in the later stages of infantile spinal paralysis, and is referable to a chronic anterior poliomyelitis. Whether the primary change is inflammatory or a simple degenerative atrophy of the ganglion cells, is uncertain. No changes may be visible to the naked eye, or a more or less distinct atrophy of the anterior horns, combined often with sclerosis of the lateral columns, may be discerned. The microscopical examination shows the various stages of pigmentary and sclerotic atrophy of the motor ganglion cells in the anterior horns, the presence of a few granular corpuscles, and increase with

[1] Lichtheim, Archiv für Psychiatrie, Bd. viii. 1878.

induration of the interstitial tissue, especially well marked in the neighborhood of the atrophied cells or cell-groups. Gray degeneration of the anterior nerve roots and of peripheral nerves supplying the affected muscles, may also be detected. The changes in the muscles are not those of a simple fatty degeneration, as was at one time supposed, but consist in a simple atrophy of the muscular fibres which become smaller and smaller, but preserve their striæ until much reduced in size. Many of the fibres possess a greatly increased number of sarcolemma-nuclei, and some may present the characters of fatty degeneration. The interstitial tissue is at the same time increased in amount, and may contain some fat cells. It is usually rich in lymphoid cells. It is a noteworthy fact that the affected muscles do not undergo atrophy in their entire volume at once, as is the case in infantile spinal paralysis, but that individual fibres or bundles of fibres become atrophied, while adjoining fibres may remain of normal size. This peculiarity of atrophy of individual fibres or of single bundles in a muscular mass, forms one of the distinguishing traits of progressive muscular atrophy.

Progressive muscular atrophy generally begins in one of the upper extremities, oftener the right than the left. The affection is at first usually limited to a certain number of muscles. In the larger proportion of cases, some of the muscles of the hand are primarily affected. The muscles forming the ball of the thumb and the interosseous muscles are atrophied. In other cases the muscles of the shoulder, or of the arm, or of the forearm, are the first to become atrophied. Corresponding muscles of the other extremity are apt to become subsequently affected, the affection thus exemplifying the law of parallelism. More or less gradually the affection extends over the muscular system. Not only the muscles of the extremities, but those of the trunk, are liable to become atrophied, and in some cases the latter are first affected. The intercostal muscles and the diaphragm may be involved, and death caused by apnœa. The muscles of deglutition may become involved, and the affection prove fatal by causing inanition. The affection is limited to the voluntary muscles.

A marked degree of atrophy of external muscles renders the appearance striking and characteristic. In a case which came under my observation, the atrophy was limited to the muscles of the left shoulder, arm, and forearm. The right scapula was well covered by its muscles, but on the left side this bone was conspicuous, its boundaries distinct, and the spinous ridge projecting. The whole of the upper limb was attenuated, presenting a remarkable contrast with its fellow. In a case reported by Reade, the patient, a young man, when stripped to the waist, "exhibited the neck, chest, and arms to the elbow-joints, reduced to the most abject degree of emaciation. The emaciation was perfectly symmetrical; the greater and lesser pectoral muscles were little more dense than the strongest brown wrapping-paper; the muscles of the neck, anterior and posterior, proportionately attenuated; the muscles on the scapulæ, particularly the supra- and infra-spinatus, were so much diminished as to show the spine of the bone with distinctness only less than the dry bone; all prominences from the deltoids were gone, and the muscles of the humeri were reduced to the cellular membrane, the mere elementary outline of the muscles, the biceps and triceps especially. From the elbows, the muscles of the forearms and hands displayed the full development of a robust and vigorous man of his stature, with all the concomitant power, sensibility, and aptitude for use. All the muscles outside the pelvis, and those of the inferior extremities, were full, strong, and well formed."[1] A patient in Bellevue Hospital presents great

[1] Dublin Quarterly Journal.

attenuation of the arms and thighs, the forearms and legs retaining a large muscular development. In this case the muscles of the back are affected, so that in walking the spine is curved backward, and on raising the upper extremities the scapulæ are thrown outward in a remarkable manner, forming what has been called the "wing shoulder." In another case the atrophy is limited to the feet and about two-thirds of the muscles of the calves, the remaining third of the latter being unaffected. The feet have the appearances of bones covered only with integument. Cases have been reported in which the affection extended over the greater part of the voluntary muscular system. The tongue and the muscles of mastication, the facial muscles, and the muscles of the larynx, may be included in the general atrophy. In a case cited by Thouvenel, the power of moving the limbs and body was lost, and the patient was only able to move the head feebly. The tongue was involved in this case, and deglutition difficult. Trousseau refers to a case treated by Bretonneau, in which the power of speech and all voluntary movements, except of the head and of the forefinger of the right hand, were lost. This patient, a female, held communications with her family by indicating letters, in this way forming words and sentences. She dictated in this manner her last will and testament. When the atrophy is limited to a few muscles, the loss of substance is rendered striking by the normal size of the adjacent muscles. Atrophy of one class of muscles, for example the flexors or extensors of the limbs, causes distortion by the contraction of the muscles which are not affected, the contraction arising from the loss of antagonism. Distortions of the head, trunk, and extremities may be produced by the limitation of the atrophy to certain muscles, or by the progress of the atrophy being much greater in some muscles than in others. The characteristic appearances belonging to the affection, give to it a physiognomy by which it is readily recognized in well-marked cases. Among the frequent deformities may be mentioned the claw-like hand or *main en griffe*. The first phalanges are extended, the second and third are flexed. This deformity is due to paralysis of the interosseous muscles. In the early part of its progress the disease may escape recognition, if a close examination be not made.

In general, the first evidence of trouble is weakness of the affected muscles, arising from the atrophy. Pain or soreness precedes and accompanies the affection in a certain proportion of cases. Generally the pain is not severe. It is referred to the affected muscles, and is of a neuralgic character. The affected parts are notably sensitive to cold, and their temperature is below that of other parts. Defective capillary circulation is sometimes shown by congestion of the surface. Quivering movements of the fibres of the affected muscles, called fibrillary contractions, are often observed, and sometimes subsultus of the tendons and slight twitchings of the parts to which the tendons are attached. These movements occur irrespective of the will, occasion no pain, and the patient may not be conscious of them. The sensibility of the surface is unaffected. The mental faculties remain intact, and there are no symptoms pointing to intra-cranial disease. The appetite, digestion, and nutrition may continue unaffected. There is no loss of power over the bladder or rectum, even when the affection is far advanced, nor does the heart become affected. Constipation may be produced by atrophy of the abdominal muscles. The affected muscles lose their electro-contractility only in proportion as they become atrophied and degenerated; the fibres which are unaffected respond to the electrical current. This serves to distinguish the affection from the wasting of muscles incident to the acute and chronic forms of chronic anterior poliomyelitis which have been considered.

The progress of the affection is slow. More or less slowly increasing, it

is, thus, as a rule, progressive, as the name implies. This rule, however, is not without many exceptions. Often it remains stationary after having progressed to a certain extent. In a few cases recovery may be said to take place; that is, the affection ceases without leaving any permanent deformity or notable debility. It may continue, slowly progressing, a great number of years before tending to a fatal result. The prognosis is extremely unfavorable. The most to be hoped for is that it will cease to progress, or that its progress will be very gradual. Retrogression is not to be expected after much change in the muscles has taken place. Life may be destroyed by apnœa, if the respiratory muscles become affected, or by inanition from atrophy of the muscles concerned in deglutition. In other cases, death takes place after a long and tedious confinement to the bed, if the patient be not carried off by some intercurrent disease.

As regards duration, the following are the results of the analysis of one hundred and five cases by Roberts: Mean duration of cases ending in recovery, one year and two months; of cases ending in permanent arrest, two years and three months; of cases ending fatally, five years and two months. Of the cases which recovered, the longest duration was two and a half years, and the shortest eight months. Of the cases proving fatal, the longest duration was twenty-three years, and the shortest twelve months. The longest case ending in arrest continued active for seven years, and the shortest for four months.

The causation is obscure. The affection rarely occurs under adult age, and it is of rare occurrence after middle life. Males are much oftener affected than females. There is no connection with social condition or particular occupations. Several members of the same family, in repeated instances, have been affected. It has been supposed, in some cases, to proceed from undue muscular exertion. Like most affections, it is sometimes attributed to the action of cold.

The great object of treatment is the arrest of the progress of the affection. The measures for this object have reference to the affected muscles and the general condition. Undue exertion of the affected muscles is to be avoided, but a certain amount of exercise is important. The circulation and nutrition within the affected muscles, are to be promoted by friction and shampooing, and the use of stimulating embrocations. As regards treatment addressed directly to the affection, however, the most potential measure is the employment of electricity. Each of the different forms of electricity is useful, and they may be employed in alternation. Measures having reference to the general condition are those which invigorate the powers of the system. Here, as in cases of progressive locomotor ataxia, judicious management, although it may fail to effect recovery, may do much toward retarding the progress of the affection and prolonging the life of the patient. The point in the progress of the affection at which the arrest is effected, is of vast importance to the patient; hence the desirableness of an early diagnosis.

In one of the cases at Bellevue Hospital which has been referred to, in which the muscles of the arm, thigh, and back are greatly atrophied, not only has there been no progress of the disease during nearly ten years, but the patient is greatly improved, and, although the atrophied muscles remain the same, he has been able for several years to do active duty as a hospital nurse and in other kinds of labor.

Progressive Unilateral Facial Atrophy.

In this rare disease the muscles are not primarily nor chiefly affected, but the atrophy commences at the surface and progresses inwardly, involving the

bones as well as the soft parts. The skin is discolored and thinned. The beard, eyebrows, and hair, on the affected side, become white and often fall out. The subcutaneous fat disappears. The muscles are more or less atrophied, but in a less degree than other structures. The bones and cartilages are atrophied. The atrophy may extend to the tongue on the opposite side, and also to the palate and uvula.

The disease occurs in women much oftener than in men, and very rarely after 25 years of age. The left much oftener than the right side of the face is affected.

The contrast between the two sides of the face renders the recognition of the disease easy, after it has made considerable progress. It cannot be confounded with facial paralysis, inasmuch as drawing of the mouth to the opposite side is slight or wanting, and the muscular movements are not lost on the affected side.

The disease progresses usually very slowly. In all other respects the patient may be perfectly well.

The pathogeny is undetermined. It is yet to be settled whether the disease is primarily seated in the affected tissues, or whether the atrophy is secondary to a neurotic affection. If the neurotic theory be adopted, it is not settled to what particular nerve or nerves the disease is to be referred. The trifacial, the facial, and the cervical sympathetic have each been supposed to be especially involved.

The disease thus far has proved intractable to treatment. An arrest of the progress is all that can be hoped for. It must be expected that the lesions which have taken place will be permanent. The progress of the disease does not endanger life, but the conspicuous deformity is not a small calamity.

Spasmodic Spinal Paralysis. Primary Lateral Sclerosis.

In 1875 Erb described a group of symptoms as a well-defined disease to which he gave the name *spastic spinal paralysis*. Charcot, who had previously recognized the main features of the disease, accepted Erb's description, but called the affection *spasmodic tabes dorsalis*. The leading symptoms are slowly developing paralysis, rigidity of the affected muscles, contractures, and increased reflex action of the tendons. There is absence of sensory and of trophic disturbances in uncomplicated cases.

It is assumed by Erb and by Charcot that the anatomical characteristic of the disease is primary sclerosis of the lateral columns of the cord. This view is in harmony with the teaching of Charcot, that sclerosis of the lateral columns, whether primary or secondary, is attended by tension of the paralyzed muscles. The assumption, however, that Erb's spasmodic spinal paralysis depends upon primary lateral sclerosis, has not as yet been satisfactorily confirmed by post-mortem examination. In the case recently reported by Stofella,[1] in which this condition of the cord was said to be present, no microscopical examination was made. Charcot himself has published a case in which he had diagnosticated this disease during life, while the autopsy revealed multiple sclerosis. Leyden takes the ground that a variety of affections of the spinal cord may produce the combination of symptoms described by Erb. The hitherto reported post-mortem examinations of cases presenting these symptoms confirm this view. In the present state of the question it seems proper to recognize as a distinct symptomatic affection the clinical picture drawn by Erb, but it is necessary to await future investi-

[1] Wiener med. Wochenschrift, Nos. 21, 23, 1878.

gations before we attempt to localize the anatomical changes which form its basis.

The combination of locomotor ataxia with lateral selerosis has been described especially by Westphal. In these cases there is an extension of the sclerotic process from the posterior to the lateral columns. Muscular rigidity is added to the characteristic ataxic symptoms. Secondary lateral sclerosis has been repeatedly mentioned already, as forming the descending secondary degeneration of Türck.

The combination of lateral sclerosis with anterior poliomyelitis, constitutes the disease called amyotrophic lateral sclerosis which will presently be described.

From a clinical point of view, the symptoms described by Seguin in 1873, and called by him "tetanoid pseudo-paraplegia," subsequently described by Erb and designated spasmodic spinal paralysis, and by Charcot under the name spasmodic dorsal tabes, represent a distinct and easily recognized paralytic affection. Cases presenting its distinctive features, as delineated by these authors, have fallen under my observation.

A synopsis of the clinical history is as follows:—

Incomplete paralysis (paresis) begins in either the lower or the upper extremities, according to Erb much oftener in the former. The paralysis very slowly increases. After having reached a certain degree, it is accompanied by twitchings of the muscles and muscular rigidity. The twitchings occur in connection with voluntary movements, irrespective of the will, and especially at night. The muscular tension or stiffness at first excited by motor acts, and lasting for a few moments only, after a time becomes persistent, and, at length, leads to a permanently rigid extension of the limbs.

Pressure on the toes excites tremor of the foot and sometimes of the leg. Tremor is excited by a rapid flexion of the foot, or by pressure with the hand upon the toes. This symptom is called reflex clonus. It is not, however, peculiar to this affection. Occurring with a certain degree of violence, and the tremor sometimes extending to the other limb, it has been called by Brown-Séquard by the inappropriate name "spinal epilepsy." It may sometimes be excited by mere contact of the fingers with the skin.

The tremor, stiffness, and spasmodic twitchings added to the paralysis, increase the difficulty in walking, and give rise to what is termed by Erb the "spastic gait," which he thus describes: "The feet seem to cleave to the ground, the tips of the feet find an obstacle in every irregularity of the ground; every step is accompanied by a peculiar hipping elevation of the whole body; . . . the patient immediately gets upon his toes, and steps forward on them, showing a tendency to fall forward. The legs are close together, held stiffly, the knees somewhat depressed forward, the upper part of the body slightly bent forward." This mode of walking is distinctive, as contrasted with the purely paralytic and the ataxic gait.[1] The difficulty in walking is out of proportion to the impairment of muscular power; yet there is no resemblance to ataxia.

Reflex motions are abnormally excited by percussion of the tendons, the affection in this respect offering a contrast to ataxia. Sensibility remains intact. The bladder and rectum are unaffected. There is no tendency to bed-sores. The sexual functions may be retained. The muscles for a long period do not undergo atrophy. Cerebral symptoms are absent. The electrical excitability of the muscles is slightly diminished.

The duration of the affection extends over many years. It may slowly

[1] *Vide* Ziemssen's Cyc. of Med., Am. ed., vol. 13, page 97.

progress in degree and gradually be diffused over all the extremities, or, having reached a certain stage, it may remain stationary for an indefinite period. Patients generally die from some intercurrent disease. If, however, it be otherwise, and the affection continue to be progressive, confinement to the bed at length is necessary. The affection may extend to the medulla oblongata, and give rise to the symptoms of bulbar paralysis, or, as in other forms of paralysis, at last cystitis and bed-sores may occur and death take place by exhaustion.

The foregoing account applies to typical cases. The symptoms may be associated with those of ataxia in different degrees. The inference, then, is that the sclerosis embraces the posterior columns. The affection may be unilateral, confined to either one limb or to the two limbs on one side. There may occur more or less speedily muscular atrophy. Under these circumstances the affection has been described by Charcot under the name amyotrophic lateral sclerosis. This form will be noticed under a separate heading.

The etiology of this affection is not less obscure than that of the other sclerotic affections of the spinal cord. In the great majority of cases the age is between 30 and 50. Men are oftener affected than women, and the affection occurs in persons apparently in robust health. In a typical case which came under my observation, the patient had suffered much from syphilis.

This form of paralysis allows a favorable prognosis as regards a fatal termination. Erb states that recovery may be said to have taken place in two cases under his observation, and notable improvement in three cases. The chief source of danger relating to the disease, is the liability to the occurrence of bulbar paralysis, and of muscular atrophy.

The principles of treatment are essentially the same as in the other varieties of sclerotic disease. Electricity, especially the galvanic current, is to be employed, and hydropathic measures may be tried with proper care and precautions. Strychnia is contra-indicated.

Amyotrophic Lateral Sclerosis.

Progressive muscular atrophy, as has already been mentioned, may be a primary affection, or may be secondary to other diseases of the spinal cord. Of the secondary or deuteropathic forms of progressive muscular atrophy, that designated by Charcot, in 1874, as amyotrophic lateral sclerosis has received especial attention. In this disease the symptoms of progressive muscular atrophy are preceded by paralysis and accompanied by rigidity. In other words the symptoms of lateral sclerosis and of progressive muscular atrophy are combined. Post-mortem examinations have revealed the lesions of progressive muscular atrophy (degeneration and atrophy of the ganglion cells of the anterior horns), together with sclerosis of the pyramidal tracts in the anterior and the lateral columns. The antero-lateral sclerosis appears to occupy the same situations as in Türck's secondary descending degeneration, that is, a narrow wedge-shaped tract on each side of the anterior median fissure, known as the columns of Türck, and a triangular column in the posterior part of each lateral column known as the pyramidal tract of these columns. The sclerosis of Türck's columns is only met with in the cervical region. Debove and Gombault,[1] who have recently described accurately the anatomical appearances, have observed bands of sclerotic tissue connecting the diseased parts of the anterior horns with the sclerosed lateral columns. The microscopical changes are those which have already been described as characterizing chronic myelitis in the form of sclerosis. The disease is, in

[1] Archives de phys. norm. et path. 1879.

the majority of cases, accompanied by the symptoms and lesions of chronic bulbar paralysis.

In the cases observed by Charcot, the spasmodic paralysis commenced generally in the upper limbs and extended to the lower, but some instances exemplified the reverse of this course. The distinctive feature is the speedy occurrence and more or less rapid progress of muscular atrophy. Extension of the disease to the medulla oblongata takes place, giving rise to the symptoms of bulbar paralysis.

The affection, as compared with simple spasmodic paralysis, runs a rapid course. It arrives at an advanced stage within six months or a year, and death takes place in from two to three years.[1]

In no instance has recovery been known to take place. The indications for treatment are those which belong to chronic anterior poliomyelitis and to bulbar paralysis. Irrespective of the muscular atrophy and bulbar paralysis, the treatment is the same as in cases of uncomplicated spasmodic spinal paralysis.

Compression of the Spinal Cord. Intra-spinal Tumors.

Compression of the spinal cord may be produced suddenly or gradually. Fractures and dislocations of the vertebræ constitute the most frequent causes of sudden compression. Their consideration belongs to the domain of surgery. Meningeal hemorrhage, and the rupture of aneurisms, abscesses, or cysts, into the spinal canal, may occasion rapid compression of the cord.

Of greater interest and importance is the study of the causes and results of slow compression of the spinal cord. The causes are many and diverse. Of the more important may be enumerated, *first*, tumors and inflammatory affections of the vertebræ, especially Pott's disease and cancer; *second*, extra-vertebral tumors, such as aneurism, cancer, abscess, which make their way into the spinal canal, either by erosion of the vertebræ or through the inter-vertebral foramina; *third*, tumors and inflammatory thickening of the meninges and of the perimeningeal tissue, and, *lastly*, tumors of the spinal cord itself. Tumors of the cord itself are less frequent than those of the meninges. They include solitary tubercle, gumma, glioma, sarcoma, neuroma, and secondary carcinoma (page 43 *et seq.*). Dilatation of the central canal is called *hydromyelus*, and is generally congenital. Cavities of variable size and length and more or less centrally located, may be developed in the spinal cord in various ways. The name *syringomyelus* or *syringomyelia* is given to these pathological canals. They may arise from cystic transformations in myelitic or apoplectic foci, from the secondary development of cavities in gliomata, or they may represent dilatation of a part or the whole of the central canal. They are most frequent in the anterior part of the posterior horns.

Of the tumors of the meninges and perimeningeal tissue, may be mentioned, lipoma, sarcoma, myxoma, fibroma, psammoma, gumma, enchondroma, secondary cancer, echinococcus, and cysticercus cysts. Calcific plates in the dura mater, and especially in the arachnoid, are not uncommon in elderly people, and, as a rule, produce no symptoms. In the list of tumefactions in this situation, which act as causes of compression, should be included hemorrhage and certain chronic inflammatory processes. Hemorrhage in the form of a tumor (hematoma) may be the result of internal hemorrhagic spinal pachymeningitis. Of the inflammatory thickenings, that described by Char-

[1] *Vide* Charcot, Leçons sur les Maladies du Système Nerveux, tome ii., Paris, 1877.

cot as *cervical hypertrophic pachymeningitis* deserves especial mention. It is characterized, anatomically, by the formation of layers of new connective tissue from the inner surface of the dura mater. This membrane thus becomes much thickened and frequently adherent to the arachnoid and pia mater, and the latter may be affected in a similar way. The cord then lies imbedded in a mass of dense fibrous tissue, by which it is compressed. It may be simply anæmic, but more frequently it is the seat of chronic transverse myelitis. This disease has its usual seat in the cervical region and is attended by more or less characteristic symptoms.

Of the causes of gradual compression of the cord, the most frequent and best studied is *caries of the vertebræ* or *Pott's disease.* It was formerly supposed that compression of the cord was due to the narrowing of the spinal canal in consequence of the angular curvature of the spine, or kyphosis, so frequently produced in this disease. It is, indeed, certain that in rare instances the cord is compressed by the displaced vertebræ, but that this displacement is not necessarily or usually the cause, is proven by the following facts: extreme angular curvature may exist without symptoms of compression; these symptoms may be present in Pott's disease without curvature, and the symptoms may disappear while the kyphosis remains unchanged. We owe to Michaud,[1] a pupil of Charcot, the explanation of the mechanism of compression in these cases. By extension of the diseased process from the vertebræ to the perimeningeal tissue and the outer layer of the dura mater, a peripachymeningitis and a pachymeningitis externa are set up, leading to the formation of new connective tissue and of pus which undergo in part a caseous metamorphosis. The caseous purulent mass thus formed between the bone and dura mater, and in the substance of the dura mater, is really the agent of compression. There may be an extension of the inflammation to the inner layers of the dura and to the other membranes of the cord, but this is not necessarily the case.

Compression renders the cord anæmic and flattened, and, if protracted, leads to inflammatory changes which present the picture of a transverse myelitis followed by secondary ascending and descending degenerations. This is known as *pressure myelitis.* In a given case it is not always easy to determine how much of the disturbance is due to compression and how much to myelitis, but that compression often plays an important part is proven by the fact that the symptoms may rapidly disappear as soon as the cause of compression is removed.

It is obvious that the symptomatology in different cases of compression of the cord must vary very much according to the cause, the seat, the amount of pressure, the nature and extent of the induced changes in the cord, etc. Diseases of the vertebræ, as well as fractures and dislocations, are determinable causes. The existence of an intra-spinal tumor can hardly be determined with certainty, and, assuming that a tumor exists, to determine its character from the symptoms is impracticable.

The prominent symptom in cases of compression from different causes is paralysis, greater or less in degree (paresis), or complete. The extent of the paralysis will, of course, depend on the seat of the affection. If seated in the cervical portion of the cord, it may give rise to general spinal paralysis. In very rare instances the paralysis may be paraplegia of the upper limbs, the lower limbs remaining unaffected. If the compression be limited to one-half of the cord, which is extremely rare, the result may be spinal hemiplegia with crossed anæsthesia, as described by Brown-Séquard.

[1] Michaud, Sur la Méningite et la Myélite dans le Mal vertebral, Paris, 1871.

Much more frequently the paralysis has the form of paraplegia affecting the lower limbs. If the spinal affection be above the lumbar region, and the latter be not involved, reflex action is not diminished, but often increased. The increase is sometimes so great as to occasion severe contractures and rigidity. Reflex action is diminished or lost if the spinal affection involve the gray matter of the lumbar region. Motor paralysis is often neither accompanied by anæsthesia at the outset, nor after a considerable period. The paralysis may or may not involve the bladder or rectum. Sooner or later, if lesions of the cord be progressive, these parts become involved; the paralysis of motion and sensation becomes complete, and death takes place as when equally destructive lesions occur independently of tumors or the various causes of compression.

Pain in the spine, in parts of the trunk below the level of the spinal affection, and in the paralyzed limbs (paraplegia dolorosa), is especially marked in cases of cancer of the vertebræ, extending to the cord. This symptom may be more or less marked, however, in other forms of disease. It is presumptive evidence of an intra-spinal cancerous tumor that, prior to the affection of the cord, cancer existed in some other situation. That an affection of the cord is syphilitic, is to be suspected whenever the patient has had syphilis; and, with reference to treatment, it is vastly important to seek for evidence of syphilis, although the existence of this disease be denied by the patient. It is to be considered that women may have been affected with syphilis without any suspicion on their part of the nature of the disease, and there are instances in which the physician must derive his knowledge on this point wholly from what he is able to observe without exciting by his questions any suspicion in the mind of the patient.

It is an important practical fact that the spinal cord may tolerate compression sufficient to cause paralysis for a long period without disorganizing changes. This is shown by the immediate disappearance of paralysis from displacement of vertebræ, in some cases after it has existed for years.

The prognosis, of course, varies, in individual cases, according to the nature of the tumor and the different causes of compression. But, inasmuch as the nature of intra-spinal tumors is rarely determinable with anything like precision, an opinion, in cases of tumor, concerning the probable course and termination, must have another basis. In general, the prognosis is unfavorable in proportion as motor paralysis is progressive, as sensation is impaired, reflex excitability diminished, and as atrophy of the muscles takes place; in other words, in proportion as the symptoms denote destructive lesions of the cord.

In cases of compression from displacement of vertebræ, recovery from paralysis, or more or less improvement, may be expected from measures to remove the compressing cause. In another work I have cited a case in which a patient who had been confined to the bed with paraplegia for three years, having suffered greatly during this period from pain and reflex muscular action, immediately recovered the use of his limbs under the treatment by Prof. Sayre, according to his method of suspension and incasing the body in a plaster-of-Paris jacket.[1] This method secures extension of the spine, and renders the spinal column immovable—objects of prime importance in cases of existing displacement and disease of the vertebræ leading thereto. As a means of securing rest, it may be found to have a wider extent of useful application than has as yet been demonstrated.

The syphilitic, alone, of the different tumors, offer encouragement in the

[1] *Vide* Clinical Medicine, 1879, p. 560.

way of medicinal treatment. Anti-syphilitic medication sometimes accomplishes much, and should be employed whenever there is ground for the suspicion that the spinal affection may be due to syphilis.

In other respects the treatment indicated is essentially the same as in cases of chronic primary spinal meningitis and myelitis.

Non-inflammatory Softening of the Spinal Cord.

Non-inflammatory softening of the cord is very rare, and we are ignorant as to its pathological and clinical characters. It is generally assumed, upon the analogy of cerebral softening, that embolism, thrombosis, and atheroma of the vessels may lead to the same forms of softening in the cord as in the brain. Thus white, yellow, and red non-inflammatory softenings of the cord have been described. Some writers consider the changes in the cord which attend compression to belong to non-inflammatory softening, but the anatomical characters are those of myelitis. In the present state of our knowledge, it would not be profitable to enter into a special consideration of non-inflammatory softening of the cord.

Pseudo-Hypertrophic, or Myo-sclerotic, Paralysis.

The characteristics of this affection were first pointed out by Meryon, in 1858. It was, however, more fully described, and its nosological individuality established subsequently by Duchenne. Jaccoud proposes, as a better name, *progressive muscular sclerosis*. Other names, proposed by German authors, are *atrophia musculorum lipomatosa* (Seidel) or *lipomatosa luxurians* (Heller). The affection is peculiar to infancy and childhood. It has been known, however, to occur at the age of 26 years.

The distinctive features are increase of the volume of certain muscles and diminished motor power. The muscles of the lower limbs are generally first affected, especially the gastrocnemii or the glutei. Subsequently the affection may extend to the muscles of the trunk and of the upper extremities. Corresponding muscles on the two sides may be affected, but there are many exceptions to this rule of symmetry. Not infrequently the affected muscles are irregularly distributed, and the affection may be limited to portions of muscles. The increase of volume may be considerable, and the enlarged muscles are in striking contrast with those not affected.

The anatomical changes in the affected muscles are, hyperplasia of the areolar tissue, an accumulation of fat between the muscular fibres, and atrophy of the latter. In respect of its pathological character, the disease belongs in the category of sclerotic or cirrhotic affections. The enlargement of the muscles denotes "false hypertrophy."

The structural changes involve diminution of motor power proportionate to the compression and consequent atrophy of the muscular fibres. Seated in the muscles of the lower limbs, the affection causes a peculiar waddling gait, the limbs in walking being widely separated. If the extensor spinal muscles be affected, a lumbo-sacral anterior curvature takes place when the posture is upright. Frequently, the affection predominating in the flexor muscles of the foot or talipes equinus, is a result of the greater action of the extensors, and with this is a claw-like deformity of the toes. After having reached a certain degree and extent, the affection may remain stationary for several years; but, at successive epochs, it is apt to increase and to become more and more diffused, until patients are reduced to a helpless condition. The progress of the affection is unattended by pain. There is neither hyperæsthesia nor anæsthesia. The functions of the bladder and

rectum are unaffected. In an advanced stage the electro-contractility of the affected muscles is notably diminished or lost. In a case reported by Dr. Balthazar Foster, after the lapse of five years the volume of the affected muscles became as much reduced as they had previously been enlarged.

It has been a pathological question whether this disease is a purely myopathic affection, or whether it is primarily neuropathic. Lockhart Clarke found "various changes in the cervical, dorsal, and lumbar regions of the spinal cord. At the level of the dorsal nerves there was almost total destruction of the gray matter on each side between the posterior vesicular columns and the intermedio-lateral tract. There were also disintegration of the nerve roots, commencing sclerosis of the lateral and posterior columns, destruction of the white commissure in various places, dilatation of vessels, and extravasations."[1] On the other hand, Charcot, Eulenberg, and Cohnheim have failed to discover any morbid changes in the cord.

As regards the prognosis, a case reported by Benedikt is cited by Jaccoud, in which a cure was effected by galvanism. Experience, however, thus far, affords little encouragement to expect a cure from any measure of treatment. Electricity should be faithfully tried. By measures having reference to the general condition of the patient, the affection may perhaps be prevented from progressing, and there may be more or less improvement. The disease rarely destroys life *per se*, death being due to some intercurrent affection. The duration in 13 cases in which the termination was ascertained, out of 85 cases analyzed by Dr. C. T. Poore, varied from two to thirty years.[2]

Scleroderma, or Sclerema.

The affection called scleroderma or sclerema, also sclerodermia and scleremia, may be here noticed, as it is analogous, in its pathological character and certain of its effects, to that just considered. Other terms than those already given have been applied to it, to wit, scleremus, scleria, sclerosis, scleroma, and sclerymus, all derived from the Greek word σκληρος (hard). Its anatomical characteristic is the production, in the lower portion of, and beneath, the skin, of dense fibrous tissue in great abundance. This renders the integument notably rigid and resisting to pressure. It is closely adherent to the muscles. It cannot be moved over these, nor pinched up in folds. The muscles are restrained in their movements by the density of the structures above them, as if a firm bandage were closely applied. More or less wasting of the muscles is caused by the pressure. Pigmentary matter is, in most cases, deposited in the cells of the rete mucosum, producing a discoloration which is yellowish, yellowish-gray, or dark-brown, more marked in some situations than in others. These changes may be either limited to certain parts or diffused over the whole surface, but vary in amount in different places.

The affection is extremely rare. A case under my observation was reported by Dr. Walter De F. Day in the American Journal of Medical Sciences, April, 1870. Dr. Day was able to collect for analysis reports of only thirty-three cases; and the case reported by him was the seventh on record in which there was an examination after death. The affection is not to be confounded with that called by some writers acute sclerema which is peculiar to infants. The latter is a variety of œdema. The affection under consideration occurs generally in middle life. It occurs much oftener in women than in men. It is a chronic affection, usually beginning insidiously, and progressing slowly, but exceptionally developed rapidly with a sudden

[1] Trans. Royal Med.-Chir. Society, 1874.
[2] New York Journal of Medicine, June, 1875.

invasion. The upper part of the body is oftenest first affected, but it may appear primarily in any part.

The affection is not necessarily associated with disease of any of the internal organs; and, if uncomplicated, it is not incompatible with good general health. Existing in a notable degree, it obstructs muscular movements by mechanical pressure and restraint, leading, at length, to more or less impairment of motor power by inducing atrophy. The surface is usually cool or cold, but the heat at times may be greater than normal. Sensibility is not impaired, and perspiration continues. The duration is variable. It may continue for months and years. A fatal termination is due to some complication or intercurrent affection. It continues, in some cases, indefinitely without improvement, and, in other cases, more or less improvement takes place without recovery; but complete recovery may be hoped for. The number of cases reported is, as yet, too few to determine the ratio of recoveries.

Various measures of treatment were employed in the cases which have been reported. It remains to be ascertained what are the remedies, if there be any, which exert a curative effect. In the case under my observation, arsenic was given for some time, and it seemed to be of service; but, in this case, there occurred grave complications, namely, pleuritis, pericarditis, and peritonitis. An analeptic course and tonic medication are rationally indicated, together with alkaline baths, and emollient applications to the skin.

CHAPTER V.

FUNCTIONAL DISEASES OF THE BRAIN AND SPINAL CORD.

Coma. Saturnine Encephalopathy. Vertigo and Ménière's Disease. Paralysis, remarks on. Treatment of Functional Paralysis. General Paralysis. Hemiplegia. Paraplegia. Acute Ascending Paralysis. Nervous Exhaustion or Neurasthenia. Spinal Irritation.

FOLLOWING the inflammatory and structural diseases of the brain and spinal cord, certain functional affections referable to these central parts of the nervous system, may be more advantageously considered as forming a separate group, than as included among the neuroses which will occupy the concluding chapter of this section. The group will embrace the following affections: coma, saturnine encephalopathy, vertigo, general paralysis, hemiplegia, paraplegia, acute ascending paralysis, nervous exhaustion or neurasthenia, and spinal irritation.

It is to be understood here and elsewhere, that the term functional is used provisionally, in a conventional sense, to distinguish diseases without any established anatomical characters. In a literal sense, a purely functional disease probably has no existence. In other words, disturbance of function always involves some anatomical change; but, in the diseases which, for the sake of convenience, are distinguished as functional, either anatomical changes have not been ascertained, or their pathological connection with these diseases is doubtful.

Mental disorders are properly embraced among the functional affections of the brain. They do not usually enter into the courses of instruction in the

Principles and Practice of Medicine. They are, however, to be included within the range of the studies of the physician. Lectures and treatises are devoted specially to these disorders, and their management constitutes one of the specialties of medical practice; but all practitioners are called upon to treat affections of the mind falling short of well-marked insanity. Melancholia and hypochondriasis, in their lighter grades, that is, not amounting to insanity, come constantly under the notice of the physician in general practice. Want of energy, lack of buoyancy, mental apathy, and inertia often exist without any obvious disease. The physician should consider these as generally denoting corporeal ailment. And this should be impressed upon the minds of patients, since they are thereby led to reformations and measures of management which will be likely to afford relief, and are better enabled to strive against the depressing influence of mental disorder. A vast amount of unhappiness is due to causes which, under intelligent medical direction, may be removed, or to functional morbid conditions which judicious treatment may relieve. It is a grave error to attribute disorders of the mind exclusively to mental causes. These few remarks open up a subject of great importance. Insanity is to be prevented by the general practitioner. They who devote themselves to the treatment of the insane, have not the opportunity of preventing the development of insanity.

The study of mental disorders is important to the physician as involving questions of medical jurisprudence. The existence or otherwise of insanity sufficient to require or warrant confinement in institutions for the insane, the exemption of responsibility for criminal acts, incompetency to perform legal obligations, to take care or dispose of property, etc., are practical questions concerning which physicians are called upon to give testimony; but for information bearing on these questions, the student and practitioner are referred to works treating of disorders of the mind and of medical jurisprudence.

Coma.

The term coma expresses a state of unconsciousness from which the patient either cannot be aroused, or is aroused with more or less difficulty. It is customary to apply this term to extreme degrees of unconsciousness, more correctly expressed by the term lethargia and carus. The latter term denotes a degree in which the patient cannot by any efforts be aroused. This degree is generally called profound coma. Sopor expresses an abnormal degree of somnolence, or moderate coma. A patient in this state is often said to be semi-comatose. Coma differs from normal sleep qualitatively as well as quantitatively. Sleep is a physiological event of essential importance to the welfare of the economy. Coma is a pathological condition from which the system derives no benefit. It follows that coma is never a substitute for sleep.

Coma is a symptom occurring in most of those diseases of the nervous system which have been considered, namely, hyperæmia and anæmia of the brain, thrombosis and embolism, cerebral and meningeal hemorrhage, meningitis, encephalitis, and tumors. In all these affections, except perhaps active hyperæmia, the rationale of the coma is diminution of the supply of oxygenated blood to the brain-substance. Coma may be an effect of cerebral anæmia (ischæmia) due to impoverishment of the blood and enfeebled circulation, as in the hydrencephaloid affection first described by Marshall Hall (*vide* page 704). Coma is a pathological element in certain of the neuroses which remain to be considered, namely, epilepsy, hysteria, and catalepsy. It is an incidental event in various diseases exclusive of those of the nervous system; examples are, acute and chronic affections of the kidneys, diffuse hepatitis, pernicious intermittent fever, scarlet fever, smallpox, typhus and typhoid fever,

etc. It may be produced by such toxic agents as opium and other narcotics, alcohol, ethers, chloroform, etc. The sudden loss of consciousness at the instant of the attack in epilepsy, is attributed to cerebral anæmia caused by spasm of the arteries within the brain. Of the other instances, the causation of the coma involves a toxical agency certainly in some, and probably in most, if not in all. The nature of these agents in the general diseases just named, and the *modus operandi*, are not understood.

There are cases of coma not connected with any of the foregoing diseases, and not clearly referable to any known morbid condition of the brain. The coma is then to be considered and treated as an individual affection. It is, of course, in these, as in other, cases merely a symptom, but the pathology and, perhaps, the etiology are unknown or conjectural. The coma may be greater or less in degree, sometimes not exceeding stupor, and sometimes so profound as to constitute carus. It may occur suddenly, constituting a veritable apoplectic attack, or it may be developed more or less slowly. It may last for a few hours, or it may continue several days. It may end, sooner or later, either in death or recovery.

In fatal cases, morbid conditions may be found after death which were not determinable during life. Examples are, thrombosis of the basilar artery or of the longitudinal sinus, and meningeal hemorrhage. The two former of these conditions, not many years since, would have escaped recognition as causes of the coma; and, so, further developments in pathological anatomy may furnish an explanation, *post mortem*, of cases in which adequate morbid appearances are not now discoverable. In the progress of etiology, too, toxical agents causing coma may be discovered of which now nothing is known. This is not an unreasonable expectation in view of the fact that urea and cholesterin have only within a few years been recognized as coma-producing products.

Coma in some instances seems attributable to cerebral exhaustion; that is, it follows prolonged or excessive mental activity in conjunction with impaired nutrition and general debility. It must be confessed that the term cerebral exhaustion does not embody any clear idea of the pathological condition which the coma represents; but it has a practical significance in relation to the causation and treatment. Of course, in deciding that coma is to be regarded as a functional affection, the various diseases and determinable morbid conditions with which it is known to have pathological connections, are to be excluded. Recognizable internal toxical agents, *e. g.*, urea, and those which are external, *e. g.*, opium, alcohol, etc., are also to be excluded. The diagnosis involves a careful investigation of the causation in these different directions.

Assuming a case in which the pathology and etiology are not determinable, the prognosis and treatment must be based upon circumstances pertaining to the coma. Other things being equal, the prognosis is unfavorable in proportion to the degree and duration of the coma. If the patient cannot be aroused sufficiently to open the eyes or protrude the tongue, the danger is great, and increases with the continuance of this comatose state. When the ability to swallow is lost, a fatal ending is to be expected. *Per contra*, if the coma be moderate in degree, the prognosis is favorable. Absence of paralysis, the temperature of the body not increased, mobility of the iris, the pupils neither contracted nor dilated, and equal in size, the ophthalmoscopic appearances normal, the respirations quiet and of regular rhythm—these are points of importance in the exclusion of grave cerebral diseases, and as bearing upon a favorable prognosis.

The treatment is to be governed by the symptomatic indications in individual cases. These rarely, if ever, point to depletion by bloodletting or

other depressing measures. The opposite treatment is usually indicated by feebleness of the circulation and general debility. Supporting treatment is especially indicated in feeble subjects, and when cerebral exhaustion is an etiological factor. It might prove a serious error, under these circumstances, to pursue therapeutical measures on the supposition of cerebral meningitis or hyperæmia.

The propriety of counter-irritation is doubtful. Rest, alimentation, nerve-tonics, and the judicious employment of wine or other alcoholics, are the measures which generally meet the indications present.

Saturnine Encephalopathy.

A rare form of poisoning by lead is characterized by cerebral disturbances of a grave character, namely, coma, convulsions, and delirium. These three events are combined in a considerable proportion of cases. An attack may occur either abruptly or after certain premonitory symptoms. These are, headache, vertigo, ringing in the ears, and, in some instances, amaurosis. Other manifestations of lead-poisoning—paralysis, arthralgia, colic—may, or may not, precede the encephalopathic attack. The coma is more or less profound. In favorable cases it disappears after having continued for one or two days. In unfavorable cases it increases in degree and continues until death. The convulsions are epileptiform in character (eclampsia vel epilepsia saturnina). Paroxysms lasting from five to twenty minutes occur after variable intervals. The delirium is in some cases active and violent, and in other cases hilarious. It is sometimes characterized by hallucinations of sight and hearing. Either of the three events may be predominant. Coma and convulsions in some instances occur without delirium, and coma between the paroxysms of convulsions is sometimes wanting. Amaurosis, if it do not precede, is apt to accompany the attack. The amaurosis is not caused by retinal changes; the ophthalmoscope shows the normal appearances.

A satisfactory pathological explanation of these effects of lead-poisoning cannot be given. They have been attributed to anæmia of the brain from changes in the minute cerebral arteries, to œdema of the brain from increased arterial pressure, and to the direct irritation caused by the presence of lead. Uræmia is probably a pathological element in some cases. The urine is diminished in quantity, and has been found to contain albumen. The effects, however, are not in all instances referable to uræmia, inasmuch as the evidence of diminished elimination of urea is not always present. Heubel has produced similar effects in dogs by poisoning them with lead, and this is one of the recognized causes of the so-called gouty or small, granular kidney.

The prognosis is grave in proportion to the frequency and violence of the convulsions, together with the degree and continuance of the coma. The rate of mortality has not been definitely ascertained, but the proportion of fatal cases is large.

There is little to be said with reference to the treatment. Depletory or debilitating measures are contra-indicated. It should be ascertained, by examinations of the urine, how far uræmia may be a factor in causing the coma and convulsions. Hydragogues and sudorific measures are indicated if there be ground for supposing that there are symptoms of the accumulation of urea in the blood. The inhalation of chloroform or the administration of the chloral hydrate may be resorted to in order to control the convulsions. The iodide of potassium should be given to the extreme of toleration.

Vertigo. Ménière's Disease.

Vertigo is a symptom occurring in various cerebral diseases, and, also, when it is to be regarded as an individual functional affection. In this article it is considered as a functional affection, and as a symptom of Ménière's disease. It occurs as a paroxysmal affection. A person, seemingly, perhaps, in good health, suddenly becomes giddy, surrounding objects appear to be revolving, or the person seems to himself to be performing movements of gyration, which, according to Charcot, always appear to be from the left to the right. The sensation is like that caused by long-continued rotatory movements of the body. If the vertigo be moderate or slight, it simply renders the person unable to walk steadily; he reels like a drunken man. In a greater degree, walking is impossible, and there may be inability to stand without support. In some instances the patient falls, but without loss of consciousness, and without muscular spasm of either the facial or other muscles. The attack is accompanied by a sense of prostration, which, however, is due in no small degree to apprehension. Nausea is a frequent symptom, and vomiting sometimes occurs. The paroxysm varies much, in different cases, in duration. It may last for a few moments, or the vertigo may continue for hours and days.

Successive attacks recur after variable intervals. Days, weeks, or months may intervene. In some cases, vertigo, for a certain period, is apt to be produced by slight exciting causes, such as any intellectual effort, sudden muscular exertion, looking upon a bright light, etc. A patient may be exempt while in the recumbent posture, but experience vertigo whenever the attempt is made to sit up or stand. For this reason patients sometimes keep the bed for a long period.

Attacks of vertigo generally give rise to great apprehension. The patient fears that apoplexy, paralysis, or a fit of some kind is impending. If the apprehension be not removed by the positive assurances from the physician of the absence of danger, it is apt to lead to a distressing state of despondency; the patient is afraid to walk or to be left alone, and all public assemblages are avoided lest something may happen to him to excite disturbance. In a case which has been under my observation, the patient, a gentleman in middle life, notwithstanding assurances of the absence of danger, has for many years been constantly attended by either a relative or a servant, although a long period has elapsed since an attack occurred, and his health is excellent. This state of anxiety has repeatedly, in cases under my observation, continued for months and years. The physician is fully warranted in giving positive assurances that these attacks of vertigo are devoid of danger. Of a large number of cases which I have observed, in no instance have apoplexy, paralysis, epilepsy, or any serious affection followed. It is an unfortunate error to state, as is done by some writers, that vertigo is premonitory of the cerebral affections just named. The needless apprehension of patients is sometimes encouraged by its being shared by the physician. I have met with cases in which danger of apoplexy and paralysis has been represented to the patient. Charcot relates a case in which the attacks were confounded with epilepsy, the patient having, for a long time, been under treatment for that disease. Assurances of the absence of danger may do much good, not only by removing needless apprehension, but in the way of effecting a cure, for the mental anxiety occasioned by the attacks increases the liability to their recurrence.

Of the pathology of vertigo, more cannot be said than that it represents a functional cerebral condition. Its etiological relations are better understood. A French writer, Ménière, in 1861, pointed out the supposed connection

of a disease characterized by deafness and vertigo with an affection of the semicircular canals of the internal ear. Subsequent clinical observations have established this causation in a certain proportion of cases. The vertigo is not infrequently preceded and accompanied by tinnitus aurium, sometimes referred to one ear and sometimes to both ears. Sudden deafness in one ear or in both ears has been observed to be coincident with the attacks of vertigo. The attacks have been found to cease on the cure of suppurative otitis, and even on the removal of an accumulation of wax or a foreign body from the meatus.[1] The most rational explanation is, that a reflex influence exerted upon the brain, emanates from the aural organs. The affection in these cases is now known as *Ménière's disease.*

All cases of functional vertigo are not cases of *vertigo ab aure læsa.* In perhaps the larger proportion there is no evidence of aural disturbance. Dyspeptic ailments appear to be causative in some cases, but not constantly, as contended by Trousseau, who called the affection stomachal vertigo (*vertigo a stomacho læso*). It is sometimes fairly attributable to prolonged overtasking of the mental faculties and anxiety of mind. Excessive venery, the immoderate use of tobacco, and intemperate indulgence in coffee or tea, have a causative influence. It may be incident to the debility which remains after convalescence from a severe disease, for example, typhoid fever.

The treatment involves, as the first and most important measure, removal of the supposed cause or causes. The ears should be carefully examined with reference to removable morbid conditions. Measures addressed to cerebral congestion, namely, bloodletting, counter-irritation, purgation, and reduced diet, are hurtful. On the contrary, tonic remedies, a nutritious diet, and hygienic means of invigorating the general health, are generally indicated. The practitioner should bear in mind the importance of assuring the patient positively of the absence of all danger. This will sometimes do much toward the cure. A cure is often soon effected, but, in some cases, the affection persists for a long time. Charcot extols the efficacy, in cases of aural vertigo, of quinia given in full doses (20 grs.) for several weeks.

Paralysis. General Remarks.

Paralysis is an important symptomatic event in the clinical history of different cerebral and spinal diseases which have been already considered. It is not always referable to either an inflammatory or structural disease, and it is then to be distinguished as functional.

By the term paralysis is understood either the loss or an abnormal diminution of voluntary power over muscles. The term is also applied to the loss or a diminution of sensibility. The latter is sensory, and the former motor, paralysis. Sensory paralysis, however, is expressed by the terms *anæsthesia* and *analgesia;* the first relating to the sensibility to touch, and the second to the sensibility to pain. Analgesia may exist without anæsthesia. A patient, for example, partly under the influence of chloroform or ether, may feel the cutting of the knife in a surgical operation, but without any sensation of pain. On the other hand, the loss of sensibility to touch (anæsthesia) carries with it the loss of sensibility to pain (analgesia). Cutaneous analgesia is ascertained, clinically, by pinching or pricking the skin. Anæsthesia is ascertained by measuring the distance from each other at which two points in contact with the skin are felt. An instrument devised for this purpose, called the æsthesiometer, may be used; but the common compasses used by the

[1] *Vide* "A Clinical Analysis of the Inflammatory Affections of the Inner Ear," by H. Knapp, in Archives of Ophthalmology and Otology, vol. ii. No. 1, 1871.

draughtsman will answer equally well, and, if these be not at hand, two pins will suffice. The further the two points of contact must be removed from each other in order that each may be separately felt, the less the sensibility to touch. The sensibility is undiminished if the patient be able to feel two points of contact approximated as closely as they are appreciable in health. The sensibility to touch differs in different parts of the body considerably in health. It is most acute on the prolabia, the tip of the tongue, and the ends of the fingers. These normal differences are to be taken into account in judging of anæsthesia, and, also, variations within normal limits in different healthy persons, and in corresponding situations on the two sides of the body. Moderate deviations from the average degree of sensibility, as thus tested, or from an exact uniformity of the two sides, are not to be considered as abnormal without corroborative evidence of sensory paralysis.

Motor paralysis is expressed by the term *akinesia* or *akinesis*. The term paralysis, however, is generally used instead of the latter terms, and, if not designated as either sensory or motor, the latter is understood. Paralysis may affect either the voluntary or the involuntary muscles. The heart, œsophagus, stomach, intestines, bladder, and arteries may be the seat of akinesia. This pathological condition enters into the consideration of these organs in other sections of this work. As pertaining to the diseases of the nervous system, akinesia is limited to the voluntary muscles.

Paralysis is complete when there is total loss of voluntary power over the paralyzed muscles. It is incomplete when this power is not entirely lost, but more or less diminished. The term *paresis* is often used in a sense equivalent to incomplete paralysis. Incomplete paralysis or paresis differs, in different cases, between the slightest appreciable impairment of the normal motor power, and a degree approaching as closely as possible completeness. Paralysis is general when it embraces the muscles of the four extremities, either with or without the muscles of the face. It is partial when a portion of the muscular system is involved, as in hemiplegia and paraplegia. It is local when a very few muscles, or, perhaps, a single muscle only, are paralyzed.

Paralysis may be *neuropathic* or *myopathic*. A myopathic paralysis depends on a primary morbid condition of the muscles paralyzed. A neuropathic paralysis depends on some cause which either prevents the action of volition upon the cerebral fibres which are continued into the nerves going to the paralyzed muscles, or obstructs the transmission of volition at some point between the muscles and the part of the brain whence the voluntary act originates. For the performance of voluntary motion there are three requisites, namely, the communication of the voluntary influence to certain parts of the brain, the conduction from the brain of this influence through motor nerves, and the ability of muscles to contract in obedience to the will. Paralysis may depend on causes affecting primarily either of these three requirements.

An important division of neuropathic paralyses is into central and peripheral. Central paralyses depend on morbid conditions seated in either the brain or spinal cord, and they may be further divided into cerebral and spinal. Peripheral paralyses depend on morbid conditions affecting nerves at any point between their terminations and central connections with either the brain or spinal cord. Paralyses are peripheral when they depend on affections of cranial or spinal nerves within the skull or spinal cord.

There are certain points of difference in the effects of cerebral, spinal, and peripheral paralysis, respectively, which are of practical importance as regards localization of causative conditions and differential diagnosis. In cerebral paralyses the reflex excitability of the affected muscles is retained

and may be increased. The electrical excitability is, also, the same as, or greater than, in health. The muscles do not speedily become atrophied. The cutaneous sensibility is often undiminished, or it is not diminished in proportion to the motor paralysis, and is regained in a short time, although the loss or impairment of the voluntary power over the muscles remains. In spinal paralysis the paralyzed muscles may, or may not, retain their reflex and electrical excitability, the differences in these respects being dependent on the situation of the affection of the cord, together with the degree and the extent of lesions. The reflex excitability is sometimes notably increased. Sensibility may be either retained, diminished, or lost. There may, or may not be trophic disturbances. These points have entered into the clinical history of the different spinal affections which have been considered.

Peripheral paralyses, which are to be considered in the next chapter, are generally local. The paralyzed muscles are often supplied by a single nervous trunk, or, perhaps, by a single branch. Anæsthesia is associated with, and is proportionate to, the motor paralysis. Atrophy of the paralyzed muscles rapidly becomes considerable. The muscles respond to the electrical current if this be applied below the point at which the conduction is obstructed, but not if applied between that point and the brain or spinal cord. The seat of the obstruction may be ascertained by finding the point at which electricity ceases to affect the paralyzed muscles.

Peripheral paralyses are characterized by the electrical phenomena described by Erb under the name "reaction of degeneration." Within a few days after paralysis caused by a lesion of a nervous trunk, the electrical excitability, both to the faradic and galvanic current, applied to the nerve below the seat of the lesion, diminishes, and during the second week becomes extinct. The extinction is permanent if there be no progress toward recovery. When regenerative processes have made some progress, muscular contractions begin to be excited by both currents applied to the nerve. But this does not take place until after the power of the will over the paralyzed muscles is restored to a greater or less extent; that is, the muscles react to the will sooner than to the electrical currents. This is true also of other stimuli applied to the nerve on the central side of the lesion, as compared with electricity applied between the lesion and the paralyzed muscles. The muscles themselves, as well as the nerve-trunk, lose their electrical excitability, for a greater or less period; but when the regenerative processes have reached a certain degree, the muscles respond to the galvanic current for some time before reaction to the faradic current takes place. These successive phenomena are of practical utility as showing, first, the occurrence of degenerative changes in the affected nerve and muscles; second, the occurrence of restorative processes; and third, the progress made in the latter.[1]

The foregoing remarks relate to paralysis dependent on different pathological conditions. Paralyses which are dependent on molecular changes not appreciable, or on histological lesions not yet ascertained, and which are therefore to be considered, at present, as functional, in general end in recovery. Their duration is variable. It may be but a few hours, and even minutes, or, on the other hand, days, weeks, and months. The paralysis is, in some cases, intermittent. The recovery is sometimes abrupt, and sometimes after a more or less gradual improvement. The paralyzed muscles do not waste, except as an effect purely of disease; that is, not from any trophic nervous influence. There may be anæsthesia, or the cutaneous sensibility may remain unaffected. The electrical excitability is retained; the phenomena of the "reaction of degeneration" are wanting. Reflex excitability

[1] *Vide* Ziemssen's Cyclopædia, Am. edition, vol. xi. p. 428.

is sometimes retained and sometimes diminished or lost. The circumstances under which the paralyses occur, and their pathological relations, are of importance in the discrimination. The paralyses which often follow diphtheria, and sometimes other acute febrile diseases, are generally to be reckoned as functional. This is especially true of the so-called hysterical paralyses. The association of paralysis with these affections is, therfore, of significance in respect of diagnosis. Causative circumstances are to be taken into account. Functional paralyses may be referable to exhaustion from prolonged muscular exertions, and to the action of cold. There is no pathological propriety in calling the paralysis attributed to the latter cause rheumatic; clinical experience affords no proof of any relationship between paralysis *à frigore* and rheumatism. The so-called reflex paralysis will be presently noticed in connection with paraplegia. Finally, the functional character of paralyses may be inferred from the probable causation by certain vegetable poisons, namely, woorara, ergot, tobacco, lathyrus sativus, absinthe, camphor, etc. Saturnine paralyses may be regarded as peripheral, and will be considered in the next chapter. Other differential points relate to the particular varieties of functional, cerebral, and spinal paralysis, namely, general paralysis, hemiplegia, and paraplegia, and will be noticed in connection with these.

Treatment of Functional Paralysis.

In the treatment of functional paralysis, a primary object is the removal of supposed direct or indirect causative agencies. Exhaustion from overexertion of body or mind is an indication for rest. Toxical agents, tobacco, etc., should not continue in operation. Anæmia claims appropriate therapeutic and hygienic measures. Cystitis, phymosis, or other local diseases which may be suspected of standing in the relation of causes by means of a reflex influence, or in other ways, should receive proper attention.

Of remedies having direct reference to the paralysis, electricity holds the first rank. Experience shows the usefulness of both the faradic and the galvanic current, different cases differing as regards the superiority of the one over the other. There need not be that delay in resorting to electricity, which is an important precaution in cases of paralysis dependent on diseases involving inflammation. Care, however, is to be taken not to employ too strong currents, nor to prolong, nor repeat unduly, their applications. For practical details, the reader is referred to works which treat specially of electricity as a curative agent. Its curative efficacy must consist in its effects upon the functional activity of the nerves and muscles involved in the paralysis, on the circulation in these parts, and on their nutrition. Its action is that of an excitant, and it is evident that, if carried too far, it may do harm rather than good. The success of electrical treatment, in all paralytic affections, will depend on the exercise of judgment in determining the indications in particular cases, and of skill in its employment. The advantage of experience in its practical application, together with the time and appliances which it requires, render it desirable that some physicians should give to it special attention. Hitherto, the employment of electro-therapeutics in this country has been too much in the hands of uneducated practitioners who know but little of the agent which they employ, and still less of the human organism.

Friction and massage, or kneading with deep pressure, are important measures of treatment. Stimulating liniments facilitate the rubbing, and are, to a certain extent, in themselves useful. These measures are serviceable by promoting the circulation and maintaining nutrition. They should be systematically carried out and persisted in. If the paralysis be complete,

passive movements are important. They should be resorted to daily, and continued as long as they are tolerated without fatigue. If the paralysis be incomplete, daily exercise of the paralyzed muscles by means of the will is of more importance than any remedial measure. As much exercise of the paralyzed muscles as can be taken without fatigue is desirable. The physician should impress the importance of this measure, the more because patients are slow to appreciate it.

Douches of alternately cold and warm water are useful. They should not be continued long enough to be followed by uncomfortable sensations; on the contrary, it is desirable that they should give rise to agreeable effects. Benefit is also often derived from the use of the sponge bath followed by brisk friction.

Of drugs, strychnia or nux vomica and phosphorus are to be recommended. Whether or not they have any specially curative effect, clinical experience affords evidence of their utility.

General Paralysis.

The disease known as general cerebral paralysis, or the paralysis of the insane (*dementia paralytica*), was included among the structural affections of the brain (*vide* page 730). The paralysis is incomplete in this affection, and is, therefore, also called general paresis. Exclusive of this disease, general paralysis referable to intracranial morbid conditions is rare. It may be a result of two attacks of hemiplegia, the first attack affecting one, and the second the other, side. Hemorrhage in the central portions of the pons Varolii may give rise to double hemiplegia, or, in other words, general paralysis. Instances of general paralysis involving muscles supplied by cranial nerves are among the curiosities of clinical experience. In a case under the observation of the late Prof. Coventry, power was lost over all the voluntary muscles except the *orbicularis palpebrarum* and the respiratory muscles. Paralysis following diphtheria has been known to involve not only the lower extremities, together with the neck and trunk, but the muscles of the face, throat, and mouth. The intellect in these cases may be intact; excito-motory or reflex movements perhaps unaffected; respiration, deglutition, digestion, and all the functions necessary to existence going on, but, as regards voluntary manifestations, the patient being in a state of living death. General paralysis involving cranial nerves has also been known to occur in connection with hysteria. In a case for many months under observation, complete paralysis of the four extremities co-existed with incomplete bilateral paralysis of the face. The paralysis in this case was attributed to lead.

In the great majority of cases, general paralysis is spinal. The seat in the spinal cord is to be inferred whenever cranial nerves are not involved, and there are no symptoms denoting cerebral disease. General spinal paralysis, as has been seen (*vide* Chapters II. and IV.), is incident to inflammatory and structural affections of the spinal cord and its meninges. These are to be excluded in arriving at the conclusion that the paralysis is functional. The paralysis may be complete, or there may be a greater or less degree of paresis, and it may or may not be associated with anæsthesia. It follows diphtheria in rare instances, and is sometimes connected with hysteria. It was produced by woorara in a case of rabies, to which reference will be made in treating of that disease. It may be caused by exhaustion and exposure to cold. This causation was exemplified in the case of a man 45 years of age, who, during a severe snow-storm, rode eight miles in a horse-car, standing on the rear platform, his back exposed to the storm. After reaching home he became unconscious for a short time, and, on recovering his consciousness,

there was complete loss of motion and sensation below the head. He was disposed to somnolency, but easily aroused, and his mental faculties were intact. I saw him on the fifth day after the date of the attack. Under a treatment consisting of stimulants, frictions, and nutritious food, he had, in a measure, recovered from the paralysis. These measures were continued, and, in a short time, the recovery was complete.

In functional spinal paralysis, the paralytic condition may be developed rapidly or more or less gradually. The muscles of all the limbs may be simultaneously affected, or the paralysis may commence in one limb and the other limbs become successively affected. The bladder and rectum are rarely involved. The respiratory movements, as a rule, are not affected. Exceptionally there is much suffering from dyspnœa. I have known paralysis of the diaphragm to occur, as shown by the breathing being purely costal, and inability to sneeze, although an intense desire and grimaces were produced by the introduction of snuff into the nostrils.

Recovery may take place after a few days, or it may be delayed many months.

Strümpell has reported a remarkable case of complete anæsthesia of the whole surface of the body and, in a nearly equal degree, of the accessible mucous membranes. All kinds of sensation were lost. There was no sense of smell nor of taste. There was complete amaurosis of the left eye, and partail deafness of the right ear. The muscular sense was gone. The patient was not conscious of muscular contractions or of fatigue. Some reflex action was preserved. There was motor paralysis of the right arm and leg, but none on the left side. The movements of the non-paralyzed limbs were normal when controlled by the eye. If the eye, the sight of which was preserved was closed, the movements were uncertain, although not ataxic. The patient at once fell asleep when the eye and the ear, the perceptions of which were preserved, were closed.

Hemiplegia.

Except from cerebral affections which have been considered, namely, hemorrhage, softening from thrombosis or embolism, encephalitis and tumors, hemiplegic paralysis is of infrequent occurrence. Examples of functional hemiplegia are as follows: Cases have been reported in which it took place suddenly during strong mental excitement, as in a fit of violent anger, recovery being sometimes speedy and sometimes slow. Todd designated the affection in these cases *emotional hemiplegia*. It sometimes follows epilepsy. In a case under my observation, in which epileptic paroxysms recurred at short intervals for several days, hemiplegia occurred before the series of paroxysms had ceased, the face as well as the limbs on one side being paralyzed. The paralysis disappeared completely after a few days. Hysterical paralysis is sometimes hemiplegic. The face and tongue are not involved, and, as a rule, the left side is paralyzed. Hemiplegia may follow chorea, the limbs paralyzed being those of the side most affected with the choreic movements. The paralysis in these cases does not extend to the face or tongue. The paralysis which follows diphtheria is sometimes hemiplegic. I have known transient hemiplegia to follow insolation.

The following cases, stated as concisely as possible, will serve to illustrate hemiplegia from either embolism or thrombosis not giving rise to softening, and hysterical hemiplegia.

A merchant, aged 75, of active habits, attending daily to business, left his home in the morning in his usual health. He was observed to act strangely; he walked with difficulty, and had difficulty in moving his left hand. He was prevailed upon to return home in a carriage, although he insisted that nothing was the matter with him. In an hour after his return I saw him.

He was somnolent, but easly roused. There was paresis of the left upper and lower limbs, together with the left side of the face. The tongue deviated to the left side. On the following day there was marked improvement. The improvement continued, and on the sixth day recovery was complete, and he insisted on attending to his business as usual. There were no signs of cardiac disease. A little laurel water and aconite were the drugs prescribed. He was allowed at once a nutritious diet. Six years afterward there had been no return of the paralysis, and the patient was in good health. Thrombosis was the probable causative condition in this case.

A man, aged about 70, after a long walk in the afternoon, retired at night, feeling well, and slept soundly until morning. On awakening, there was paresis of the upper and the lower limb on the right side. The face and tongue were not involved, but there was aphasia, the patient being able to speak but a few words. Aside from these symptoms he had no ailment. His appetite was unaffected. The paralysis and aphasia disappeared in the course of a few days, no treatment being employed. Three years afterwards he had had no return of paralysis, and was in good health. The diagnosis, in this case, lies between thrombosis and embolism.

A case at my hospital clinic exemplified the occurrence, first of embolism, and afterwards of thrombosis. The first attack was sudden, without loss of consciousness, and the paralysis was of the right side. The paralysis was complete ; but after an hour it had entirely disappeared. Several months afterward, hemiplegia again occurred. In this attack the paralysis was developed gradually, becoming nearly complete in the course of a week. In a few weeks there was only a slight diminution of motor power.

Intermittent hemiplegia of very brief duration was exemplified in the case of a clerk, aged 40 years, who, at breakfast, and apparently in perfect health, had a sudden attack of complete hemiplegia of the right side, without loss of consciousness or any confusion of ideas. The paralysis disappeared completely in the course of an hour. During the following two weeks he had ten or twelve recurrences of the hemiplegia, the paralysis lasting for a few moments only, his health otherwise being perfectly good. The attacks then ceased to recur, and I learned several months afterward that he was well. This patient had had rheumatism, but there were no signs of cardiac disease.

A dressmaker, aged 18, a patient in Bellevue Hospital, exemplified hysterical hemiplegia. Three weeks before her admission, having retired perfectly well the previous night, in the morning she was unable to move the left lower limb. Sensibility was also lost. Toward evening she suddenly lost sensibility and the power of motion in the left upper limb. After a week she recovered power over the upper limb. The paralysis of the lower limb persisted. In walking by means of a crutch, she dragged the paralyzed limb. There was no facial paralysis, and the tongue was not deflected from a right line. There were no symptoms of cerebral disease. She had retention of urine, requiring the catheter, but, after a time, she succeeded in urinating, the physician in charge refusing to continue the use of the catheter. She was notably hysterical, and the globus hystericus was well marked. A month after her admission she was much frightened by a thunder storm, and had hysterical convulsions. The cold douche promptly arrested the convulsions, and, on recovering full consciousness, she at once regained, almost completely, power over the paralyzed limb. The next day she walked without difficulty, and the following day went out of the hospital on a permit. Suddenly, after the lapse of a week, she again became hemiplegic on the same side as before. She recovered in a short time under the use of the shower bath. She subsequently had paraplegia, with analgesia and anæsthesia. She recovered and was discharged from the hospital well.

Spinal hemiplegia, with motor paralysis on one side, and anæsthesia on the opposite side, probably always implies a lesion limited to the half of the cervical portion of the cord on the side of the akinesia.

Instances have been observed of paralysis affecting the upper limb of one side, and the lower limb of the other side.

Malingerers sometimes feign hemiplegia. They are apt to pretend that there is loss of sensation as well as of motion; this should excite suspicion. Hughlings Jackson has pointed out a method of discovering this deception. The malingerer keeps the arm close to the body when asked to stoop forward. In doing this, he exerts a voluntary power over the limb. In hemiplegia, when the patient stoops, the palsied arm falls forward.

Paraplegia.

Paraplegia is to be considered as functional when the absence of any anatomical change is to be inferred from the symptoms and course of the affection. As a functional affection it is much more frequent in its occurrence than general paralysis and hemiplegia. It is the most frequent form of hysterical paralysis. I have met with a case in which repeated attacks had occurred between the ages of 7 and 10 years, the patient being subject to other hysterical manifestations. It is a not infrequent sequel of diphtheria. It may be referable to exhaustion and exposure to cold. The following case is probably an example of sexual excess as a causative agent: a young women, admitted into Bellevue Hospital, stated that she found both lower limbs completely paralyzed on awakening in the morning. She was subject to nocturnal attacks of epilepsy, and a paroxysm occurred during the night when the paralysis took place. She was a prostitute, and had had sexual intercourse with several persons on that night. There was complete loss of sensibility. Slight reflex movement could be excited. On the ninth day after her admission, recovery of motion and sensation was complete, and she was well enough to be discharged on the thirteenth day, having had no treatment directed specially to the paralysis.

The subject of *reflex paralysis* has relation chiefly to paraplegia. Many clinical observers, within late years, have seen cases of paraplegia associated with various affections of different organs—the kidneys, bladder, uterus, ovaries, intestines, etc.—and a causative connection has been inferred from the fact that patients recover from the paralysis, after recovery from their local affections. The latter, it is supposed, induce paralysis by a morbid influence transmitted through the reflex system of nerves; hence the significance of the name *reflex paraplegia*. Now, in order to establish a causative connection between different local diseases and paralysis, it is necessary to show that the former precede the occurrence of the latter in a number of cases too large to be explained by mere coincidence. That facts sufficient to show this have been accumulated, may fairly be doubted, and when, on the other hand, it is considered that the various local diseases supposed to have a causative connection, are not associated with paralysis in the vast majority of cases, such a connection, when the association exists, is conjectural.

The pathological explanations of reflex paralysis are far from satisfactory. The theory of Brown-Séquard is, that a reflex influence causes spasm of the arteries of the spinal cord, and the paralysis is due to anæmia and defective nutrition thus induced. Assuming spasm of the vessels limited to a segment of the cord to be caused by a reflex influence, that this condition is persistent enough to produce the pathological effects attributed to it, is highly improbable. Another explanation is that the supposed reflex influence has a paralyzing effect exerted through the vaso-motor nerves upon the arteries, and

causes paraplegia by inducing congestion of the cord. But paraplegia does not take place in connection with diseases which must induce spinal congestion, such as the cold stages of intermittent fever, dilatation of the right side of the heart, etc., and it is, to say the least, conjectural to reckon congestion of the cord among the causative conditions giving rise to paraplegia.

In some reported cases of supposed reflex paraplegia, lesions of the spinal cord have been found after death. Leyden, Duménil, Weir Mitchell, and others think that the extension of neuritis centripetally sometimes to the spinal cord, will explain the occurrence of paralysis in the cases in which it is supposed to be due to a reflex influence.

In view of these considerations, the theory of reflex paralysis lacks a solid foundation.

Paraplegia may be an imagined disease. I have met with an instance in which this self-deception was diagnosticated, the case being analogous to one reported by J. Russell Reynolds, and called by him paralysis "dependent on idea." These cases are to be distinguished from cases of simulated paraplegia. I have met with the latter in connection with hysteria. Kunze relates the case of a woman who, having kept the bed for a considerable time, under the conviction that she had paraplegia, on the occasion of the house taking fire, resumed instantly the use of her limbs, and, on reaching the house of a relative, at once became again a paraplegic. It is not easy to discriminate imagined paraplegia, inasmuch as hysterical paralysis may instantly be removed by a mental impression. This is seen in cases of aphonia from laryngeal paralysis. I have given the synopsis of a case in which paraplegia disappeared under fright from a thunder storm. Caution is to be observed in the diagnosis; and, if made, the physician is to use discretion in either asserting that the supposed paralysis is imagined, or in employing electricity or some other method of treatment with reference to a physical influence, conjoined with a confident assurance that the treatment will be successful.

Acute Ascending Paralysis.

Under this name Landry, Leyden, Westphal, Harley, Lockhart Clarke and others have described a disease having a characteristic course implied in the name, generally fatal, and without any anatomical characters as yet ascertained.[1]

After prodromic symptoms of an indefinite character, with slight fever, lasting for a few days and sometimes for several weeks, paresis of the lower extremities occurs. The paresis begins in the feet, and, in the course of a few days, extends over the limbs, the paralysis increasing in degree and becoming complete. The paralysis extends to the trunk, and thence to the upper extremities. The respiratory muscles are affected and dyspnœa becomes a prominent symptom. Subsequently the muscles concerned in speech, mastication, and deglutition, are involved. Death takes place by apnœa, and exhaustion from innutrition. The duration varies from a few days to several weeks, the average being from eight to twelve days.

The intellect remains intact, and those cranial nerves only are implicated which arise from the medulla oblongata. Sensibility of the skin and muscles is but little, if at all, affected. There is sometimes hyperæsthesia. The paralyzed muscles do not become atrophied; their electrical excitability is

[1] Cases resembling acute ascending paralysis except by the presence of sensory and electrical disturbances have been attributed to multiple degenerative neuritis. In a typical case of Landry's paralysis Déjérine found degeneration of peripheral nerve-fibres, which, however, he attributes to undiscovered lesions in the gray matter of the cord.

unaffected, and reflex excitability is not diminished until the latter part of the disease. The rectum and the bladder are not affected. Fever is slight or wanting.

Landry was the first to point out the distinctive clinical features of the disease (1859), and it is therefore sometimes called "Landry's paralysis."

In a small proportion of cases, the disease ceases its progress before grave symptoms are manifested, and recovery shortly takes place.

The disease affects men oftener than women, and the majority of cases are in persons between twenty and forty years of age. Beyond these facts, nothing is known of the etiology. In the absence of any anatomical characters, Landry, Westphal, and others have attributed the disease to an unknown toxical agent. This seems a reasonable conclusion in view of the fact that expert histological observers have failed to find any lesion of the spinal cord.

Clinical experience has thus far afforded no evidence of the success of any particular method of treatment. The iodide of potassium, nux vomica, the wet pack, and the galvanic current are recommended. Alcoholics, ammonia, and stimulating tonics, together with sustaining nourishment, are indicated with a view to obviate the tendency to death.

Nervous Asthenia. Neurasthenia.

The term nervous asthenia may be used to denote a morbid condition common in this country, especially in the larger cities. As the name signifies, debility, prostration, or exhaustion, affecting especially the nervous system, constitutes the affection. It occurs without anæmia or any notable disorder of the vital functions. It proceeds from undue functional activity of the nervous system, connected with the exercise of the intellectual and emotional faculties. This morbid condition was considered as a distinct functional affection in the first edition of this work (1866). So far as I know, it had not been so considered prior to that date. Dr. G. M. Beard has devoted to it a practical treatise, substituting for the term nervous asthenia, the name neurasthenia. Other recent neurological writers have accorded to it a place among the functional disorders of the nervous system. The name nervous asthenia was suggested to me by Prof. Fordyce Barker.

Physicians are often consulted by patients who, although far from being well, have no well-defined malady. They complain of languor, lassitude, want of buoyancy, aching of the limbs, and mental depression. They are wakeful during the night, and enter upon their daily pursuits with a sense of fatigue. Under the pressure of mental excitement, they may be able to exert themselves with their usual energy, but when the excitement subsides, they are jaded and worn out. They become apprehensive that their powers are giving way, and are apt to fancy the existence of some serious malady. An investigation of the different organs of the body reveals no evidence of disease; the lungs, heart, kidneys, etc., are sound. None of the affections embraced in the nosological catalogue may be discovered; yet, the morbid condition is real. This brief sketch represents a class of cases with which every physician is familiar.

An inquiry into the habits and circumstances connected with the daily life in the cases now referred to, will show that the mind has been for a long period unduly taxed by the cares and responsibilities of business, over-exertion in the pursuit of wealth or other objects of ambition, long-continued anxiety or inquietude—in short, the patient is suffering from wear and tear of the nervous system. The action of mental causes is increased by other causes which tend to diminish the vigor of the body, such as irregular habits with respect to diet, the hours devoted to sleep and rest, etc. The causes

which act directly through the mind are especially operative in this country, owing to the early age at which persons engage in the active pursuits of life, the great inducements to excessive exertions, and the emulation excited by the activity of others. It is not uncommon to meet with persons who have overtasked the nervous system, without any rest or recreation, for many consecutive years.

The condition of nervous asthenia is, in itself, not a small evil, causing much discomfort and unhappiness to the patient, and rendering him uncomfortable to others by inducing depression, irritability, or moroseness. That this condition favors the development of diseases to which there may be a predisposition, or co-operates with the various causes of disease, is probable. It is apt to engender a desire for stimulants, and thus lead to intemperance. It may eventuate in confirmed melancholia, hypochondriasis, or other forms of mental derangement.

An essential part of the treatment relates to the causation. Frequently it is desirable to endeavor to procure, temporarily, complete relief from exertion and care. It is, however, extremely injudicious to advise permanent relinquishment of active occupations. After rest and recreation for a season sufficient for recuperation of the nervous system, a return to accustomed pursuits is advisable, with injunctions to observe proper moderation, and to comply with the laws of health as regards a fair apportionment of time to recreation, and a proportionate exercise of all the faculties of the mind. It is, of course, desirable that causes of mental uneasiness and anxiety should be removed, but this part of the treatment often is not within the range of medical control. Habits tending to impair bodily vigor are to be corrected, such as dietetic imprudences, late hours, sexual errors or vices, the immoderate use of tobacco, etc. Hygienic measures to invigorate the body are important, such as nutritious alimentation, out-of-door life, sea-bathing, or the sponge-bath, etc. Tonic remedies, varied from time to time, and long-continued, are serviceable both morally and medicinally.

At the present time (1880) there is, perhaps, a tendency to exaggerate the pathological relations of the neurasthenic morbid condition. No anatomical system in the body tolerates functional activity better than the nervous system, provided the organism is sound and the requirements of health in other respects are observed. Patients are sometimes disposed to attribute to over-exertion of the mental faculties what is really due to other violations of the laws of health. The opinion that the symptoms denote excessive brain-work is apt to be received with satisfaction. In some cases, considering the small amount of intellectual work accomplished and the limited capabilities of the brain, this opinion seems ludicrous.

Spinal Irritation.

The name spinal irritation dates from the publication of a paper by Brown, of Scotland, in 1828. Shortly afterward, the work of Teale on neuralgia, and that of Tate on hysteria, appeared, these authors referring the phenomena of these diseases to irritation of the spinal cord. In 1834 the published observations of W. and D. Griffin claimed, in behalf of the supposed morbid condition thus named, a larger scope of application, and this condition soon came to be generally recognized as an individual functional affection. In an article contained in the *American Journal of the Medical Sciences* for April, 1844, I gave the results of an analysis of 58 cases which I had observed and recorded. For several years I was accustomed, in medical lectures, to include spinal irritation among the functional diseases of the nervous system. I was at length satisfied that the phenomena grouped under this name had other

pathological connections, and that the claim of spinal irritation to a place in the nosology was not well grounded. Others held this opinion, and the name had nearly passed out of use; but, within the past few years, it has again come into vogue, and is now recognized by many as denoting a neuropathic affection.

In so-called spinal irritation, more or less pain is referred to the spine, and pressure over certain parts of the column, these parts differing in different cases in number and extent, shows greater or less tenderness. This tenderness is also shown by the application of ice, a hot sponge, and electricity. With the spinal tenderness are associated, in different cases, a variety of symptomatic phenomena, and these, in their situations, are in correspondence with the relations of the latter to the spinal cord. Thus, intercostal and cervico-occipital pains, nausea, vomiting, singultus, palpitations, nervous cough are associated with tenderness over the cervical and dorsal vertebræ, whereas pain in the lower parts of the body, tympanites, colic, dysuria are associated with lumbar tenderness. Patients generally are mentally depressed, the power of physical or mental endurance is diminished, sleeplessness is common, general hyperæsthesia of the surface of the body is sometimes marked, the extremities are cold, and different cases offer a great variety of subjective symptoms. The great majority of patients are women.

That there are cases which exemplify the clinical history of spinal irritation, as described formerly and at the present time, cannot be denied. But that the phenomena are caused by irritation of the spinal cord, or that they are attributable to a morbid condition (either to hyperæmia or ischæmia) in this part of the nervous system, is by no means certain. In a large proportion of cases the phenomena are effects of general anæmia. In some instances they may be due to toxical blood conditions, and they may be caused by reflex influences originating in local disorders of different organs.

Clinical observations show that when there is tenderness over the spine, in connection with disorders of various kinds, soothing applications or mild counter-irritants over the tender portion or portions, are often serviceable as palliative measures of treatment. Curative measures must be employed in other directions.

It is important not to consider the pains and tenderness referred to the spine, in cases of so-called spinal irritation, as symptoms of inflammation of the cord or of its meninges. The absence of fever, the sex of the patient, the existence of anæmia and often of hysteria, point to a purely functional disorder, and render the exclusion of spinal meningitis and myelitis easy.

The name spinal irritation was introduced at a time when local pain and tenderness were regarded as evidence of inflammation, and, as the name denotes a functional condition, its introduction had a favorable influence on the treatment, inasmuch as, at that time, antiphlogistic measures, namely, bleeding, cathartics, mercury, severe counter-irritation, were considered indispensable in treating inflammatory affections.

CHAPTER VI.

DISEASES OF THE NERVES.

Neuritis. Peripheral Paralysis. Paralysis of the Third Cranial Nerve. Paralysis of the Fourth Cranial Nerve. Paralysis of the Fifth Cranial Nerve. Paralysis of the Sixth Cranial Nerve. Paralysis of the Motor Portion of the Seventh Cranial Nerve. Paralysis of the Eighth Cranial Nerve. Paralysis of the Ninth Cranial Nerve. Local Paralysis of other than Cranial Nerves. Paralysis of the Cervical Sympathetic Nerve. Paralysis from Lead. Paralysis from Arsenic, Copper, and Mercury. Neuralgia. Trifacial Neuralgia. Cervico-occipital Neuralgia. Cervico-brachial Neuralgia. Dorso-intercostal Neuralgia. Lumbo-abdominal Neuralgia. Crural Neuralgia. Sciatic Neuralgia. Dermalgia. Myalgia. Cephalalgia.

THE diseases to be considered in this chapter are those affecting either nervous trunks, their branches, or their terminal distributions; in other words, diseases of the peripheral nervous system. In this division are embraced neuritis, paralytic affections and neuralgia referable to nervous trunks or branches. Paralysis from lead will be included among the peripheral paralyses.

Neuritis.

Although inflammation of the nerves is often spoken of in connection with various neuralgic, paralytic, and spasmodic affections, its existence has not often been demonstrated after death. The nerves, in fact, seem to be peculiarly exempt from inflammatory processes. In suppurative inflammation it is not rare to find them comparatively intact, while the surrounding tissues are infiltrated with pus. Nevertheless, the occurrence of both acute and chronic neuritis has been satisfactorily proven, and, of late years, merited consideration has been given to these pathological conditions.

In acute neuritis the nerves are swollen, reddened, and more succulent than normal. Microscopical examination shows hyperæmia, often ecchymoses, serum, and emigrated white blood-corpuscles in the interstitial tissue between the nerve-fibres. Large granular corpuscles may also be present. The nerve-fibres may be little changed, or their medullary sheaths may be broken up and the fibres undergo degenerative atrophy.

Chronic neuritis is characterized by increase of the interstitial tissue (sclerosis) and consequent compression and degeneration of the nerve-fibres. The nerve is firmer than normal, usually diminished, but sometimes increased in size from interstitial deposit of fat, and of a grayish color.

Neuritis may affect only a small portion of a nerve in its course, or may extend from a primary focus of inflammation either in a central or a peripheral direction. We thus distinguish *circumscribed neuritis* and *ascending* or *descending neuritis*. It is also held that a neuritis may extend irregularly along the course of a nerve so as to attack certain spots and leave the intervening portions unaffected. This variety is called *neuritis disseminata* or *neuritis migrans*. In opposition to the positive results of Klemm, Feinberg, and Tiesler, the recent careful experiments of Rosenbach[1] failed to produce a

[1] Rosenbach, Arch. f. experim. Pathologie, viii. p. 223.

disseminated neuritis, so that the experimental evidence for this variety of neuritis is not conclusive. A remarkable case of acute neuritis attacking in succession most of the peripheral nerves of the body, and leading to progressive paralysis of the extremities with anæsthesia, has been recently described by Eichhorst under the name acute progressive neuritis.[1] With the exception of the presence of anæsthesia and of loss of electro-muscular reaction, the symptoms resembled those of acute general paralysis.

Leyden[2] has recently described under the name *multiple degenerative neuritis* an affection characterized by inflammation of a number of the peripheral nerves, particularly the motor. The symptoms consist of a widespread acute or subacute motor paralysis followed by atrophy of the affected muscles, and frequently neuralgic pains, hyperæsthesia, and tenderness on pressure over the nerves and muscles involved. The clinical history resembles in all essential particulars the subacute spinal paralysis of Duchenne (page 751).

Among the more important causes of acute neuritis may be mentioned, direct injuries to the nerves as by wounds or blows, the extension of inflammation from adjoining parts (the nerve seems to resist the inflammatory process until its sheath is destroyed), exposure to cold and the poison of certain infectious diseases. In Eichhorst's case, and in some others of acute neuritis, no evident cause could be assigned. As already stated, many cases of so-called reflex paralysis are referred by Leyden and others to an ascending or migrating neuritis extending from the region of irritation (for example, an inflamed bladder) to the spinal cord, where an acute or chronic myelitis may be induced. The secondary degeneration of the nerves which sometimes follows myelitis and other diseases of the spinal cord, is considered by some writers as chronic neuritis.

Neuritis seated in a sensory nerve gives rise to pain extending along the affected nerve, perhaps to its terminal branches. Subsequently, there may be anæsthesia, either with or without analgesia.

Neuritis seated in motor nerves, or those containing motor fibres, may give rise to muscular contractions, and paralysis of motion may be a secondary effect. Other effects are loss of reflex and of electrical conduction. The paralyzed muscles, in these cases, rapidly become atrophied. Erythema of the skin, vesicular eruptions, and dark-colored patches are supposed to be sometimes dependent on a neuritis. The symptoms of the multiple degenerative neuritis of Leyden have already been mentioned.

The diagnosis involves a discrimination from neuralgia. Points which distinguish a neuritis are as follows: The pain more continuous, that is, not occurring in paroxysms, or the exacerbations less marked; the occurrence of paralysis when motor or mixed nerves are affected, and the loss of reflex and electric conduction. If the affected nerve be superficial, or accessible to pressure, there is tenderness over it and from the inflamed part along the whole tract, the tenderness not confined to certain isolated points as in neuralgia. The inflamed nerve may be felt to be like a hard cord. The skin is reddened over the site of the inflammation.

In most cases, neuritis being due to the presence of a foreign substance, a wound, the pressure of a tumor, or the existence of inflammation in an adjacent situation, the treatment has reference to the local causative circumstances. When the affection is independent of these, revulsive and soothing local applications are indicated. Subcutaneous injections may be required to relieve

[1] Eichhorst, Virchow's Archiv, Bd. 69.
[2] Leyden, Zeitschrift f. klin. Med., Bd. I. p. 405, 1880.

the intensity of pain. The anæsthesia and motor paralysis which may follow, call for the employment of electricity.

Peripheral Paralysis.

Characteristics distinguishing peripheral from central paralysis have been already stated (*vide* p. 771). In peripheral paralysis, generally, a single nerve is affected, and not infrequently a division or a branch of a nervous trunk. If the paralysis be limited to parts supplied by a division or a branch of a particular nerve, that is, if parts supplied by divisions or branches of the affected nerve between the paralyzed parts and the brain or spinal cord be not involved, the paralysis is probably peripheral, not central. That paralysis is peripheral is sometimes shown by the fact that convulsive movements or spasms having a central origin affect muscles to which certain divisions or branches of a nerve are distributed, while the paralyzed muscles to which other divisions or branches of the same nerve are distributed remain unaffected.

Peripheral paralysis is often attributed to traumatic causes, such as wounds, contusions, stretching, and external pressure. It may be due to neuritis, lesions resulting from inflammation, neuromata, and tumors of various kinds so situated as to press upon the affected nerve. In certain situations it is caused by exposure to cold. It occurs when its causation is not discoverable, and when its occurrence is not explained by any appreciable change in the nerve affected. Paralysis from causes which lead to degenerative changes in the affected nerve and muscles, is characterized by the phenomena described by Erb under the name "reaction of degeneration" (*vide* page 771).

The treatment, in cases of peripheral paralysis, has relation to local causes whenever these can be ascertained and reached. Their continued operation is, if possible, to be prevented. Lacerations and divisions of nerves are to receive proper surgical treatment with reference to the restoration and reunion of separated or injured parts. Tumors pressing upon nerves are to be removed if practicable, abscesses opened, and inflammation treated according to the indications. It is obvious that the probability of improvement and recovery must depend on the nature of the causes and the extent to which they can be successfully treated. Cases in which the paralysis is due to cold or to transient external pressure, and those in which there is no discoverable causation or appreciable lesion, generally tend to a favorable termination, and this may be hastened by therapeutic measures.

The chief therapeutic agent is electricity. The employment of this agent is to be governed by rules, the consideration of which is not embraced within the scope of this work. Local frictions, the use of stimulating liniments, the cold and warm douche, the topical application of strychnia, and voluntary exercise of the paralyzed muscles whenever the conduction of volition is not wholly obstructed, are measures of utility in peripheral, as in central, paralysis. In cases of peripheral, as of central, paralysis, the probability or the possibility of a syphilitic connection is to be considered with reference to the treatment. Anti-syphilitic medication should be employed whenever there is ground for a suspicion of this connection.

Paralysis of either of the nerves of special sense, namely, the olfactory, the optic, or the auditory nerve, is frequently dependent on abnormal conditions relating to the apparatus provided for the exercise of smell, sight, and hearing. This remark applies more especially to the eye and ear. Affections of the eye and ear, involving loss or impairment of sight and hearing, belong in the province of surgery, and treatises are devoted specially to them. It is

important, however, for the physician to take cognizance of paralysis affecting these senses, as denoting intra-cranial disease. In most cases, paralysis of these nerves of special sense, if due to intra-cranial disease, is associated with paralysis of other parts. Paralyses of the other cranial nerves severally claim brief consideration. It is more correct to say paralysis of the parts to which the branches of a nerve are distributed than to apply the term to the nerve, but the latter is a convenient mode of expression, and is sanctioned by usage.

Paralysis of the Third Cranial Nerve.

Paralysis of this nerve, the *motor oculi communis*, gives rise to dropping of the upper eyelid or ptosis, diverging strabismus, protrusion of the eyeball, and dilatation of the pupil. These effects correspond with the distribution of the several branches of the third pair of nerves. The internus rectus muscle being paralyzed, the eyeball is turned outward by the externus rectus and the superior oblique muscle; dilatation of the pupil is caused by paralysis of the circular fibres of the iris. The effects are so obvious and characteristic as at once to be referable to paralysis of this nerve. Paralysis of this nerve may be produced by an injury in the neighborhood of the eye, by the action of cold, and by over-exertion in occupations which require especially the use of the eyes. If produced by cold or over-use, it is functional, and will not be permanent. Double vision frequently accompanies paralysis of this nerve. The paralysis is rarely limited to this nerve if it proceed from intra-cranial lesions; but it is associated with paralysis affecting other nerves, or with other marked effects of cerebral disease. It is rare in cases of hemiplegia. Occasionally it is the first event pointing to grave cerebral lesions. It may be a forerunner of hemiplegia, convulsions, or coma. In a case under my observation, paralysis affecting this nerve on the right side occurred without other central symptoms three weeks before an attack of apoplexy and left hemiplegia, the latter proving fatal two hours after the attack. If ptosis exist without strabismus and dilatation of the pupil, it may be inferred that the paralysis is not central but peripheral. The paralysis is then limited to the upper branch of the nerve. So, also, if the inferior branch be alone affected, causing external strabismus and dilatation of the pupil without ptosis, the paralysis is probably peripheral.

Paralysis of the Fourth Cranial Nerve.

Paralysis of this nerve, the *patheticus*, produces effects less marked than those of the third nerve. The power of moving the eye in the orbit is not much impaired, but there is double vision. Paralysis of this nerve is an isolated affection in some cases of syphilis.

Paralysis of the Fifth Cranial Nerve.

The effects of complete paralysis of this nerve are shown by its division within the skull in inferior animals. Loss of sensibility (anæsthesia and analgesia) on one side of the face, on the mucous membrane within the mouth, the conjunctival membrane on that side, and the anterior portion of the tongue, with paralysis of the masticatory muscles on the same side, immediately follows. The intra-cranial division of this nerve is followed within a short time by ulceration of the cornea, and sometimes by suppurative inflammation of the whole eye. These effects do not follow if the eye be suitably protected from injury and from dryness. There is not sufficient evidence for the view that the ulceration of the cornea is due to the withdrawal of trophic nervous

influence. Complete paralysis of the trigeminus from disease is rare. The motor portion may be affected either separately or in conjunction with the sensory divisions. Impairment or loss of the power of mastication denotes paralysis of the motor or third division. Bilateral paralysis of the motor portion occurs in cases of bulbar paralysis. The different sensory divisions may be affected separately, namely, the ophthalmic, the superior and the inferior maxillary. The loss or impairment of sensibility is then confined to the portions of skin and mucous membrane supplied by the branches of the paralyzed division.

Ulceration of the cornea, absence of reflex conduction, redness and swelling of the face together with the gums, constitute evidence that the paralysis is peripheral, the local cause being perhaps intra-cranial but extra-cerebral. When the paralysis is central, it is accompanied by symptoms denoting cerebral disease; and generally other cranial nerves are involved.

Pain is sometimes referred to parts supplied by the branches of the nerve, notwithstanding anæsthesia and analgesia in these parts are complete (anæsthesia dolorosa). The cause of the pain is situated in the portion of the nerve posterior to the seat of the affection which causes the paralysis. The explanation is the same as when, after an amputation, pain is felt to be in the amputated limb ("eccentric projection of perception").

Bilateral paralysis of this nerve is sometimes observed. In a case reported by Althaus the common sensibility of the face and scalp was lost, together with the sense of temperature and of tact; the mucous membrane of the eyes, nose, and mouth was completely anæsthetic; the sense of taste was preserved, although the exercise of it seemed less prompt than in health; the muscles of mastication were completely paralyzed. The tongue presented a frightful spectacle, having been bitten and lacerated in every direction during the act of taking food. The patient experienced no pain when a tooth was drawn. The lips were covered with froth. The sense of smell and of sight were not affected, except that the latter was obstructed by thick leucoma of both corneæ. He suffered much from photophobia. There was an abundant secretion of mucus from the Schneiderian membrane. Hearing was intact, but the patient was greatly annoyed by tinnitus aurium. The paralysis was produced by long exposure of the face to a keen wind, the morbid condition being supposed to be inflammation of the neurilemma where the nerve emerges from between the transverse fibres of the pons Varolii at the base of the brain. The brain was unaffected, and the paralysis was limited strictly to the distributions of the fifth pair. At the end of three months, under treatment consisting of the systematic application of the continuous galvanic current to the several branches of the affected nerve, the recovery was nearly complete.[1]

Paralysis of the Sixth Cranial Nerve.

Paralysis of this nerve, the *motor externus* or *abducens*, leads to converging strabismus, the eyeball being turned inward by the action of the internal rectus or adductor muscle, from the loss of the antagonism of the external rectus or abductor muscle. The patient is unable to turn the eyeball outward, whereas, in ordinary cases of strabismus, this can be done if the other eye be closed. Paralysis of this nerve sometimes occurs in cases of cerebral meningitis, and in connection with lesions giving rise to hemiplegia. This nerve, however, escapes in the majority of the cases in which paralysis of other parts occurs from intracranial affections. When the nerve is paral-

[1] Transactions of the Royal Medical and Chirurgical Society of London, vol. lii.. 1869.

yzed, paralysis of the third cranial nerve is frequently associated. The effect of paralysis of both these nerves is immobility of the eyeball, as regards lateral movements; it can neither be turned inward nor outward. Double vision is likely to exist when the paralysis is limited to the sixth nerve. Functional paralysis of this nerve is not uncommon. It may be caused by neuritis, and is sometimes attributable to syphilis.

Paralysis of the Motor Portion of the Seventh Cranial Pair. Bell's Paralysis. Mimetic Paralysis.

Paralysis of this nerve, the *portia dura*, or the motor facial nerve *par excellence*, is much less infrequent than paralysis of the sensitive portion of the fifth nerve. Complete paralysis of this nerve produces characteristic appearances, by means of which the affection is at once recognized. The expression of the physiognomy peculiar to the person is abolished on the affected side. The naso-labial fold is flattened on this side. In speaking or smiling, the mouth and sometimes the extremity of the nose are drawn to the opposite side. This appearance is so striking and distinctive, that the existence of the paralysis is immediately apparent. The power over the *orbicularis palpebrarum* being lost, the patient is unable to wink or to close the eye; when the attempt to close the eye is made, the eyeball is turned upward so that the cornea is concealed by the upper lid; the upper lid is abnormally elevated and the lower lid depressed, so that the eye appears to project more than in health. Owing to the loss of power over the orbicular muscle, the tears are not diffused over the conjunctiva as in health, and hence results epiphora. From the constant exposure of the conjunctiva in sleep as well as in waking hours, it becomes inflamed, and opacity of the cornea may be a result of the conjunctivitis. The eyebrow is lowered, and the patient is unable to frown or to wrinkle the forehead on the affected side, from loss of power over the *corrugator supercilii* and the anterior portion of the *occipito-frontalis* muscle. The *ala nasi* ceases to dilate, but may contract in inspiration, and dilatation, if it occur, is in expiration. Loss of power over the *orbicularis oris* on the affected side, renders the patient unable to whistle; expuition is imperfect, the saliva dribbles from the angle of the mouth, and the pronunciation of certain letters, namely, o, b, p, is difficult. Loss of power over the *buccinator* renders the cheek flaccid; it is liable to be wounded in mastication, and the patient is annoyed by the accumulation between the cheek and gums of food which he is obliged to remove with the finger. The cheek and lips of the affected side are sometimes puffed outward by the expired breath, as in the act of expelling tobacco smoke from the mouth. These obvious appearances are readily understood by reference to the anatomical distribution of the branches of this nerve. They are, of course, less marked in proportion as the paralysis is incomplete. The *velum pendulum palati* on the paralyzed side is sometimes abnormally flaccid, and the *uvula* deflected to the opposite side. The auditory sense on the paralyzed side is more acute than in health. After long continuance of the paralysis, contracture of the paralyzed muscles may develop, causing deviation of the features to the affected side.

Paralysis of this nerve is not very infrequently an isolated affection, existing independently of cerebral disease. The seat of the affection may be intracranial, but extra-cerebral, that is, the seat although within the skull, is between the central connection of the nerve and its entrance into the meatus auditorius. It may be due to the pressure of a tumor on the nerve after it emerges from the stylo-mastoid foramen. The nerve may be affected within the petrous portion of the temporal bone, from fracture, or in connection with

caries of this bone resulting from median or internal otitis. Facial paralysis occurs not infrequently from the action of cold upon the face. I have met with instances of its occurrence in connection with anæmia. It is sometimes produced in new-born children by the employment of the forceps in labor. Facial paralysis may proceed from the various intra-cranial affections which have been considered. In these cases, it is frequently associated with paralysis affecting other nerves. It is sometimes a forerunner of a grave cerebral affection.

If central, the paralysis is generally preceded or accompanied by symptoms denoting a cerebral affection. If the nerve be affected in a situation involving the *chorda tympani*, the sense of taste on the lateral half of the anterior portion of the tongue corresponding to the paralyzed side is diminished, as shown by comparing the sensations produced by placing successively on the two sides of the anterior extremity of the tongue some bitter substance in powder, for example aloes. The salivary secretion is also diminished. These effects are due to the *chorda tympani* being involved in the paralysis. The taste and the salivary secretion are not affected if the cause producing the paralysis act upon the nerve anterior to the situation at which the chorda tympani is given off. Flaccidity of the palatine arch on the affected side, and deflection of the uvula to the sound side, denote that the cause of the paralysis acts upon the nerve either within the aqueductus Fallopii or before it enters this canal, the branches supplying the levator palati and the azygos uvulæ muscles being here given off. If the paralysis be central, the electro-muscular contractility is preserved; if it be peripheral, the reaction is rapidly lost. The paralysis is peripheral when the nerve is affected at any point beyond its origin. Paralysis of the sixth nerve accompanying paralysis of the facial nerve, denotes a central lesion, these nerves arising near each other in the floor of the fourth ventricle. The absence of reflex movements is evidence that the paralysis is peripheral. If winking be not produced by touching the eyeball, the sensibility of the latter being preserved, the nerve is affected after leaving its central connection; on the other hand, if the eye be closed involuntarily by an impression made on the conjunctiva, when the voluntary power is lost, the paralysis is central. Abnormal acuteness of hearing is evidence that the nerve is affected behind the point at which the twig going to the stapedius muscle is given off. The paralysis is much oftener complete when it is peripheral than when it is central. Accompanying hemiplegia, the paralysis is generally incomplete, and the orbicular muscle of the eye is but little affected. It is rarely wholly unaffected, as stated by Todd. Evident diseases of the ear or of the parotid gland, often account for the paralysis as well as its peripheral character, and point to the seat of the affection.

In cases of facial paralysis dependent on neuritis caused by cold, or when it is functional, recovery may be expected after the lapse of several weeks. If the paralysis continue without improvement for two or three months, it is probably not functional, but, if not dependent on central lesions, it proceeds from either disease of the nerve or something pressing upon it and occasioning obstruction. Under these circumstances, it will be likely to remain a permanent affection. The prognosis is also grave in proportion as the electro-muscular contractility is diminished.

Bilateral paralysis (diplegia facialis) has been repeatedly observed, but examples are extremely rare.[1] It may result from injury or disease of the two nerves, or from intra-cranial lesions. The expression is then abolished

[1] For a report of 28 cases of double-faced paralysis, see article by Dr. Pierreson, in Archives Générales de Médecine, Aôut et Septembre, 1867.

on both sides of the face. The face remains immovable, the only changes which are observed relating to the circulation. It is as if the face were covered by a mask. Relaxation of the soft palate may co-exist, rendering the voice unnatural. Moreover, articulation is difficult from the immobility of the lips. Mastication is difficult from the same cause. The saliva dribbles from the mouth. The eyes are constantly open and staring (lagophthalmus). Aside from the great inconvenience which bilateral facial paralysis occasions, the prognosis is serious, or otherwise, according to the situation and nature of the morbid conditions on which the paralysis is dependent. In a case which came under my observation, with the double facial paralysis was associated incomplete general paralysis, and the patient died by apnœa from inability to expel, by coughing, matter in the air-passages. Paralysis affecting the *alæ nasi* may lead to an amount of depression with inspiration sufficient to occasion notable obstruction. The cartilaginous portions of the nostrils on both sides are sucked in with the inspired breath to such an extent as to constitute a serious obstacle to respiration.

Paralysis of the Eighth Cranial Nerve.

The paralysis affecting the pharynx, which occurs as a sequel of diphtheria in certain cases, and which is sometimes limited to this situation, is to be considered as a paralysis of that division of the eighth nerve called the *glosso-pharyngeal*. This local paralysis will be referred to in treating of diphtheria. Occurring in that connection it is functional and ends in recovery.

Paralysis of this nerve, together with the *par vagum*, occurs in various cerebral affections which produce deep coma, giving rise to impairment and loss of power of deglutition and diminished frequency of the respirations. This paralysis precedes a fatal termination. It may occur from a small extravasation of blood into or near the medulla oblongata. I have met with an example, the apoplectic attack being characterized by notable disturbance of respiration and inability to swallow, without complete loss of consciousness. The vagus is an inhibitory nerve of the heart; its irritation causes slowing of the heart-beats, and, if intense, their cessation in diastole; its paralysis causes increased rapidity of the cardiac pulsations.

Paralysis of the spinal accessory nerve, giving rise to aphonia, has been already referred to in treating of the affections of the larynx. Incomplete aphonia may be a result of paralysis of this nerve from the pressure of an aneurismal or other tumor on the recurrent laryngeal nerve, and it is sometimes produced by the surgeon in operations on the neck.

Paralysis of the Ninth Cranial Nerve.

Paralysis of this nerve, the *hypoglossus*, on one side, involves loss of power over the genio-hyo-glossus muscle on that side. The effect is a deviation of the tongue from a right line when protruded, the apex pointing to the side of the paralysis. The direction in which the apex points is readily understood when the action of the muscles which protrude the tongue is considered. These muscles extend from the chin to the base of the tongue, and when, from paralysis, the protrusion is affected by the muscle on one side, the base is drawn toward that side, and, as a result of the base moving in one direction, the apex turns to the opposite direction, the latter being the paralyzed side. Paralysis of this nerve rarely exists as an isolated affection, and is generally symptomatic of intra-cranial disease. It exists frequently in cases of hemiplegia.

In determining the existence of this paralysis, it is to be borne in mind

that the tongue may deviate from a right line in consequence of absence of teeth on the side to which the apex is turned, or of irregular inward projection of teeth on the other side. Dropping of the upper lip on one side produces an appearance as if the tongue deviated to the opposite side; and to obviate liability to error on this score, the upper lip should be raised with the finger while the tongue is protruded.

Paralysis of the hypoglossal nerve on both sides is extremely rare, but cases are sometimes observed. In complete paralysis of this nerve on both sides, there is inability to protrude the tongue, and the power of speech is lost from inability to articulate. Incomplete paralysis renders protrusion of the tongue and articulation more or less imperfect. Paralysis of this nerve on both sides enters into the paralytic affection which has been considered under the name bulbar paralysis.

Local Paralysis of other than Cranial Nerves.

Paralysis may be produced by injuries or diseases affecting nervous trunks in any part of the body. The loss or impairment of motion or sensation, or both, extends over the parts supplied with the nervous filaments given off by the nerve below the situation of the injury or disease. Traumatic local paralysis follows division or wounding of nerves and contusions. If a contusion give rise to paralysis by simple shock or stunning the nerve, recovery may be expected. But paralysis due to palpable injury of the structure of a nerve is apt to be permanent, although reunion, with a restoration of function, may take place after the division of a nerve of considerable size. Diseases which give rise to local paralysis by affecting nerves, are tumors or morbid growths situated within and without the neurilemma, and inflammation of the neurilemma, or of the nerve-substance. The latter generally occurs by extension of inflammation seated primarily in the structures adjacent to the nerve affected, idiopathic neuritis being a rare affection (*vide* page 781). Paralysis due to the pressure of a tumor may be recovered from if the pressure be removed before disorganization or atrophy has resulted.

Pressure on a nervous trunk, continued steadily for several hours, may lead to temporary or even permanent paralysis. Paralysis of an upper extremity has repeatedly occurred from remaining in profound sleep, or in a state of intoxication, with the arm hanging over the back of a chair, the paralysis being due to pressure on the brachial plexus. I have met with many examples of paralysis of the forearm attributable to lying, intoxicated, with the weight of the body upon the arm. Paralysis of a single muscle, or a small group of muscles, when not traumatic, is significant of syphilis as the cause.[1]

The following interesting case of local sensory paralysis from injury has fallen under my observation. The injury was received by falling from a considerable height upon the deck of a vessel, and striking upon the nates, in a sitting posture. Permanent paralysis of the sensibility of the rectum and anus followed the contusion. Excrescences which at one time existed around the anus, were removed without any sensation of pain. The patient has no consciousness of the accumulation of feces in the rectum, and never experiences the desire for defecation. Hence, the bowels are habitually constipated. The contraction of the sphincter, due to reflex influence, is intact. Involuntary evacuations occur only when diarrhœa exists, and when voluntary power over the muscles is requisite to prevent their occurrence. There is no paraplegia, no difficulty in evacuating the bladder, and no sexual

[1] *Vide* Art. by Dr. Keyes, in the New York Med. Journal, Nov. 1870.

deficiency. The accident occurred more than forty years ago, and in the mean time the person has had good health.

Paralysis of the Cervical Sympathetic Nerve.

The experiment of dividing the sympathetic in the neck, repeated by Bernard in 1851, and its effects studied more fully than by previous observers, is now made familiar to medical students by those teachers in physiology who employ vivisections. The reader is, therefore, presumed to know that the immediate results of this experiment are, congestion of the head on the side corresponding to the section, rise of temperature due to an increase of the processes of nutrition, and contraction of the pupil on the same side. The effects on the circulation and nutrition are attributable to paralysis of vaso-motor nervous filaments. Paralysis of this nerve occurs from pressure upon it of a tumor, and it has followed surgical operations and other wounds. Contraction of the pupil is one of the symptoms of aortic aneurism when the tumor is so situated as to press upon this nerve. Dr. S. Weir Mitchell has reported a cases in which paralysis of the right sympathetic was caused by a wound from a musket ball. The right pupil was contracted, and this eye myopic. On exercise, the right side of the face became flushed, while the left side was pale.[1] Dr. William Ogle has reported a case in which, from the local appearance and the phenomena, it was inferred that the right sympathetic had been destroyed by an abscess in the neck. In this case, the right pupil was contracted, and the eyeball somewhat retracted. The right side of the head was redder and warmer than the left, especially after exercise. A singular feature in this case was that the patient sweated on the left side of the face only. This was observed repeatedly after active exercise, and during exposure to great heat in taking a Turkish bath. Although this condition had existed for two years, no inflammatory process had followed.[2] Functional paralysis of the sympathetic system, in different situations, has been supposed to be involved in certain cases of paralysis affecting the upper and lower limbs, and to enter largely into the pathology of nervous affections accompanied by disturbances of circulation, secretion, and nutrition. These views are founded chiefly on the relations of the sympathetic system to the vaso-motor nerves, as shown by experimental observations on inferior animals.

Paralysis from Lead.

The accumulation of lead within the system may give rise to partial and even general paralysis, but, as a rule, the paralysis due to this cause is local. In the great majority of cases, the paralysis is limited to the extensor muscles of the upper or lower extremities, and the extensors of the upper are much more frequently affected than those of the lower extremities. The muscles of the upper extremity supplied by the radial nerve are those chiefly affected. The supinators escape. The usual form of lead paralysis is that commonly known as *wrist-drop*. This name expresses the peculiar appearance of the upper extremities. The patient is unable to raise the hand on a line with the forearm. Frequently the first series of the phalangeal bones of the hand cannot be brought on a line with the back of the hand, but the second and third series can generally be extended, as they are acted upon by the interossei muscles. The dropping of the hands is characteristic of this affection.

[1] *Vide* Injuries of Nerves, by S. Weir Mitchell, M.D., 1872.
[2] *Vide* Trans. Royal Med. and Chirurg. Society of London, vol. lii., 1869.

Whenever the peculiar appearance referred to is presented, the physician is justified in assuming that the paralysis is from lead. Paralysis of the extensors of the lower limbs is shown by inability to raise the feet with the heels resting on the floor, or to raise the toes; the feet drop when the patient walks, and he therefore steps high to avoid tripping. If the extensors of the legs be affected, the patient throws them forward with feebleness as compared with the force with which they may be flexed. Paralysis of the extensors of the lower limbs is not common. In a case under my observation, the extensors of both the feet and hands are paralyzed; the patient is affected with dropping at the ankle as well as at the wrist.

The appearance is diagnostic, but other evidence of lead-poisoning may almost always be obtained. As a rule, paralysis succeeds other characteristic effects of lead, more especially the affection known as lead-colic (*vide* page 540). The blue line on the gums, referred to in treating of lead-colic, is always to be sought for. Generally the occupation of the patient suggests the source of the paralysis, but in some cases the mode in which the lead has been introduced into the system is ascertained only after careful investigation. An examination of the urine for the presence of lead should not be omitted.

Lead-paralysis belongs among the symmetrical or bilateral affections. It is very rarely limited to one side, and corresponding muscles on the two sides are usually affected, but, in general, differently as regards the degree of paralysis. The paralysis may be complete or incomplete, and different cases differ much in respect of its degree. The power over the flexor muscles is frequently more or less impaired, but in some cases, with almost complete loss of power over the extensors, the flexors are but little, if at all, affected. This fact was illustrated in a striking manner in a case under my observation at Bellevue Hospital. Wishing to group several cases of paralysis for a clinical lecture in the hospital amphitheatre, which is situated at the top of the building, I desired to have a patient affected with complete paraplegia carried up from a ward on the ground-floor. Four flights of stairs were to be mounted. One of the patients, who was to make part of the group, was affected with lead-paralysis, the extensors of the hand being nearly powerless. He was a man of great strength, and he volunteered to carry his fellow-patient to the amphitheatre on his back. It was necessary to assist him in obtaining a firm grasp of the patient, and when this was obtained, he performed the feat with ease, and, after the lecture, brought the patient down to the ward.

The pathology of lead-paralysis remains to be elucidated. Whether the paralysis be myopathic, peripheral, or central, is not settled. In the absence of ascertained facts sufficient to warrant a conclusion, discussion respecting its seat, and the *modus operandi* of the poison, is waived. The electric excitability and sensibility of the affected muscles is diminished. This has been observed to precede impairment of voluntary power, and the latter, after paralysis has occurred, may be regained before the normal reaction to electricity returns. The paralyzed muscles sometimes respond to the galvanic, and not to the faradic, current. The paralyzed muscles are speedily atrophied. These facts are characteristic of peripheral and certain spinal paralyses.

It is to be borne in mind that other muscles than those involved in the common form of lead paralysis, or the wrist-drop, may be paralyzed by this cause. The evidence of lead-poisoning is therefore to be sought after in cases of paralysis in which other adequate causes are not evident, that is, in cases in which the paralysis is not traumatic nor connected with evident lesions. Amaurosis is one of the occasional effects of lead-poisoning. Anæsthesia and

analgesia of the surface have also been observed, affecting limited portions of the integument of the body and extremities. The muscles of the larynx concerned in phonation have been known to become affected, leading to aphonia; also the lips and lingual muscles, rendering articulation difficult.

The duration of lead-paralysis is very variable. It is sometimes of short duration, but much oftener continues for a considerable period, and improvement, if it take place, is very gradual. If no improvement take place for several weeks, the prognosis is unfavorable as regards recovery; the paralysis will be likely to be permanent. If the paralysis continue long enough to lead to notable atrophy of the affected muscles, and they do not react to either the faradic or galvanic current, the condition, as regards recovery or improvement, is hopeless. The proportion of cases in which this result takes place is not small.

The treatment of paralysis from lead involves, in addition to the measures applicable in general to paralysis, remedies having reference to the elimination of lead from the system. The iodide of potassium is supposed to form with the lead a soluble compound, and, in this way, to promote its elimination. It must be admitted that the clinical proof of this effect of the remedy is not very conclusive. Warm baths and the hot-air bath are useful. It is doubtful whether sulphur baths, which have been much recommended, derive any advantage from the action of sulphur on the body. As regards the treatment addressed to the paralysis, the clinical evidence of the benefit of strychnia, given internally and applied endermically, is conclusive. A most important measure of treatment is the employment of electricity, more especially of faradism.

Paralysis from Arsenic, Copper, and Mercury.

Paralysis is an occasional effect of either acute or chronic arsenical poisoning, oftener of the former than of the latter. The paralysis may be confined to a few muscles, or it may embrace the muscles of the lower extremities (paraplegia). General paralysis is sometimes produced by this metal. Recovery takes place as a rule, with some exceptions.

Paralysis from copper is preceded by the symptoms of gastro-duodenitis. Instances of paralysis from this cause are extremely rare.

Mercury sometimes causes paralysis which is always preceded by mercurial tremor. The effects of mercury upon the mouth, conjoined with the occurrence of tremor, point to the cause of the paralysis.

The iodide of potassium is supposed to promote the elimination of mercury, as well as of lead, from the system, and is therefore indicated in cases of mercurial poisoning.

The treatment having direct reference to the nerves and muscles involved in the paralytic affections caused by these metals, is the same as in cases of paralysis from other causes.

Neuralgia.

The term neuralgia is used to distinguish functional affections of which the chief characteristic is pain. In a purely neuralgic disease there is neither inflammation nor any appreciable lesion in the painful part. There is a condition of morbid sensibility, and this is all that can be said of its essential pathological character. Visceral neuralgias, as they are called, that is, neuralgia seated in organs belonging to the respiratory, circulatory, digestive, and urinary systems, are considered in the several sections devoted to the diseases of these organs. The neuralgic affections to be here considered

relate to nervous trunks or their branches not embraced in the organs composing the foregoing physiological systems.

As regards symptomatology, diagnosis, causation, prognosis, and the general principles of treatment, whatever is true of any one of these affections, is mainly true of all of them. In order to avoid repetitions, therefore, I shall first consider these neuralgic affections collectively, or neuralgia in general, under the several aspects just named, and afterward notice briefly the more important of the affections individually.

Neuralgia may occur abruptly, but in the great majority of cases there are premonitions. The premonitions are a feeling of weight, a sense of heat or some uncomfortable sensation in the seat of the affection. The neuralgic pain is either chiefly or exclusively in paroxysms, or there may be more or less continued pain with exacerbations in which the pain is much increased. The continued pain may be dull or contusive, but during the paroxysms or exacerbations the pain is described as darting, tearing, lancinating, and it is often excruciating. The paroxysms or exacerbations are of variable duration, lasting in some cases for a few seconds only, and in other cases for several hours or even days. The intermissions or remissions are not less variable in different cases; their duration may only be a few seconds or moments, and they may extend to days. The lancinating pain shoots in the direction of a nervous trunk and its branches; patients sometimes delineate the tract and distribution of the nerve affected, in defining the directions in which the pain extends. In the great majority of cases neuralgia is unilateral.

Tenderness on pressure, limited to circumscribed points, is an important diagnostic feature of neuralgia. Valleix was the first to show that, as regards their relations to the nerves, the tender points are situated as follows: 1st. Where nervous trunks or branches emerge from the skull or spinal canal; 2d. Over branches which penetrate muscles on their way to the integument; 3d. At the termination of branches which are lost on the surface; and, 4th. In places over trunks near the surface. The situation of the tender points in intercostal neuralgia has been stated in treating of that affection (*vide* page 191). The diagnostic evidence to be derived from this source in other neuralgic affections will be stated when these are severally noticed. Pain may not be produced by pressure made with the open palm; indeed, firm pressure thus made often relieves the pain. The tenderness is shown by pressure made with the ends of the fingers or by percussion. The pain thus produced is often acute, causing the patient to cry out or to try to escape from the exploration. If, however, the pressure be continued, the tenderness is often found to diminish or temporarily to disappear. The tender points are frequently quite limited, the end of the finger being often sufficient to cover them. As a rule, the pain produced by pressure is acute in proportion to the acuteness of the spontaneous pain. The tenderness is most marked during paroxysms or exacerbations of pain. In the intervals between paroxysms, the patient being entirely free from pain, the tenderness on pressure may disappear. Exclusive of the tender points, there may be either hyperæsthesia or anæsthesia of the surface, and the latter may follow the former in the same case.

Paroxysms or exacerbations of pain are excited or increased by sudden or violent movements of parts in which the affected nerves are situated. A concussion of the whole body, as in coughing or sneezing, excites or increases the pain. Cold or hot applications to the surface over the seat of pain, in some cases, are insupportable.

Fever or any notable constitutional disturbance does not belong to the clinical history of neuralgia. The functions of parts to which the affected nerves are distributed may not be notably disturbed. A neuralgic attack,

however, often induces hyperæmia in the site of the pain, as shown by temporary redness of the conjunctiva in cases of neuralgia affecting the ophthalmic division of the fifth pair. Involuntary contractions of muscles and cramps sometimes occur. An increased secretion of tears, saliva, and mucus may accompany paroxysms of neuralgia affecting the several divisions of the fifth pair; and glandular organs within the body are probably in like manner excited in the visceral neuralgias.

Neuralgic affections have no fixed duration. They may end, either spontaneously or under the influence of treatment, in a few hours or days, and they may continue for years or during life in spite of all methods of treatment. The prognosis is always favorable as regards a fatal termination. Persons who suffer attacks at variable intervals for a lifetime are at length carried off by other maladies not developed in consequence of the continuance of the neuralgia.

Neuralgic pain may proceed from a palpable lesion, such as a tumor either involving or pressing on the affected nerve, the presence of a foreign body, the traction of a cicatrix from neuritis, etc. In such cases, the neuralgia is not, strictly speaking, functional. As a functional malady its causation differs in different cases. It proceeds, in certain cases, from malaria. This is always to be suspected in cases occurring in so-called malarious districts. When due to this cause, the paroxysms sometimes recur with the same regularity as the paroxysms of intermittent fever. But it may proceed from this cause when the paroxysms do not exemplify a law of periodicity. It is one of the effects of lead-poisoning. Next to lead colic (and this is, in fact, a neuralgic affection), neuralgia is the most frequent form in which the poisonous effect of lead is manifested. Anæmia, by whatever cause induced, favors the occurrence of neuralgia. A large proportion of those who suffer from neuralgic affections are anæmic.[1] Persons are most apt to suffer from neuralgia between the age of twenty and of fifty. Prior to ten years of age it is extremely rare. Women are more subject to it than men, and, of the different species of neuralgic affections, some occur most frequently in the male and some in the female sex. Females, for example, are more subject to intercostal neuralgia, and males to sciatic neuralgia. A neuralgic attack is sometimes referable to exposure to cold, particularly to a current of cold moist air continued upon the part which becomes affected. Cases occur more frequently in the cold than in the warm seasons of the year.

The situation of the pain is not evidence of the seat of the morbid condition giving rise to neuralgia. The mind may refer the pain to the terminal branches, or the parts to which they are distributed, when the morbid condition is seated at any point in the course of a nervous trunk, or at the point of connection of a nerve with the spinal cord. This is illustrated by the fact that, after an amputation, the condition of the extremities of the divided nerves gives rise to pain which the patient refers to the amputated limb. Anstie held that, as a rule, in the neuralgic affections denominated functional, there is some morbid change at the central connection of the nerve or nerves to which the pain is referred. He was also led to think that, in a large proportion of cases, an hereditary tendency is involved in the causation; and, further, that the development of these affections is favored by exhaustion and debility, aside from anæmia.[2] There is ground for the belief that local diseases may cause neuralgia of nerves at a distance by a reflected morbid influence (reflex or irradiated neuralgias). Weir Mitchell has observed cases in

[1] With regard to the dependence of neuralgia on anæmia, Romberg says: "It seems as if pain were the prayer of the nerve for healthy blood."

[2] Neuralgia and the Diseases that Resemble it, 1872.

which injury of a nerve was followed by neuralgia in other and remotely situated nerves.

The diagnosis of neuralgia is to be based on the character of the pain, its situation in the course of a nervous trunk or its branches, and tenderness in certain circumscribed spaces on the surface. Other diagnostic points are the recurrence of pain in paroxysms or marked exacerbations, shifting of the situation of the pain and tenderness, and the difference, as regards pain, between pressure with the ends of the fingers and with the open palm. In the shifting of pain from one nerve to another, which is a highly diagnostic feature, the nervous trunks successively affected do not always have a common origin; thus, the neuralgia may be transferred from a cranial to a spinal nerve. These are the positive diagnostic points. Negative points are those by which inflammation and structural lesions are excluded, such as the absence of fever, etc. In determining the affection to be functional, neuritis is to be excluded, and it is to be ascertained, if practicable, that the pain is not dependent on a local mechanical cause, such as a tumor pressing on the nerve at some point in its course. Syphilitic periostitis is also to be excluded.

The treatment of neuralgia is rational, and empirical. The rational treatment consists, in the first place, in fulfilling indications which relate to morbid conditions suspected of standing in a causative relation to the neuralgia. The physician, in individual cases, is to seek for evidence of malaria or lead-poisoning, conditions having diagnostic criteria irrespective of the neuralgic affection. Appropriate measures of treatment are to be addressed to these or any other associated morbid conditions under the supposition that they may have more or less to do with the existence of the neuralgia. Diathetic conditions, especially the rheumatic and gouty, are to be considered as probably contributing to the neuralgic affection, and, with reference to the cure of the latter, these conditions claim appropriate measures of treatment. Attention is always to be directed to the co-existence of anæmia. Symptomatic phenomena together with the venous hum in the neck may denote the anæmic condition when it is not manifested by pallor of the face and the prolabia. If anæmia co-exist, preparations of iron should be continued for a long period. An eligible plan is to give in succession different ferruginous preparations, for weeks or months, enjoining upon the patient not to expect restoration to health until after a long continuance of the remedies. This treatment addressed to the anæmia is indicated, provided the anæmic condition continues, notwithstanding the neuralgia may cease. The disappearance of the venous hum is evidence that the anæmic condition is removed.

The relief of pain enters into the rational treatment. In severe paroxysms or exacerbations, opiates are called for. Large doses are sometimes indicated by the intensity of pain. The most prompt and effective method of affording relief is the hypodermic injection of a solution of morphia. In the use of opiates for the relief of neuralgic pain, the risk of the formation of the habit of taking opium is always to be borne in mind, yet in severe cases which resist therapeutical measures, this risk must sometimes be incurred. If the pain be not intense, relief may be obtained by belladonna, hyoscyamus, stramonium, conium, the preparation known as chlorodyne, and the tincture of aconite. Local applications will often do much toward the relief of pain. Of these, the most efficient are liniments of the tincture of aconite, chloroform, and opium. Belladonna, stramonium, veratria, and aconitia, applied in the form of ointment, are sometimes efficacious.

An arrest of the paroxysms of pain by opiates is sometimes curative, that is, the paroxysms or exacerbations do not recur. If the development of the affection have been recent, it is not easy to decide whether a cure be effected by the remedy or whether the affection has no intrinsic tendency to continue;

but the paroxysms sometimes cease to recur, after having been once or repeatedly arrested, when the affection has existed for a greater or less period, and in these cases it is fair to attribute a curative efficacy to the arrest. In order to arrest a paroxysm, a full opiate should be given as soon as the paroxysm begins, or, if practicable, the occurrence of the paroxysm may be anticipated by a full opiate. Before abandoning this plan of treatment, it should be employed in several recurring paroxysms. The continued employment of some form of opiate, or of some one of the narcotic extracts, especially belladonna, during the intermissions or remissions, in some cases effects a cure. Gelsemium, and the hydrate of chloral or the croton-chloral are to be included amongst the palliative remedies.

The empirical treatment of neuralgia consists in the use of remedies which experience has shown to be sometimes curative, and which are to be tried without following any particular rational indications. These remedies are in some cases efficacious and in other cases devoid of any curative effect; and often there are no means of determining beforehand which one of the remedies will be most likely to prove successful. In rebellious cases, the different remedies are to be tried in succession. Methodic counter-irritation is undoubtedly efficacious in a large proportion of cases. Of the different modes of counter-irritation, Valleix preferred the actual cautery, the hot iron being passed along the course of the affected nerve, taking care that cauterization shall be superficial so as not to lead to deep eschars and suppuration. To avoid the pain occasioned by the cautery, he advised etherization. He stated that he had resorted to the actual cautery in more than 150 cases, and always with success, if the neuralgia were functional. This method may be resorted to in cases which resist milder means of counter-irritation, together with other empirical remedies. Milder means should first be tried. Of the latter, a succession of small blisters, applied over the painful and tender points, will frequently prove successful. Prof. Alfred Stillé advises blisters of only half an inch in diameter, the period of application to be from one to two hours only, the vesicated surfaces to be healed as rapidly as possible, and the blisters to be repeated in a few days if the neuralgia continue. He states, as a result of the employment of this method of treatment in almost every case which has came under his observation in public and private practice for many years, that "in no single instance has it failed to mitigate the symptoms, and in very many it alone has achieved a cure."[1] During the process of vesication the neuralgic pain is frequently increased. When quickness of vesication is desirable, it may be effected in a few moments by the strong aqua ammoniæ, and still more quickly by means of a hammer heated by hot water. By the latter means, or by an instrument devised for the operation known as *firing*, a rubefacient effect may be quickly and conveniently produced, and in mild cases this may suffice without vesication. Sinapisms are proverbially useful, and, in certain cases, will suffice, in conjunction with internal remedies.

Electricity is a therapeutical agent of great power in many cases of neuralgia. Both the faradic and the galvanic forms are useful, but the latter is in most cases to be preferred. Applied in conjunction with acupuncture it has been successfully resorted to in some rebellious cases. Duchenne recommended the method called cutaneous faradization. The palliative effect of electricity is probably due to a temporary blunting of the excitability of the nerve or nerves to which the pain is referred; their capacity either to originate or to conduct painful sensations is diminished or annulled by passing through them the electrical current. This measure, however, in many cases, has not only a palliative, but a curative, efficacy. The testimony of those

[1] Therapeutics and Materia Medica.

who have had great experience in its employment, is stronger than that which can be cited in behalf of any other remedy. Strong pressure upon an affected nervous trunk sometimes has a palliative effect; the pressure, at first, may occasion great pain, but, continued or repeated at short intervals, it is borne without suffering and diminishes for a time the excitability of the nerve.

Of the internal remedies which experience has shown to be efficacious, the more important are quinia, arsenic, the precipitated carbonate of iron, the preparations of zinc, strychnia, the essential oil of turpentine, the iodide of potassium, and phosphorus.

Quinia, as already stated, is especially indicated when the neuralgia is attributable to malaria, and it will be most likely to prove successful when paroxysms occur periodically. But it is efficacious in cases in which there is no ground for suspecting a malarious causation, and in which there is no observance of the law of periodicity. To be fairly tried, this remedy should be given in full doses—from 15 to 30 grains daily to an adult—and continued for a week or ten days. Of the foregoing list of remedies, this is entitled to the first rank. Arsenic may be tried in cases in which there is an intolerance of quinia, or when the latter fails to effect a cure. It is a remedy of great value in neuralgic affections. To be fairly tried, it should be carried to the extent of producing some of its characteristic toxical effects.

The precipitated carbonate of iron, advocated some years ago by Hutchinson, is sometimes efficacious. It is to be given in large doses, namely, from one to two drachms twice or thrice daily. Ferruginous remedies are rationally indicated by co-existing anæmia, and this condition is present in a very large proportion of the cases of neuralgia. Tho efficacy of the preparation named is doubtless, in a measure at least, attributable to the co-existence of anæmia. The hydrochlorate, nitrate, and valerianate of ammonia have been found in some cases notably efficacious. Bartholow extols, as the most successful of the different methods of treatment, the injection of from five to ten minims of pure chloroform in the neighborhood of the affected nerve. This treatment is especially useful in neuralgia affecting nerves superficially situated.[1]

Of the preparations of zinc, the valerianate is best suited to cases of neuralgia. Strychnia may be given internally, or applied locally upon a blistered surface. In the latter mode of administration, the benefit may in some cases be measurably, and perhaps chiefly, due to the counter-irritation. The oil of turpentine is but little used in neuralgic affections, but I have known it to prove promptly successful, in doses of a drachm combined with castor oil given on alternate days, after a variety of remedies had been employed without success. The iodide of potassium has been advocated by Graves, Watson, and especially by Neucort.[2] The writer last named advised its use in large doses. The co-existence of the rheumatic diathesis is regarded as indicating specially this remedy. The bromide of potassium has been found efficacious in certain cases. According to Anstie, this remedy is especially useful in young persons who may be supposed to suffer from the nervous consequences of unsatisfied sexual desire. He thinks its efficacy is rarely secured under a less quantity per diem than ninety grains. In some cases of neuralgia, large doses of phosphorus have been found to be of great benefit.

Division of a nerve (neurotomy) and the removal of a section (neurectomy), are surgical procedures resorted to chiefly in cases of neuralgia affecting the fifth or trifacial nerve. They will be noticed in connection with facial neuralgia. Stretching of an affected nerve is another method of treatment, the consideration of which belongs to surgery.

[1] *Vide* Practice of Medicine, p. 630.

[2] De la Névralgie lombaire, etc., Archives Générales de Médecine, 1858.

In conclusion, a permanent cure in cases of neuralgia will often depend on the correct appreciation and judicious management of associated morbid conditions, together with hygienic measures to invigorate the general health. Good alimentation is always indicated, and it is desirable that fatty articles of food should enter largely into the diet. Cod-liver oil, if well tolerated, is useful.

Trifacial Neuralgia. Prosopalgia. Tic Douloureux.

In this neuralgic affection the pain is seated in the sensory fibres of the fifth or trifacial nerve. Pain and tenderness on pressure are either limited to, or most marked in, circumscribed spaces, situated as follows: The point of exit of the frontal branch above the orbit, the upper eyelid, the upper and lateral portion of the nose, the point of exit of the infra-orbitar branch, the lower margin of the malar bone, over the temporal bone, the point of exit of the inferior maxillary branch, and over the parietal bone. It is rare that pain and tenderness are seated in all these spaces, but generally in at least one of the spaces within the range of the three branches of this nerve whence it receives its name—trifacial. In different cases the pain is either limited to, or especially marked in, different branches of the nerve, namely, the supra-orbital, infra-orbital, infra-maxillary, etc. It is rare for this affection to be limited to a single branch, with the exception of that portion of the inferior maxillary which is contained within the inferior maxillary bone.

When the first of the three branches of the nerve is the seat of the neuralgia, during the paroxysms of pain there is intolerance of light, with redness of the eye on the affected side, and more or less abundant secretion of tears. In this situation the neuralgic affection has been called migraine, hemicrania, and brow-ague. Increased heat of the nostril and an abundant secretion of mucus are effects of the neuralgic affection when seated in the second of the three divisions, and salivation sometimes attends an affection of the third division. The branches which accompany the facial nerve (portio dura) may be the seat of pain, a fact which formerly led to the supposition that the latter nerve was affected. Spasmodic contraction of the muscles of the face on the affected side is an occasional effect; hence the affection was formerly called *tic douloureux*, or painful spasm. The affection in the vast majority of cases is limited to the nerve on one side, that is, it is unilateral. The right and the left side are affected in about an equal proportion of cases.

Trifacial neuralgia in point of frequency ranks with intercostal and sciatic neuralgia. An occasional cause is caries of the teeth. It is by no means frequently referable to this cause, but that it is so occasionally cannot be doubted. Teeth, however, are often needlessly sacrificed from a supposed causative connection. It is not sufficient to show such a connection that there is tenderness on striking one or more of the teeth. If the neuralgia proceed from this cause, touching the offending tooth or teeth will excite a paroxysm of pain extending into more or less of the branches of the nerve.

Trifacial neuralgia is to be discriminated from inflammation of the membrane lining the supra-orbital and the maxillary antrum, and from syphilitic periostitis. The two former of these affections are distinguished by the different character of the pain, its fixed situation, and the occurrence of a discharge into the anterior nares. The latter affection is recognized by the fixed tenderness on pressure, the existence of swellings or nodes, the aggravation of pain in the night-time, and other evidence of syphilitic disease. Neuralgia in this situation is often dependent on malaria, and the paroxysms of pain sometimes exemplify the same laws of periodicity which govern the recurrence of the paroxysms of intermittent fever. Trifacial neuralgia rarely

occurs in infancy. In the majority of cases the age is between 30 and 50 years, and it oftener occurs in women than in men.

This neuralgic affection is curable in the majority of cases. Exceptionally it resists all the therapeutical measures which have been considered as applicable to neuralgic affections in general. The branches which are generally affected, in these rebellious cases, are the frontal and the inferior maxillary. As a last alternative, division or excision of a portion of the affected branch is sometimes resorted to. The long-continued and extreme suffering from frequently recurring paroxysms, in some cases, warrants this procedure after other measures have been faithfully tried. Mere division of a nervous branch usually affords only temporary relief. The affection returns after the divided extremities have united. A portion of the nervous branch must be removed to prevent or delay reunion. The removal of a portion of the inferior maxillary nerve within the inferior maxillary bone has sometimes proved successful after the failure of all other measures; but in a considerable proportion of cases the affection returns sooner or later. In a case under my observation, in which the patient had suffered from paroxysms of intense pain recurring at intervals of a few moments for the greater part of ten years, the removal of a portion of the nerve by trephining the inferior maxilla, the operation being performed by Prof. Hamilton, procured relief for several months, but the pain subsequently returned.

Facial neuralgia, persisting indefinitely, resisting medication, and characterized by spasmodic movements of the muscles of the face during the paroxysms of pain, is distinguished by Trousseau as *epileptiform neuralgia*. There are few forms of disease more distressing than this, or more hopeless as regards the prospect of effecting a cure. A case which came under my observation exemplified the persistency of this form of neuralgia, and also exemption from suffering for an unusually long period procured by simple division of the nerve. The patient, a man aged about 60, had suffered intensely from neuralgia affecting the supra-orbital branch of the fifth pair on the left side for more than two years. The paroxysms of pain recurred at intervals of a few minutes, and were often excruciating beyond description. After trying a great variety of remedies and different systems of practice, the nerve was divided by Valentine Mott, and the patient was comparatively free from suffering for the space of three years. At the end of this period, while under treatment for enlargement of the heart and general dropsy, the neuralgia suddenly returned with the same violence as before the operation. Paroxysms were produced by mastication, by movements of the lips in pronouncing words containing labial letters, by touching the face, and they occurred without any exciting cause. The nerve was divided a second time by Prof. J. R. Wood, with immediate and almost complete relief which continued until the patient's death, several weeks after the operation.

Carnochan was the first to perform neurectomy beyond the spheno-palatine ganglion for the relief of persistent neuralgia of the superior maxillary branch. He reported three cases of the successful performance of this operation in 1857.[1] This operation, since that date, has been performed by James R. Wood, and others with success.[2]

Facial neuralgia, after having persisted for a long period, sometimes occasions disturbance of nutrition on the affected side of the face, denoted by tumefaction, an increase of adipose tissue, thickness and firmness of the beard; and it sometimes appears to give rise to pustular or erythematous

[2] For an analysis of 21 cases, and the practical conclusions deduced therefrom, *vide* article on "Neurotomy of the Superior Maxillary Branch of the Trigeminus," by Frederick S. Dennis, M.D., in the New York Med. Journal, June, 1879.

inflammation. An analysis of one hundred and twenty-eight cases by Notta, showed, as occasional complications, in addition to those already mentioned, paralysis, either complete or incomplete, of the retina, iritis, glaucoma, inflammation and ulceration of the cornea, tumefaction of the tongue on one side, paralysis of the motor oculi, deafness, and anæsthesia of the face on the affected side.[1] Certain of these complications are attributable to paralysis of the vaso-motor nerves. Anstie, who verified the correctness of Notta's observations, observed, in addition, grayness of the hair on the affected side, and discoloration of the skin from the presence of dark pigment.[2]

Cervico-Occipital Neuralgia.

The pain in this neuralgic affection is seated in the posterior branches of the first four of the cervical nerves, and especially in that branch of the second cervical nerve, called, from its size and distribution, the *occipitalis major*. The nerves on both sides may be affected.

Painful and tender points are situated as follows: Between the mastoid process and the cervical vertebræ, over the posterior cervical plexus, on the parietal portion of the head, on the mastoid process, and in the *concha auris*. Shooting pains start from the cervical vertebræ just below the occiput, and extend thence over the posterior and superior portion of the cranium. Darting pains are sometimes referred to the external *meatus auditorius*. In cases of neuralgia affecting primarily the cervico-occipital nerves, the pain is apt to extend to the branches of the trifacial distributed to the frontal portion of the head, and in like manner, in cases of neuralgia affecting primarily the superior division of the trifacial, the pain is apt to extend to the branches of the cervico-occipital nerves.

Cervico-occipital neuralgia is to be discriminated from myalgia affecting the muscles of the neck, or *torticollis*. In the latter affection, the pain is limited to the affected muscles, the tenderness on pressure is more diffuse, and not confined to circumscribed points; the pain is excited exclusively by movements of the affected muscles, and so long as the head remains immovable, there are no painful paroxysms.

Cervico-Brachial Neuralgia.

In cervico-brachial neuralgia, sensory fibres of the four lower cervical nerves and of the first dorsal nerve are affected. The pain is frequently referred to the shoulder, and it may extend to the neck. It shoots downward along the arm, to the forearm and hand, following the course of one or more of the nervous trunks of the upper extremity. The affection may be limited to either the ulnar, radial, median or musculo-cutaneous nerve, giving rise to different varieties of the species. Of these varieties the most frequent is neuralgia affecting the ulnar nerve. Painful and tender points are situated as follows: Near the last cervical vertebra, near the acromial end of the clavicle, over the upper part of the deltoid muscle, in the axilla, at the inner condyle of the humerus, near the lower end of the ulna and of the radius.

Pain referable to the cervico-brachial nerves is sometimes an effect of injury of the upper extremity by a wound, a burn, or a contusion. Functional neuralgia is to be discriminated from the pain incident to neuroma or other mor-

[1] Archives Générales de Médecine, 1854. *Vide*, also, Treatise by Anstie.

[2] For a report of cases observed and collected by Prof. Henry D. Noyes, with reference particularly to the effect upon the eye of paralysis of this nerve, *vide* New York Journal of Medicine, vol. xiv. p. 163.

bid growths affecting the periphery of these nerves, by the failure to discover a tumor in the course of the nerves. Pain referred to these nerves may be symptomatic of vertebral lesions, and, also, of cervical arthritis. In cases of the latter, movements of the head, especially those of rotation, even in the intervals between the paroxysms, are painful. Another feature is, the patient, when lying down, is obliged to raise the head with a hand on the occiput, to avoid pain. Myalgia affecting the muscles of the upper extremity is to be discriminated by the larger extent of surface which is tender on pressure, by the absence of paroxysms of pain except when provoked by movements of the affected muscles, and by the limitation of the pain to the affected muscles.

Herpetic vesicles in patches, constituting Herpes Zoster, sometimes occur in the course of the nerves involved in this affection.

Dorso-Intercostal Neuralgia.

This affection has been considered in the section devoted to diseases affecting the respiratory system, to which the reader is referred (page 191).

Lumbo-Abdominal Neuralgia.

Neuralgia, having its seat in the branches of the five lumbar nerves, is of not infrequent occurrence. It occurs much oftener in females than in males. Pain is apt to be referred to the hypogastrium, and may resemble that of colic. Uterine pain is incident to this affection. In males the affection is sometimes characterized by pain extending along the spermatic cord into the scrotum, accompanied by notable tenderness of the testicle.

Painful and tender points are situated near the upper lumbar vertebræ, a little above the middle of the crest of the ilium, in the neighborhood of the inguinal ring, in the scrotum, and, in the female, on the *labia majora*. Pains are excited by muscular efforts, the acts of coughing or sneezing, straining at stool, and sometimes by micturition.

Myalgia affecting the lumbar muscles or lumbago is to be discriminated by the existence of pain and tenderness on both sides, whereas in neuralgia they are generally confined to one side; by the tenderness being diffused over the affected muscles and not limited to certain points, and by the absence of paroxysmal pain except when produced by movements of the affected muscles.

In the case in which pain extends to the uterus, inflammation of the organ, or metritis, and carcinoma are to be excluded. In uterine neuralgia the *os uteri* is tender on pressure, and the tenderness is either limited to, or most marked on, one side. The pains in these species of neuralgia may simulate those caused by the passage of a calculus along the ureter, or renal colic. The pains in the latter are more intense and persisting; they are suddenly developed, whereas the development of a neuralgic affection is generally gradual. The absence of symptoms which distinguish renal colic warrants its exclusion.

Crural Neuralgia.

This neuralgic affection is rare. It is characterized by shooting pains in the direction of the trunk of the anterior crural nerve and its branches, and by painful and tender points in the groin, the inner aspect of the thigh, knee, and ankle.

Sciatic Neuralgia.

Sciatic neuralgia, or sciatica, in frequency ranks with intercostal and facial neuralgia. It occurs in men oftener than in women, the relative proportion of cases being as three to two. It very rarely occurs before the age of

twenty and rarely after sixty. It is sometimes symptomatic of pregnancy, of enlargement of the retro-peritoneal lymphatic glands, of accumulation of feces or foreign substances in the sigmoid flexure of the colon, and of intra-pelvic tumors, but, in the great majority of cases, it is a functional affection.

As in the foregoing neuralgic affections, shooting pains, in paroxysms or exacerbations, extend along the trunk and branches of the affected nerve. In indicating the course of the pain, the patient often delineates with accuracy the anatomical distribution of the sciatic nerve. The character of the pain is sometimes described as burning, and sometimes as a sensation of coldness; the patient feels as if a current of hot or cold liquid were flowing in the course of the affected nerve. A continued, contusive pain, more or less intense, exists in the larger proportion of cases. This pain, as in the other species of neuralgia, is referred to the circumscribed spaces which are tender on pressure.

Painful and tender points in this neuralgic affection are found in more or less of the following situations: On the sacrum, over the sacro-iliac junction, about the middle of the crest of the ilium, at the sciatic notch, between the trochanter major and the tuber ischii, on the thigh along the track of the nerve, in the popliteal space, on the external border of the patella, over the articulation of the fibula with the tibia, where the nerve passes around the fibula, over the lower and posterior part of the external malleolus, on the dorsum and outer portion of the sole of the feet. The points situated at the sacro-iliac junction behind the trochanter major, at the head of the fibula, and the external malleolus, are those most frequently painful and tender. Pressure with the finger upon some of the foregoing points may not only be more or less painful, but excite a paroxysm or exacerbation of pain extending to other parts in the course of the affected nerve.

The intensity of the pain, as in the other species of neuralgia, varies much in different cases. The movements of the affected limb, in some cases, occasion such an amount of suffering that the patient remains in bed, keeping the limb as nearly immovable as possible. In other cases, the patient is able to walk, but with more or less difficulty; pain is felt especially when the weight of the body falls upon the affected limb, and relief is found in the use of a cane. Sometimes difficulty in walking is only felt in beginning to walk, and after a short time the patient walks with ease; the suffering is occasionally relieved by exercise. In severe cases muscular twitchings and cramps accompany the paroxysms or exacerbations of pain.

Sciatic neuralgia rarely, as compared especially with facial neuralgia, exemplifies, in the recurrence of paroxysms, the law of periodicity. Like other neuralgic affections, its duration is very variable. As a rule, in favorable cases it persists for several weeks, disappearing, as it is usually developed, gradually. In the vast majority of cases, sooner or later it ends in recovery, but, in some cases, it continues indefinitely in spite of all remedial measures. If it continue for a considerable period so severely as to lead the patient to avoid, as much as possible, movements of the affected limb, the repose of the muscles may render them for a time incompletely paralyzed. The muscles, under these circumstances, become flaccid and diminished in volume.

The diagnosis of sciatic neuralgia involves its discrimination from muscular rheumatism and from the affection of the hip-joint commonly known as morbus coxarius. Muscular rheumatism here, as in other situations, differs from neuralgia in the limitation of pain to the affected muscles, in the diffusion of tenderness over a considerable space, namely, a space corresponding to the number of muscles affected, and in the fact that paroxysms of pain are excited exclusively by movements of the affected muscles.

Morbus coxarius is distinguished by the pain in the hip-joint produced by

pressure upon the great trochanter and by flexion and extension of the thigh. Moreover, febrile movement, general debility, emaciation, etc., in conjunction with the local symptoms, point to the existence of chronic inflammation within the joint.

The name sciatica, as commonly used, is applied to cases in which pain is referred to sacral nerves, although the sciatic nerves may be unaffected. Pain, of a neuralgic character, in the nerves composing the sacral plexus, is often symptomatic of lesions within the pelvis and abdomen, such as aneurismal, carcinomatous, or other tumors, enlargement of glands, etc.; also, of lesions of the sacrum and vertebral column, and those occurring within the spinal canal. Here, too, as in other situations, it may be dependent on neuritis. This is to be inferred from the speedy occurrence of paralysis and atrophy of the muscles to which the nerves are distributed.

The co-existence of two or more of the foregoing different neuralgic affections, or their successive occurrence, is frequently observed. Proximate or inosculating nerves are apt to be simultaneously or successively affected. Thus, trifacial and cervico-occipital neuralgia are not infrequently associated, and this is true of sciatic and crural neuralgia. A cure or spontaneous cessation of neuralgia in one situation is apt to be followed by the development of the affection in another situation. These facts go to show the dependence of neuralgia on constitutional or general morbid conditions.

Dermalgia.

Neuralgia is sometimes limited to the skin. Cases are occasionally observed in which pain is felt on the surface of the head, trunk, or extremities, together with notable tenderness on pressure, the nervous trunks being free from pain or tenderness. This form of neuralgia has been called *dermalgia*. Under this heading may be placed the form of neuralgia described by Weir Mitchell as incident to injury of nerves, and called by him causalgia. This is characterized by a burning pain in the soles of the feet and palms of the hands. I have reported an instance of causalgia affecting the soles of the feet, occurring without any injury of a nervous trunk or any other symptom; also, a case in which a paroxysmal burning pain was referred to the abdomen and lower limbs.[1]

Myalgia. Muscular Rheumatism.

Neuralgia affecting sensory nerves in muscular organs may be distinguished as myalgia. Under this head I shall enumerate certain local affections which it has been customary to embrace under the name *muscular rheumatism*. The term rheumatism, as applied to these affections, is manifestly inappropriate, and it is desirable that the term, in this application, should become obsolete. The myalgic affections were designated by Valleix by the suffix *dynia*, added to the name of the muscle or group of muscles affected. This designation, having the same derivative meaning as words ending in *algia*, is appropriate.

Myalgia is of frequent occurrence as an acute and a chronic affection. The symptomatic features of the acute affection are as follows: The development is usually gradual. A dull pain is at first felt in certain muscles, which increases, and, at length, becomes more or less severe. The pain is comparatively slight when the affected muscles are at rest. In certain positions

[1] *Vide* Clinical Medicine.

the patient may be nearly or quite free from suffering. A constant pain of a contusive character is often felt when the muscles are at rest, and this may be aggravated by spasmodic pains occurring from time to time. In movements which involve contraction of the affected muscles, the pain is severe, cramp-like, and sometimes so excruciating that the patient can hardly repress loud groans or cries. Voluntary movements which occasion the severe pain are avoided as much as possible, but as it is impossible to maintain rigidly fixed positions of the body as a whole or of its different parts, the affected muscles are at times thrown into painful contractions, however much the patient may desire to avoid them. Movements occurring during sleep occasion the attacks of pain, and, hence, the patient is awakened at brief intervals. In some cases the affection changes its seat from certain muscles to others, but oftener it remains fixed in the muscles first affected.

The affected muscles are more or less tender on pressure, the tenderness being diffused over the whole of the space which the muscles occupy, not limited to certain points as in ordinary neuralgia. The tenderness is usually not great. Aside from the tenderness, there are no local characters, such as swelling, heat, or redness. The local phenomena are not those of inflammation, as in articular rheumatism. If the local symptoms denote inflammation of the muscles, the affection is not myalgia. Uniform firm pressure over the affected muscles is not only well borne, but affords relief in cases of muscular rheumatism.

There is little or no constitutional disturbance beyond that occasioned by the suffering and loss of sleep. The appetite and digestion may not be impaired, and there is no fever.

In the subacute or chronic form of the affection, pain similar to that which belongs to the acute form may be excited only when the affected muscles are contracted with unusual force; the patient experiences suffering when he makes certain violent movements. In other cases, pain is excited by particular movements when they are first made after a period of rest, and the pain shortly disappears if the movements be continued. The chronic, oftener than the acute, affection is apt to shift its situation, affecting now certain muscles, and now those in another part. If the chronic affection remain fixed in particular muscles, they may become somewhat atrophied in consequence of their being kept as much as possible in a state of quietude.

The duration of acute myalgia varies from a few hours to a week. Exceptionally the affection continues for several weeks. The duration of the chronic form is indefinite. It is often a very obstinate affection, persisting for many months. The course of the latter is usually marked by remissions or intermissions. In certain situations, namely, the loins, the walls of the chest, and muscles of the scapulæ, the chronic affection is apt to be long persisting.

The following are the principal situations of myalgia in the acute and chronic form:—

1. *The Muscles of the Head.*—Situated in the occipito-frontal muscle, the affection is distinguished from neuralgia affecting the trifacial and the occipital nerve, by the pain being referred to both sides of the head, by its being excited by movements of the muscle, and comparatively slight so long as the muscle is at rest, and by the absence of tenderness in disseminated points. The muscles of the eye are sometimes the seat. Movements of the eye then occasion more or less severe pain. The temporal and the masseter muscle may be affected, causing pain in mastication.

2. *The Muscles of the Neck.*—In this situation the affection, as it commonly occurs, has been known by the name *rheumatic torticollis*. This name is applied to the affection when situated in the muscles of the antero-

lateral aspect of the neck. The muscles on the posterior part of the neck are sometimes the seat of the affection. Valleix applied to the affection in the latter situation the name *cervicodynia*. In this situation the affection is to be distinguished from ordinary occipital neuralgia.

3. *The Muscles of the Back.*—Valleix called the affection in this situation *dorsodynia*. Seated in these muscles, the pain is caused especially by movements which approximate the scapulæ.

4. *The Muscles of the Loins.*—In this situation the affection is commonly known as *lumbago*. Valleix designated it *lumbodynia*. This is a frequent seat of the affection in a chronic form. It is to be discriminated from lumbar abscess, lumbo-abdominal neuralgia, and the pains incident to aneurism of the descending aorta.

5. *The Thoracic Muscles.*—Here the affection goes by the name *pleurodynia*. In making the diagnosis, pleuritis and intercostal neuralgia are to be excluded. This may easily be done by ascertaining the absence of the diagnostic characters of the two latter affections. The pain excited by forced breathing, coughing, and sneezing is not unlike that in pleuritis and intercostal neuralgia. In this situation the pectoral and intercostal muscles are affected.

6. *Muscles of the Shoulder.*—Valleix entitled the affection here situated *scapulodynia*. It is seated especially in the deltoid muscles, and it is liable to be confounded with arthritis situated in the shoulder-joint.

7. *The Muscles of the Extremities.*—Seated in the extremities, the affection is to be discriminated from neuralgia affecting the nervous trunks, and from the affection commonly known as syphilitic rheumatism.

8. *The Abdominal Muscles.*—The pain and soreness caused by the affection in this situation may suggest as probable or possible the existence of peritonitis. This disease is to be excluded by the absence of the general symptoms, and by firm pressure with the palm of the hand being well borne, as in cases of cutaneous hyperæsthesia.

9. *The Visceral Muscular Structures.*—The tongue, muscles of the pharynx and œsophagus may be the seat of myalgia, giving rise to pain in speaking and in deglutition. Examples, however, are extremely rare. Seated in the stomach, intestines, and uterus, as it probably may be, to distinguish the affection from visceral neuralgias is impossible, and in fact to consider it as distinct from the latter is to make a distinction without any essential difference. There is reason to believe that the diaphragm may be the seat of myalgia. It is, perhaps, more reasonable to consider this as the affection, rather than diaphragmatic pleuritis, in certain cases characterized by the instinctive arrest of diaphragmatic movements in consequence of pain, and by the intense suffering caused by coughing and sneezing, febrile movement and pleuritic effusion being wanting. It may be doubted if the affection be ever seated in the muscular walls of the heart.

In all these situations, the most marked diagnostic feature is the connection of cramp-like pain, more or less severe, with the movements which bring into play certain muscles in the parts to which the pain is referred, pain, irrespective of contractions of the affected muscles, being comparatively slight and sometimes wanting. This diagnostic feature distinguishes myalgia from neuralgic affections seated in the different nervous trunks. Another diagnostic feature is the diffusion of soreness over the affected muscles, whereas, neuralgia, seated in nervous trunks, is characterized by tenderness in circumscribed points. Inflammation affecting muscles is distinguished from myalgia by the constancy of pain or the absence of the remissions or intermissions which belong to the latter affection, by the existence of swelling and some-

times redness, by the greater degree of tenderness on pressure, and by the presence of more or less symptomatic fever.

The treatment of the acute form of the affection consists of sinapisms, followed by soothing, emollient applications over the affected muscles, rest in the position most favorable to avoid contractions of the affected muscles, and the employment of anodynes either internally or by hypodermic injection. In the chronic form, small blisters in succession are useful, but not in the same degree as in cases of ordinary neuralgia. The employment of the induced electrical current I have known to be beneficial in obstinate cases. The constant current has been found, also, highly efficacious. Friction or shampooing, either dry or with stimulating and anodyne liniments, affords relief and promotes a cure. "Firing" is recommended. The bromide of potassium and of ammonium I have found useful. The hydropathic treatment is said to prove successful in some obstinate cases, water being employed locally and generally. The salts of quinia, in full doses, are sometimes efficacious, especially when the affection is intermittent. Measures to invigorate the general health are important in chronic cases. If anæmia exist, preparations of iron should be continued for a long time, in small doses, or until the venous hum disappears from the neck. Anstie recommends, as especially useful, the muriate of ammonia in doses of from twenty to thirty grains.

Persons prone to this affection are apt to have an attack after exposure of a portion of the body to a current of air, especially during sleep, or when the body is perspiring. The susceptibility to this cause of disease is to be overcome by the daily use of the sponge bath, by avoiding an over-abundance of clothing, and by becoming habituated to out-of-door exercise in all kinds of weather.

Cephalalgia—Headache.

Pain in the head is a symptom occurring in many affections, such as, active cerebral congestion, cerebral meningitis, cerebritis, and the essential fevers, acute dyspepsia, syphilitic periostitis of the head, intra-cranial tumors, etc. etc. It is frequently due to neuralgia affecting either the cervico-occipital nerves or the supra-orbital division of the fifth pair. Pain limited to one side of the head, or hemicrania, is due to neuralgia affecting the nerves just named. According to Valleix, idiopathic cephalalgia or headache is in all cases resolvable into hemicrania (migraine). This opinion does not seem to me to be correct. In certain cases the pain does not follow the direction of these nerves, it is not limited to one side of the head, disseminated tender points may not be found, and in its behavior the affection differs from neuralgia affecting these or other of the nervous trunks and branches. Hence, cephalalgia or headache may denote a functional neuropathic affection distinct from hemicrania. The seat of the affection when confined to one side, in certain cases has been supposed to be the branches of the trifacial nerve which are distributed to the dura mater. It has also been supposed that the sensory filaments entering into the composition of the brain may be the seat of neuralgia.

Cephalalgia is extremely common. It occurs in paroxysms, lasting usually from 12 to 24 hours, in some cases being of shorter duration, and occasionally continuing for two or three days. There are few persons who do not occasionally experience an attack after childhood or adult age, and there are very many who are subject to attacks recurring sometimes at regular, but usually at irregular, intervals for many years, or during lifetime. A host of persons suffer from it who either do not consider it of sufficient importance to resort

to medical treatment, or, having found medical treatment ineffectual, resign themselves to it as an irremediable malady.

The pain in different cases, or in different attacks in the same case, differs much in degree. An attack is often not severe enough to prevent habitual occupations, but in some instances the intensity of the pain is such that the patient is unable to be about, and perhaps is obliged to take to the bed. The pain is sometimes referred to the forehead, sometimes to the occiput, and sometimes to the whole head. The character of the pain, as described by patients, differs. It is sometimes sharp or lancinating, like the pain in neuralgic paroxysms; in other cases it is a dull, heavy pain. Patients sometimes say that they feel as if the head would burst. Firm pressure upon the head, especially over the temples, often affords momentary relief. Frequently rubbing or shampooing the scalp with considerable force diminishes the pain. There is frequently an abnormal sensitiveness to light and sounds, and in severe attacks the patient seeks perfect quietude in a dark room away from all noise. The appetite during the attack is either impaired or lost. The odor of food is often disagreeable. Nausea and vomiting occur in a certain proportion of cases, and then it is common to call the affection *sick headache*. Without nausea or vomiting, the affection is commonly known as *nervous headache*. The face is in some cases flushed, and the eyes suffused, and the temperature of the head raised; in other cases, especially if nausea and vomiting occur, the face is pallid and the head may be cool. Free vomiting, although the stomach may not contain any aliment, is sometimes followed by relief.

Accompanying the foregoing local symptoms, is more or less general debility or prostration. There is rarely fever; the pulse is generally small and feeble, and the surface of the body cool. Occasional shiverings are not uncommon. Disturbed action of the heart, or palpitation, is not uncommon during the attack.

The attack gradually passes off, sometimes with the occurrence of free evacuations from the bowels, or an abundant secretion of urine, or a slight perspiration. The attack is apt to be developed in the morning, pain being experienced on awakening from sleep, and it is apt to continue until after sleep is obtained on the following night. Persons subject to the affection are able, sometimes, to predict its advent by a feeling of lassitude, depression of spirits, or a sense of indefinite discomfort. After the attack has passed off, there is frequently, for some time, a sense of soreness in the head, with more or less general debility. Often, however, the mental faculties are unusually clear and spirits buoyant after recovery from an attack.

The affection involves a constitutional predisposition. Persons are subject to periodical attacks of headache, as of asthma or epilepsy. The predisposition existing, various exciting causes may determine an attack, such as mental excitement, deprivation of sleep, bodily fatigue, exposure to the sun's rays, and dietetic imprudences. Not infrequently attacks occur without any obvious exciting causes. Women are more subject to the affection than men, and it is apt to occur at the menstrual period. The predisposition varies in degree in different cases, as shown by the frequency or rareness of the attacks. The predisposition frequently ceases after the age of 40 or 50; persons who have experienced attacks, more or less frequently, from adult age up to the periods of life just named, thereafter are exempt from their recurrence. This may be stated as a rule, but, unhappily, there are not a few exceptions.

The affection is neuralgic in its character, but it is difficult to determine its precise seat. It is a reasonable supposition that it involves a toxical agent in the blood. Cephalalgia, it is well known, is produced by different toxical agents, namely, opium, alcohol, strychnia, quinia, and the accumula-

tion of urea. Assuming the correctness of this supposition, the nature and source of the toxical agent, or agencies, are unknown. It has been conjectured that the immediate causative condition may be either spasm or paralysis of the muscular fibres of the arteries within the skull, from an influence exerted through the vaso-motor nerves. The pallor and coolness of the face and head in some cases, and the redness and heat in other cases, sometimes bilateral and sometimes unilateral, afford support to this conjecture; and it is not an incongruity that anæmia and congestion alike may give rise to the cephalalgia. In accordance with these pathological views, inhalation of the nitrite of amyl has been suggested as an appropriate remedy when the appearances denote anæmia, and ergot where there is congestion. Assuming the existence of spasm or paralysis of the arterial muscles, it is reasonable to suppose that the vaso-motor influence depends on a toxical agent acting on the sympathetic nerves.

Periodical headache, as regards successful treatment, belongs among the opprobria of medical art; yet, in not a few cases, much benefit may be derived from treatment. The treatment embraces measures to be employed at the time of an attack, and during the intervals.

If patients be not affected unpleasantly by opiates, an attack may be sometimes warded off, or abridged, or its severity lessened, by a full dose of opium in some of its forms, or of its alkaloids, morphia or codeia. The carbonate of ammonia is sometimes successful in affording relief. A saline purgative, taken at the commencement of the attack, is in some cases an effectual remedy. The bromides given in full doses are sometimes efficacious. This statement will also apply to the hydrate of chloral, in doses of fifteen grains, repeated once or twice after an hour's interval, if relief be not obtained.

Various palliative measures may be resorted to with advantage. The inhalation of a little of the vapor of chloroform is sometimes an efficient palliative. Evaporating lotions to the head—alcohol, spirits, vinegar, ether —in some cases afford marked relief. In some cases a towel or napkin wrung out in water as hot as can be borne, and wound around the head, is more efficient than cold applications. Warm stimulating pediluvia are useful. Strong coffee or tea affords marked relief in some cases. Electricity has been found in some cases effective in arresting and preventing the recurrence of the paroxysms. The electrical treatment should not be abandoned until after a fair trial of the faradic and the galvanic current. Guarana, given in the form of powder, infusion, or extract, sometimes is an efficient palliative remedy. It is an uncertain remedy, and generally after a few paroxysms it fails to afford relief.

During the intervals, remedies which are sometimes useful, by way of prophylaxis, are, nux vomica or strychnia in small doses, arsenic, small doses of quinia, belladonna, and the preparations of zinc, more especially the valerianate. These remedies may be tried in succession. Hygienic measures are important. In general terms, the liability to attacks is less, the more the laws of health are observed. Avoidance, as far as possible, of everything which experience shows, in individual cases, to act as exciting causes, is an important part of the management.

CHAPTER VII.

THE NEUROSES.

Chorea. Anomalous Muscular Movements. Local Spasms. Tremor. Epilepsy.

CERTAIN of the neuroses or functional affections of the nervous system are characterized by disordered muscular movements. Chorea is one of these affections. Anomalous movements proceed from disordered volition. Disorders manifested by involuntary movements are grouped under the names tremor and local spasms. In these groups belong senile trembling or paralysis agitans, writer's cramp, and athetosis. Epilepsy is an important functional affection. The foregoing affections will be considered in this chapter.

Chorea.

The affection called *chorea*, *chorea sancti Viti*, or *St. Vitus's dance*, is characterized by irregular clonic contractions of more or less of the voluntary muscles, giving rise to movements which are either involuntary or not under the guidance of the will. The manifestations of the affection are usually at first limited to a portion of the body, to one of the upper extremities oftener than elsewhere, and sometimes they are confined, for a time, to the fingers of one hand. The movements increase and progressively extend to both upper extremities, the muscles of the face, and frequently to the lower extremities and to the trunk. The appearances consist of frequently recurring or unceasing movements of the parts affected, producing in the face varied and ludicrous grimaces, and in the extremities and trunk grotesque contortions and fantastic gesticulations.

The spectacle afforded by the manifestations of this affection is comical, and it is difficult to realize that it is not a performance for the amusement of observers. The condition has been well designated an "insanity of movement." The condition, however, if the affection be severe, is truly distressing. The incessant activity of the muscles induces fatigue. The patient may be unable to perform the voluntary acts which the wants of the body require, and is completely dependent upon others. Speech may be impaired or lost. Locomotion may be impossible. The isolation is sometimes more complete than in cases in which a considerable portion of the body is paralyzed or several senses abolished. Want of ability to direct and harmonize voluntary movements is a feature of this affection. Acts of volition give rise to the irregular movements; but movements, to a greater or less extent, take place without the stimulus of volition, that is, they are involuntary. In the latter respect chorea differs from locomotor ataxia, the movements in ataxia being never wholly involuntary. The movements in chorea are usually suspended during sleep, but they sometimes continue, although always more or less diminished. They are increased generally when the patient is conscious of being observed, and under any emotional excitement. The movements are frequently more marked on one side of the body, and this is generally the left side. They are sometimes confined to this side, and the affection is then called *hemi-chorea*. The choreic manifestations are confined to the voluntary muscles. The sphincters are rarely affected; and this is true of

the muscles concerned in respiration, inclusive of the laryngeal muscles, as, also, those of the pharynx. In extreme cases the disordered movements are so violent as to give rise to contusions and excoriations, unless the patient be properly protected. In consequence of incessant movements it may be difficult or impossible to feed the patient. This severe form of the disease is called *chorea major*, and is happily very rare.

The affection is not accompanied by fever. If this exist, it is due to an intercurrent or co-existing affection. The appetite is usually more or less impaired and the bowels are constipated. Anæmia often co-exists. Irritability of temper is a notable feature. The mental faculties are weakened. The grimaces give to the physiognomy an appearance of idiocy, and, if the affection becomes chronic, patients fall into a condition of apparent imbecility. The mind fails, in these cases, from the deficiency of exercise of the mental faculties. If the speech be lost, it is difficult to estimate the amount of intelligence which is preserved. The power of the affected muscles is more or less diminished, and this impairment of power, or incomplete paralysis, is most marked on the side most affected with the chorea. Anæsthesia of the surface, on one or both sides of the body, is sometimes observed; oftener, however, there is hyperæsthesia which is especially marked in the tract of nerves. Tenderness along the spinal column exists in a large proportion of cases. There is an exaggerated susceptibility to reflex excitations, and the electrical excitability of both the muscles and skin is abnormally increased. Pressure upon tender points over nervous trunks excites the choreic movements.

Endocardial murmurs are not infrequently found in cases of chorea. If these be aortic or pulmonic, accompanying the first sound of the heart, they are to be regarded as inorganic or anæmic murmurs. They do not constitute evidence of endocarditis. Nor is a mitral murmur, in this affection, always evidence of endocarditis. I have observed a mitral systolic murmur during the continuance of chorea, and the disappearance of the murmur after recovery from the chorea.

As one of the neuroses, this affection, of course, has no ascertained anatomical characters. In cases which have proved fatal, morbid changes, not uniform in character or seat, have been found in the nervous centres. Minute embolic obstructions in the corpus striatum have been observed by J. Hughlings Jackson and Bastian in hemi-chorea. The opinion is held by many that there is a pathological connection between it and rheumatism. The statistical researches of Sée and Henri Roger, in France, appear to show that, in a considerable proportion of cases, chorea either follows, or is coincident with, rheumatism. The same results have not been obtained by the analysis of cases in Germany. Endocarditis appears to co-exist in a certain proportion of cases without other evidence of rheumatism; but it is probable that, in some of these cases, the existence of endocardial inflammation has been incorrectly inferred from physical signs. It is certain that endocardial inflammation does not exist in a sufficient number of cases to afford any ground for the theory of Kirkes, that chorea is caused by the passage into the blood of the inflammatory products of endocarditis. It is perhaps correct to say that there is no essential pathological connection between rheumatism and chorea, but that in children the former predisposes to the latter disease.

The causation is obscure. It is common to suspect the presence of worms in the alimentary canal, but there is little evidence that the affection is caused by worms. It is sometimes traced distinctly to fright, or to violent mental excitement, as a fit of anger. Its development is favored by anæmia; in most cases patients are anæmic. There is reason for suspecting sexual excitation as a cause in some instances. It may be produced by unconscious

imitation. This has been shown repeatedly by its prevalence in schools. It occurs occasionally in pregnancy (chorea gravidarum).

Chorea occurs especially between 10 and 15 years of age. It rarely occurs under 6 years of age. It may occur at any period of life. Henri Roger has reported a case occurring in a female aged 84 years. Graves observed a well-marked case in a male aged 72 years. On the other hand, cases have been observed in infants shortly after birth. Girls are more liable to it than boys, the ratio being as three to one.

The duration varies from a few weeks to several months. The average duration is from two to three months. In the vast majority of cases the termination is in recovery. After a variable duration, the affection tends intrinsically to this termination. In a very small proportion of cases it becomes chronic, and is incurable. Life may be destroyed by intercurrent affections which, in general, do not suspend the choreic phenomena. A fatal result may take place without any superadded disease, the patient being worn out by prolonged irritation, loss of sleep, and inanition. The incessant movements sometimes give rise to contusions and excoriations which may lead to erysieplas and abscesses, and these may contribute to a fatal result. Occurring in pregnancy it is apt to lead to abortion or premature delivery, and, hence, is not without danger.

Relapses are apt to occur after intervals varying from a few months to two or three years. As a rule, the relapsing, are shorter than the primary, attacks.

A diversity of remedies have been advocated as effecting a cure of this disease. In general, when different methods of treatment of any disease are found to be successful, it is a fair inference that the disease ends favorably from an intrinsic tendency. This is undoubtedly true of chorea. Of the diverse remedies indicated, none can be relied upon for promptly arresting the course of the disease, and it is doubtful if any exert a special curative agency. It by no means follows, however, that much benefit may not be derived from judicious treatment. The greater part of the remedies are doubtless more or less useful, and the physician is to exercise judgment in adapting them, severally, to individual cases, and in employing them successively in the same case.

Rational indications, in the first place, are to be sought for in co-existing disorders or morbid conditions. If there be symptoms, aside from the chorea, pointing to rheumatism, remedies addressed to this condition are called for. Anæmia, in a large proportion of cases, calls for appropriate treatment. Constipation, if present, claims attention. Purgative remedies are among those advocated as efficacious in curing the disease. Causes of peripheral irritation, especially those of sexual origin, should be removed.

Of remedies, other than purgatives, which experience has shown to be useful, the more important are, arsenic, the carbonate and prussiate of iron, zinc, strychnia, opium, cannabis Indica, and various antispasmodics. Of the efficacy of arsenic there is abundant and strong testimony. Fowler's solution is the most eligible preparation. Commencing with three or four drops, three times daily, the doses should be gradually increased until the characteristic effects are observed. Of the preparations of iron, the carbonate and prussiate have been supposed to exert a curative effect, aside from their usefulness with reference to co-existing anæmia. Of the preparations of zinc, the oxide has been especially advocated as curative in this affection. Strychnia was advocated by Trousseau, who preferred the sulphate dissolved in syrup. He commenced the treatment with a very small dose, namely, one twenty-fifth of a grain once daily, and increased the dose very gradually. Opium was also advocated by Trousseau as a curative remedy. He gave it

in a full dose, producing slight narcotism which is to be maintained for several days. He affirmed that this method of treatment is often extraordinarily successful. To the efficacy of cannabis Indica, testimony is borne by many. Cimicifuga, in some parts of this country, has been a popular remedy, and its value is attested by numerous eminent physicians. Conium pushed to its physiological action has been employed with benefit. Of antispasmodic remedies, those which have been found especially useful are hyoscyamin, valerian, assafœtida, and camphor. Keeping the patient daily under the influence of chloroform for half an hour or more has been found serviceable. This measure is hardly to be advised save in cases in which the movements are unusually violent and constant. In chorea major it may be necessary to anæsthetize the patient in order to introduce the stomach-pump for feeding him. The application of ether spray to the spine, for four or five minutes at a time, daily, or on every alternate day, has been found efficacious. The testimony respecting the usefulness of electricity is conflicting. Benedikt and Jaccoud claim signal success by galvanization of the spine. Beard and Rockwell have found general faradization uniformly successful. The result of galvanization of the spine in a few cases was unsatisfactory in their hands, and also in the experience of Meyer. This discrepancy may be, perhaps, in a measure explained by differences as regards the mode of employing both the direct and induced current; and also by differences as regards the period of the disease when the treatment was entered on, bearing in mind that this disease may be said to have a self-limited duration. The bromides, in my experience, have failed to meet the expectations which I had been led to form of their usefulness in this affection.

Hygienic measures are certainly not less important than remedies. Alimentation as nutritious as possible is desirable. Daily exposure, and, if practicable, exercise in the open air, are highly important. The cold sponge bath is useful, provided it be not dreaded by the patient, and it be followed by brisk reaction; the shower bath, with the same provisions, is admissible. On the other hand, the tepid bath, as a palliative measure, is highly useful. In the Children's Hospital in Paris for many years much reliance has been placed on gymnastic exercises for the cure of chorea. Of course, these are practicable only in the cases in which the ability to co-ordinate movements by the will, although more or less impaired, is not lost. The exercises consist of systematic movements performed under the direction of assistants, and enlivened by music.[1] After the choreic movements have ceased, more or less inability to co-ordinate movements, together with muscular weakness, remains, and these effects of the disease are to be removed by exercise. The power of again directing the muscles is to be acquired as in infancy, but it is acquired rapidly.

Anomalous Muscular Movements. Local Spasms. Tremor.

Certain abnormal muscular movements are considered, incorrectly, as denoting varieties of chorea. Persons, sometimes, without motive or purpose, impelled apparently by an irresistible impulse, perform extraordinary acts. One of these is leaping suddenly and violently, and sometimes jumping upon chairs or tables. Such movements have been considered as denoting a variety called *chorea saltatoria*. A patient subject to epilepsy was brought to me

[1] For details concerning gymnastic exercises, *vide* papers by M. Sée, and by M. Blache in Mémoirs de l'Acad. de Médecine, Paris, 1855. For a summary of these details, *vide* Meigs on Diseases of Children.

for examination, a young man aged about 20, who, at variable intervals, had paroxysms of jumping vigorously for a few seconds. He declared he was unable to avoid these movements. In other cases there is a propensity to run, and the patient, unexpectedly, when walking, rushes forward with a rapid pace for several minutes. These movements have been considered as denoting another variety, called *chorea festinans vel procursiva.* Rotating and vibrating movements are performed in other cases (*chorea oscillatoria*). Moving the head and body alternately backward and forward, constituting what has been called *Salaam convulsions*, belongs in the same category. In a case which came under my observation, the patient, a young married woman, had for several months, during her waking hours, constantly pounded some object before her with both hands. In another case, a young unmarried woman had frequently recurring paroxysms in which, for several hours, she rotated the head rapidly, and, also, at times, performed rapid projectile movements of the tongue. This patient for three years maintained the position of emprosthotonos in sitting, walking, or standing, always ceasing to maintain it when recumbent.

These movements, although abnormal, proceed from the action of the will. They denote a species of mental aberration. They are manifestations of a delirious volition, resembling in this respect certain of the convulsive movements in hysteria. They are sometimes connected with cerebral disease, but in most cases they are purely functional. In some cases it is undoubtedly true that patients are unable to resist the impulse which impels to the abnormal acts, but a morbid propensity to excite wonder and interest doubtless enters into the rationale in some cases.

The treatment embraces remedies and hygienic measures to invigorate the nervous system, together with efforts to overcome the propensity which gives rise to the abnormal movements.

Allied to the cases just referred to, are those in which twitching of certain parts becomes habitual. Thus some persons acquire the habit of jerking the head, raising the shoulders, or making other motions, especially under mental excitement. In many, if not most, of these cases, the habit may be overcome by persevering efforts before it becomes confirmed. Convulsive movements of certain of the muscles of the face, producing sometimes notable grimaces, are involuntary, and closely allied to chorea. These are apt to become confirmed and irremediable. Spasm of the eyelids is called blepharospasmus. When the angles of the mouth are raised, the peculiar expression is significantly styled risus caninus, or the sardonic grin. The convulsive movements or spasms of the muscles of the face, called by Romberg mimic or histrionic, may be either clonic or tonic. They are oftenest the former. The involuntary grimaces which are sometimes produced, occasion much mortification. The clonic spasms come in paroxysms which generally last but an instant. They are apt to occur especially under mental excitement. Sometimes they interfere with mastication and articulation. They are almost always unilateral. Involuntary or spasmodic movements of the head, with or without grimaces, characterize some cases. In a case at Bellevue Hospital, there was violent jerking of the head from side to side at intervals of a few seconds, and with these there were rapid lateral oscillations of the eyeballs. Aside from these symptoms there was no evidence of cerebral disease. They followed a debauch. The patient soon left the hospital, the movements continuing. In another case, the head was moved spasmodically to the left side at short intervals, with some contraction of the facial muscles on that side. Notable improvement, in this case, took place under the use of the bromide of potassium. Pressure over the branches of the trifacial nerve, and at certain points on the cervical portion of the spinal column,

sometimes has an inhibitory effect upon facial spasms. These are known as "pressure points." They may be found in local spasms situated elsewhere, and the galvanic current applied at these points not only has the same inhibitory effect as pressure, but it may prove curative. These pressure points should be sought after in all cases of local spasm. Pressure at certain points is found, in some cases, to increase the spasms instead of having an inhibitory effect. Hypodermic injections of morphia are sometimes an effectual method of treatment, if the spasmodic affection has not been of long duration. The injections should be made at the "pressure points." Facial spasms often continue and become permanent in spite of measures of treatment. Electricity and counter-irritation are chiefly to be relied upon, and should be faithfully tried.

An affection characterized by inability to co-ordinate the muscles engaged in the act of writing, has been called *chorea scriptorum*, or *writer's cramp* (grapho-spasmus). Whenever the act of writing is attempted, the flexor muscles especially, but sometimes the extensors of the thumb and fingers, either become rigidly contracted or contract irregularly, and guidance of the pen is impossible. Persons who employ certain muscles constantly in other acts than writing, are sometimes similarly affected. Thus, pianists and violinists are no longer able to play, printers cannot compose, tailors and seamstresses lose the power of guiding the needle, and turners are unable to move the lathe with the foot. In all these instances, other movements, calling into exercise the same muscles, are performed without difficulty. In the treatment of writer's cramp and allied affections, discontinuance of acts which occasion the spasm is essential. The period of rest should extend over several months. If this be resorted to early, recovery may be hoped for. Galvanic electricity is useful. If discontinuance of writing cannot be enforced, as in cases in which the livelihood of the patient depends on writing, the habit should be acquired of using the pen with the left hand. This is sometimes only a temporary resource, as the affection is apt to occur in the left hand after some use. Changing the size of the pen, and adopting contrivances to change the action of muscles which are co-ordinated in writing, will sometimes enable writers to continue their occupation. The affection consists in impairment of the power of co-ordination for the performance of certain acts, and it is a consequence of the long continued performance of these acts. It is a fair inference from these facts that it is a central, not a peripheral, affection. If timely and complete rest be not resorted to, recovery is not to be expected.

Painful contraction of muscles, irrespective of affections of which this is a symptom, such as tetanus, epidemic cholera, etc., and not produced by any obvious cause, is known as *cramp*. Some persons are liable to suffer much from cramp of the muscles of the leg or feet, occurring especially at night. A method of treatment proposed by Bardsley, of Manchester, England, is said to be generally successful. This consists of sleeping on an inclined plane—the bed being twelve inches higher at the head that at the feet.

Under the name *essential or idiopathic spasm of the muscles of the extremities* (*contracture essentielle ou idiopathique des extrêmités*), French writers describe an affection characterized by tonic contraction occurring with either intermissions or marked exacerbations. It occurs especially in young subjects between the age of 17 and 25, and in children from one to three years of age. Females are subject to it more than males. The puerperal state and lactation predispose to it. It is observed as a sequel of certain diseases, such as the continued or eruptive fevers, articular rheumatism, and

chorea. In children it appears to be connected with dentition, intestinal worms, and gastric disorders. The spasm or cramp affects first the muscles of the upper extremities, and especially the flexors of the forearm. It extends generally to the lower extremities, and here the extensors are the muscles most apt to be affected. The hand is often firmly closed, the fingers concealing the thumb which is in close apposition to the palm, and the flexion may embrace both the phalanges and the metacarpal bones; or, more rarely, the fingers are separated and partially flexed so as to give rise to the claw-like appearance. Sometimes the position of the fingers is like that in the act of writing. Exceptionally, the extensors of the wrist are affected. The contractions are powerful. Generally they are bilateral, but they are sometimes confined to one side. In some cases the spasm extends to the muscles of the arm, shoulder, thigh, trunk, and neck, together with those of the jaws. In these cases the affection simulates tetanus. It has been called intermittent tetanus. In tetanus the trismus is primary, whereas, in this affection, it is secondary. Moreover, in this affection, the associated symptoms denoting gravity of disease are wanting. The intermissions sometimes observe the laws of periodicity governing the different types of intermittent fever. The affection belongs among the neuroses, that is, it is a functional affection, the duration varying generally from one to three weeks. Relapses are apt to occur. The spasm sometimes leads to paralysis of the muscles which are affected. The affection tends to a favorable termination. Cases, however, have been observed in which a fatal result has been due to paralysis, following spasm, of the muscles concerned in respiration, and to spasm of the glottis. The indications for treatment relate to the pathological conditions with which it is associated. Quinia in full doses is indicated, if the affection be intermittent. Belladonna, opium, or the hypodermic injection of morphia may be resorted to for palliation of the pain and spasm.[1]

Tremor, that is, alternate contraction and relaxation of muscles in rapid succession, is a symptom of certain lesions of the nervous centres, especially of multiple or disseminated sclerosis of the brain and spinal cord. It is not infrequently incident to advanced age; and it is then observed especially in the upper extremities, but, in some cases, constant lateral motions of the head take place during waking hours, and they do not always cease during sleep. The *senile trembling*, as it is called, although not dependent on any known lesions, is irremediable. Tremulousness, especially of the hands, occurs in early and middle life, as a result of the abuse of alcohol, the habitual use of opium, nicotism, sexual excesses, and other causes which tend to depress or disorder the nervous system. Under these circumstances it may be purely functional. The trembling sometimes extends to the lower extremities and to the trunk.

The treatment in cases of tremor from these several causes, of course, involves, as the first and most important measure, the withdrawal of the causes. Other measures indicated are those which have reference to associated disorders and the general condition of the system.

The affection known as *paralysis agitans*, sometimes called Parkinson's disease, from an English author who described the affection in 1817, under the name shaking palsy, belongs in the group of affections characterized by tremor, rather than among the paralytic affections. It is to be included with the neuroses, inasmuch as it has no ascertained anatomical characters.

[1] *Vide* Traité de Pathologie Interne par Jaccoud.

Diverse morbid changes have been found after death in different cases, but in some cases no changes have been discovered.

It is an affection of middle or advanced life, the age being very rarely under forty years. Men, much oftener than women, are affected. These are all the facts at present known respecting the etiology.

The tremor consists of feeble, rapidly recurring, rhythmical movements, at times, under mental excitement or physical exertion, much increased in range and force. The movements generally begin in the fingers and hands; they extend gradually over the upper extremities, and, after variable periods, the affection invades the lower limbs, the facial muscles, the muscles of articulation, those of the head and sometimes the trunk. They are in some instances for a long time, or permanently, unilateral. The muscles which are involved retain their normal electrical excitability. Paresis follows the tremor, the latter preceding the former for a considerable or long period. Stiffness of certain muscles, especially of the flexors, is gradually induced. The head and the trunk incline forward; the elbows stand out from the chest; the forearm and hands are moderately flexed; the thumb and forefinger are sometimes in the position of holding a pen, and the fingers may be distorted as in cases of chronic rheumatism. The lower limbs are often correspondingly affected. They are knock-kneed; the feet have the appearance of talipes equinus, and there is virtually incomplete paraplegia. Festination, or a tendency to run forward, is sometimes observed. The tremor, as a rule, either ceases or is much diminished during sleep.

This affection is to be distinguished from tremor incident to cerebro-spinal sclerosis. The differential points are as follows: In sclerosis, paralysis is either coincident with, or antecedent to, the tremor; the tremor is excited by volition; it commences in the lower limbs, and it is not very infrequent under forty years of age. *Per contra*, in paralysis agitans, paralysis does not precede nor accompany the tremor at an early period; the tremor is not dependent on volition; it commences in the upper limbs, and persons under forty years of age are exempt from this affection.

The independence of volition distinguishes the tremor from that in chorea. The muscular movements are shorter in paralysis agitans than in chorea. The greater degree of tremor, and often the age, distinguishes this affection from senile trembling. The tremulousness from alcoholism and other causes which are readily ascertained in individual cases, is excluded without difficulty.

As regards the pathology, it is to be said, as of other functional affections, that the existence of morbid changes is logically certain, but their nature and their seat are yet to be ascertained. The affection is probably not myopathic nor peripheral, but whether the morbid condition is seated in the brain or spinal cord, or in both, is an unsettled question.

It is also an unsettled question whether recovery ever takes place. If the few reported instances be not open to distrust, it is certain that the probability of recovery is so small as to be almost nil in any individual case. The affection, however, is not incompatible with the duration of life and fair general health for an indefinite period. Patients generally die from intercurrent affections. The affection proves fatal, *per se*, by inducing general paralysis after many years' duration, death taking place by exhaustion.

The objects of treatment are, the prevention of the continued progress of the affection, and more or less amelioration as regards the tremor. A variety of remedies in the hands of different observers have appeared to be not without considerable effect in certain cases. The objects of the treatment are of sufficient importance to render the trial of these various remedies a duty, without abandoning a case as offering no encouragement in the way of im-

provement. Elliotson claimed to have effected a cure by the carbonate of iron, Brown-Séquard by the chloride of barium, Reynolds and Remak by galvanization of the spine. Arsenic, administered hypodermically, has been found highly useful by Eulenberg. Charcot and others have given hyoscyamus with benefit. Strychnia was advocated by Trousseau. The iodide of potassium in large doses proved beneficial in a case observed by Villemin. Other remedies are opium, belladonna, ergot, the Calabar bean, curare, chloral hydrate, and the bromides. All these cannot be expected to have more than a palliative effect. Measures to improve and invigorate the general health are, perhaps, more likely to be of real benefit. Among them the sponge bath and the cold pack are to be included. Bandaging the limbs, and applying to them the tincture of aconite, small doses of strychnia being also given, diminished the tremor considerably in a case under my observation.

Mercurial tremor denotes trembling movements of the limbs, the muscles of the face, the tongue, and sometimes the trunk, due to poisoning by mercury. The tremor occurs especially when the patient makes voluntary movements; in this respect it is analogous to chorea. This affection, formerly not infrequent, of late years is rarely seen, in consequence of improvements in mechanical processes involving the use of mercury, and the better observance of precautionary measures. The inhalation of vaporized mercury is most apt to give rise to it, but it has been produced by the use of mercury as a medicine and by mercurial inunctions. In the only case which has fallen under my observation, the gums were swollen, reddened, and spongy, and the teeth had been loosened. These appearances, together with other symptoms of the mercurial cachexia, and, generally, knowledge of the fact of exposure to mercurial poisoning as incident to the occupation of the patient, will lead to the diagnosis.

Recovery may be expected under the use of tonic remedies with an invigorating regimen, provided the continued introduction of mercury into the system be prevented. The iodide of potassium is supposed to effect the elimination of mercury from the body.

A variety of spasmodic movements was described by Hammond in 1871, and designated *athetosis* (ἀθετος, without fixed position). It is characterized by persistent irregular movements of the fingers and toes, and inability to retain them in any fixed position. The movements are wholly independent of volition. The patient can rarely arrest them by an act of the will even for an instant. In most instances the affection is confined to one side (hemi-athetosis), but in some instances both sides are affected (bilateral athetosis). It may affect either the fingers or the toes separately, or both conjointly. In rare instances, spasmodic movements of either the face, neck, or forearm, are associated. The movements of the fingers and toes are constant during waking hours, and sometimes continue, although diminished, during sleep. If they cease during sleep, the fingers rest in abnormal relative positions. The abnormal movements resemble those of chorea, but differ from them by their slower rhythm and greater regularity. They are also distinguished from choreic movements by affecting chiefly or exclusively the fingers and toes. In many cases more or less anæsthesia was present on the affected sides. The muscles of the forearm involved in the movements may become hypertrophied.

In a large proportion of cases, hemi-athetosis is a sequel of hemiplegia. The movements of the fingers and toes are on the paralyzed side. Some writers consider that lesions involving the posterior third of the internal capsule are especially apt to be followed by athetosis. Others think that the

lesion is to be sought in the motor cortical tract of the brain. Further observations are needed to determine the pathology of this affection. Athetosis may occur as a primary affection without paralysis. Although bilateral athetosis is not associated with well-marked paralysis on both sides, there is often general muscular weakness. The affection in this form occurs in idiots or those who are congenitally feeble-minded. It doubtless proceeds from a cerebral affection, although it has been observed in connection with locomotor ataxia.

Experience has furnished few data for a favorable prognosis. Grauck has reported a cure effected by the constant electrical current and the use of bromide of potassium. Gowers has found this agent essentially beneficial, and so has Oulmont.[1]

The anomalous movements described by S. Weir Mitchell under the name "post-paralytic chorea,"[2] and by Charcot under the name "post-hemiplegic hemi-chorea,"[3] are analogous to those of athetosis. The terms athetosis and post-hemiplegic chorea have been used to describe the same affection. As already remarked, athetosis may occur independently of hemiplegia. Charcot places the lesion of post-hemiplegic chorea in the posterior part of the internal capsule and surrounding brain-substance. The choreic movements may, however, follow lesions of other parts of the brain.

Epilepsy.

Epilepsy is a chronic paroxysmal affection. The paroxysms are characterized by loss of consciousness, and in the most characteristic cases by convulsive movements extending over more or less of the voluntary muscular system. Convulsions analogous to those of epilepsy are symptomatic of different cerebral affections, of uræmia, of injuries of the head; and they may be caused by certain toxical agents, for example, strychnia. These are to be distinguished as epileptiform convulsions. Epilepsy, as one of the neuroses, is a functional affection, that is, it is not necessarily connected with any appreciable lesions. Related to the affection, sometimes preceding its development, and sometimes occurring in those who are epileptics, are attacks in which convulsive movements are slight and sometimes wanting. Epileptic attacks in which convulsions are slight or wanting constitute that form of the disease which is called mild epilepsy or *epilepsia mitior*, also by French writers *le petit mal* and *epileptic vertigo*. They may be distinguished as *epileptoid attacks*. In distinction from epilepsia mitior, the common form with general convulsions is called *epilepsia gravior* or *le grand mal*. This form is to be first considered.

In the majority of cases a paroxysm occurs without premonition. The loss of consciousness is as sudden as if produced by a stunning blow upon the head. The person falls, and, hence, the affection has been popularly known as the "falling sickness." In a minority of cases there is a brief warning of the approaching fit. Generally the premonition consists in a sensation which the patient is unable to describe. The sense of a "cold vapor" emanating from some part of the body and mounting to the head, has been called the *aura epileptica*. This sensation was first described by Galen, and, as remarked by Herpin, "the commentators of Galen and those who copied from them handed down the phrase, until the existence of an aura

[1] *Vide* Real-Encyklopädie, Wien und Leipzig, 1880, art. Athetose.
[2] Am. Journ. of Med. Sciences, Oct. 1874.
[3] Leçons sur les Maladies du Système nerveux, Paris, 1877.

seemed to be accepted as an ascertained fact." It is a traditional error to consider such a sensation as a frequent warning of an epileptic paroxysm, and it is certainly extremely rare for the patient to experience any sensation emanating from a particular part of the body. The onset of the paroxysm is often marked by a loud, short, and piercing shriek or cry, which, from its intensity and unnatural character, is sometimes truly terrific. The face, at the time of the seizure, becomes notably pale. The direction in which the fall takes place is almost always forward on the face. The face is not infrequently wounded or bruised by the force of the fall, and severe burns are sometimes caused by falling upon heated stoves or into the fire. The convulsive movements at once begin. These are at first tonic, that is, the muscles are forcibly contracted, and the contraction persists for several seconds. The muscles of the face, neck, arms, forearms, the lower extremities, the abdomen and chest, are involved, and have a tetanic rigidity. In most cases the muscles of one side of the body are more affected than those of the other side, and sometimes, although very rarely, the convulsions are limited to one side. The tonic convulsions last for a period varying from a few seconds to half a minute or somewhat more. The convulsions then become clonic, that is, the muscles present forcible contractions and relaxations in rapid succession. The face is hideously distorted, the head is moved upon the trunk, the upper and lower limbs and the body jerk with violence. The tongue is sometimes caught between the teeth and wounded by the tonic contraction of the muscles of the lower jaw. This more frequently happens during the clonic convulsions. Respiration is nearly suspended by the tonic, and is irregular and difficult during the clonic, convulsions. A quackling noise accompanies the respiratory acts. The face during the convulsions becomes deeply congested and livid. Convulsive masticatory movements are accompanied by the ejection of foamy saliva, frequently commingled with blood from the wounded tongue, or from a portion of the cheek being caught between the teeth. The violent clonic convulsions continue for a period varying from half a minute to three minutes. The period to the observer seems to be much longer, but, if observed by the watch, it is rarely found to exceed three minutes, and generally does not last more than a minute. The convulsive movements now become less rapid and violent, the embarrassment of respiration diminishes, the patient fetches a deep sigh, and the paroxysm, so far as the convulsions are concerned, is ended. The paroxysms in different cases, and different paroxysms in the same case, differ much as regards the violence of the convulsive movements, and the extent of the muscular system involved. The convulsions are sometimes especially marked in the face and upper extremities, and they may be limited to these parts. Paroxysms differ also as regards duration. The violence of the convulsive movements of the muscles of the shoulder is sometimes sufficient to produce luxation of the humerus. A case in which this repeatedly occurred has fallen under my observation. During the convulsions the urine and feces are sometimes expelled, and an emission of semen may take place. The pupils, during the paroxysm, are dilated and do not contract on exposure to a bright light. The eyelids, however, close when the conjunctiva is touched, showing the preservation of the reflex function.

After the convulsions have ceased, consciousness may be speedily regained, and the patient may only experience a sense of fatigue, with, usually, a disposition to sleep. But in most cases the state of coma continues for a variable period. Frequently the respiration for some time is stertorous, and the lips are puffed out with expiration. The patient remains in this state for a period varying from a few minutes to half an hour; the pupils are still dilated and do not contract on exposure to light, and he cannot be roused from the comatose

state. Gradually he emerges from this state, opens his eyes, appears confused, and some time elapses before he is able to appreciate his situation and reply to questions. If he attempt at once to walk, he reels like a person intoxicated. Occasionally the patient passes from the apoplectiform state into one of delirium. He talks incoherently, manifests hallucinations, and sometimes the delirium assumes the form of mania, during which he may be dangerous to himself or others. After recovery of the mental faculties, there is complete inability to recall anything which has occurred during the paroxysm.

The paroxysms recur after intervals which are extremely variable in different cases. The intervals may extend over many months or years. On the other hand, they recur, in some cases, daily and even many times daily. When a paroxysm has once occurred, other paroxysms are almost sure to follow sooner or later. In most cases the paroxysms at first are more widely separated than after they have repeatedly recurred; they become, as a rule, more and more frequent until the affection is confirmed. In some cases the recurrence is periodical. In women sometimes paroxysms occur regularly at the menstrual period. Periodicity, however, is not the rule, the intervals generally varying considerably in the same case; but in certain cases of confirmed epilepsy, about the same number of paroxysms take place in successive periods of a quarter, a half, or the whole of a year. Exceptionally, the recurrence of the paroxysms becomes less frequent after a time, and a patient who, for several years, has been subject to paroxysms after short intervals, may afterward have long intermissions. Occasionally, having recurred more or less frequently for months or years, they cease altogether for a considerable period, and then return with not less, and perhaps greater, frequency than before.

In some cases paroxysms occur in rapid succession during a day or during several successive days. This condition constitutes the so-called *status epilepticus*. As many as one hundred and even a larger number of paroxysms have been known to occur during twenty-four hours. In a case under my observation paroxysms took place at intervals of a few moments for fourteen consecutive days. The patient recovered, and the paroxysms did not again recur for several months. When a series of paroxysms thus occur, the mind is notably impaired for a time; the patient is childish and perhaps idiotic for several days, but gradually recovers the habitual state of the mental faculties. Hemiplegia occasionally follows a series of paroxysms. This occurred in the case just referred to. The paralysis, in such cases, is usually of brief duration.

Epileptic paroxysms occur at all hours of the day or night. They are apt to occur during the night. In some cases, for a greater or less period, they occur only at night. In these cases the affection may have existed long before its existence is ascertained. I have known a case in which, the paroxysms never occurring in the daytime, the existence of the affection was for a long period concealed from the patient. It is a curious fact that the paroxysms are usually suspended during the course of an acute disease. A patient, for example, subject to daily paroxysms, became affected with typhoid fever; during the career of the fever no paroxysms occurred, and among the events denoting convalescence was the return of the epilepsy.

The morbid condition giving rise to epileptic paroxysms is seated in the medulla oblongata and pons Varolii. This is true of all epileptiform convulsions; but, from a clinical point of view, epilepsy, as just described, has distinctive characters which render it proper to consider it as an individual disease. The appearances found after death in the medulla, which were described by Van der Kolk, more than twenty years ago, while they corroborate the statement as to the seat of the disease, are not its anatomical characters, but,

probably, effects. From its paroxysmal character, and the fact that often there are no symptoms of disease in the intervals, it might be inferred that epilepsy cannot involve the existence of permanent marked lesions.

As regards its pathology, this disease is not to be excepted in making the statement that our present knowledge of the functions of the nervous system warrants only conjectures with respect to the nature of the morbid perversions which constitute the neuroses. Epileptiform or true epileptic paroxysms are in some cases connected with, and doubtless in some way dependent upon, intra-cranial lesions, such as tumors of various kinds, especially those involving the cortex cerebri, syphilitic affections, meningitis, and they sometimes follow fracture with depression of the skull. The experiments of Brown-Séquard and others on animals show, also, a pathological connection between peripheral irritations and epileptiform convulsions. But in addition, and, in a certain proportion of cases, exclusive of all discoverable lesions or injuries of the brain, there must be a morbid condition which is the immediate cause of the epileptic paroxysms. This condition, it is fair to presume, is the same in true epilepsy and in epileptiform convulsions when the latter are symptomatic of cerebral lesions, or when they are evidently attributable to toxical causes, as in uræmia, alcoholism, etc. What is this condition? Anæmia (ischæmia) of the brain from arterial spasm, is the answer which is most consistent with our present knowledge. This anæmia is the result of irritation of the vaso-motor centre. According to the theory of Brown-Séquard, this centre in epileptics is in an excitable state, so that it responds to the action of even slight irritants. The view that epileptic paroxysms and epileptiform convulsions depend upon cerebral anæmia, is rendered probable by the known effects of sudden cerebral anæmia from hemorrhage, from ligation or compression of the arteries carrying blood to the brain, by the notable pallor of the face at the commencement of an attack of epilepsy, together with the appearance of the *fundus oculi*, as observed by means of the ophthalmoscope.

Assuming the correctness of the foregoing explanation, it does not cover the whole ground of the pathology. It is further to be asked, what causes the irritation of the vaso-motor centre? This appears to be caused in some instances by centric, and in other instances by ex-centric agencies. But in a large proportion of the cases of epilepsy no sources of such agencies are apparent. That, under these circumstances, the epileptic paroxysms are due to the action of an internal and, at present, unknown toxical agent, seems to me the most rational hypothesis. Epilepsy, according to this hypothesis, is a toxæmia, analogous to uræmia, the toxical agent being produced at variable intervals, the quantity and the continuance of its production not being sufficient to endanger life, in this respect the contrast with uræmia being striking. If this pathological view be correct, knowledge of the nature and source of the toxical agent, which may perhaps be acquired, will, as we may hope, render this disease controllable.

Epilepsy is reckoned among the hereditary diseases. It has, however, been customary to consider the existence of other nervous affections in parents or progenitors as evidence of an inherited predisposition. Heredity, limited strictly to this disease, does not often enter into the causation. While the possibility of the transmission of the disease to offspring should not be ignored, it is to be borne in mind, as a fact which may be of inexpressible comfort to many persons, that an epileptic parentage by no means entails this or any other disease on descendants, either proximate or remote. It would be easy to collect instances of families in which the husband or wife were subject to epilepsy, whose children and grandchildren were free from the disease and in all respects healthy.

Age is of considerable weight in the causation. In a small proportion of cases the disease either exists from birth or is developed in infancy. In nearly one-third of the cases it dates from 2 to 10 years of age, and in a somewhat larger proportion from 10 to 20 years. The number of cases in which the development is between 20 and 30 years is much less, and at a later period of life the number is comparatively small. In the great majority of cases, at the commencement of the disease the age is between 2 and 20 years.

Of particular causes little is positively known. It is certain that intemperance, as regards the use of alcohol, may give rise to it. Epileptic paroxysms occur not infrequently in drunkards, and cease to recur in cases in which reformation of intemperate habits is effected. It is one of the occasional effects of lead-poisoning. Venereal excesses, and especially habits of masturbation, have been supposed to be not infrequent causes. The supposition is highly probable, but an accumulation of facts establishing this causative connection is desirable. A female patient, 23 years of age, unmarried, who had been subject to paroxysms occurring almost nightly for two years, stated to me, voluntarily, that she was taught to masturbate at six years of age, and continued the practice almost daily until she was fourteen. At this age she became convinced of the sinfulness of the habit, and discontinued it. She was afterwards tormented with sexual desires, and experienced the venereal orgasm almost nightly during sleep. She was led to disclose this private history by a conviction, at which she had arrived of her own accord, that it was important with reference to the source of the epilepsy. To what extent the antecedent history in cases of epilepsy would furnish corresponding facts can only be conjectured. The number of instances in which congenital phymosis exists in epileptics, and the cessation of the paroxysms after removal of the prepuce, show a causative connection. Epilepsy has been known to occur in persons affected with tænia, and to cease after the expulsion of the worm.

In persons subject to epilepsy, the paroxysms, in the great majority of cases, occur without obvious exciting causes. The causes determining the attack, as a rule, are intrinsic. Persons not infrequently are able to judge, by experience, from certain indefinite sensations, that they will ere long have a paroxysm. The sensations disappear after the paroxysm has occurred; and it is not uncommon for persons to feel better after recovery from the immediate effects of a paroxysm, than for some time prior to its occurrence. It has been supposed that the aura which sometimes precedes the paroxysm, denotes the existence of an exciting cause emanating from the part to which the aura is referred. It is more correct to regard the aura as a peripheral sensation dependent upon some central irritation. A case has fallen under my observation in which the patient, a female, experienced the first paroxysm during the first act of sexual congress after marriage. Subsequently, a paroxysm occurred at each marital connection, but, after a time, paroxysms took place without this exciting cause, and the patient became a confirmed epileptic. It is a remarkable fact that an attack may occur from imitation. An instance has fallen under my observation. A woman, subject to epilepsy, had a series of paroxysms in quick succession. Her female attendant, while these paroxysms were in progress, first manifested hysterical phenomena, and finally experienced a distinct epileptic paroxysm. She had never before had an attack of epilepsy, nor did another paroxysm take place, the person remaining within my observation for several years afterward. It is well known that dogs, cats, and other domestic animals are liable to epilepsy. Prof. Dalton has related to me the following interesting illustration of the effect of imitation in the canine race: A dog, not previously affected with epilepsy, was

in company with another dog, who was subject to this affection; the latter being seized with an epileptic paroxysm, the former immediately afterward had a similar attack. This occurred under Prof. Dalton's observation.

The diagnosis of epilepsy, in its ordinary form, rarely offers much difficulty. The disease is, in general, readily ascertained, when it has become confirmed. In cases in which the practitioner has not an opportunity of witnessing any of the paroxysms, he may generally obtain sufficient information respecting the distinctive features to feel sure of the diagnosis. The prominent points of inquiry are, the sudden seizure, the cry at the beginning of the paroxysm, the loss of consciousness, the tonic and clonic convulsions, embarrassed respiration, ejection from the mouth of frothy saliva often mixed with blood, and the short duration of the fits. An examination of the tongue, if repeated paroxysms have occurred, in some cases shows cicatrices, resulting from the wounds of this organ, which are quite diagnostic.

The affection is to be discriminated from hysterical convulsions; but these present points of difference which are usually sufficiently marked. The convulsive movements are not purely automatic, as in epilepsy, but proceed from a delirious volition. They are of longer duration than the convulsive movements in a paroxysm of epilepsy; they are developed gradually. Foaming at the mouth does not accompany hysterical convulsions; the pupils are not dilated. Epilepsy, however, may be developed in persons subject to hysteria, and the two affections may be associated.

If called to a patient, not known to be an epileptic, in the comatose state which succeeds the convulsions, apoplexy might at first be suspected; but if the convulsions which precede this state have been observed by any one, information respecting their occurrence suffices for the diagnosis. If the convulsions have not been observed, the appearance of foam and blood upon the lips is diagnostic. The age of the patient is to be considered, and the absence of hemiplegia which often occurs in cases of apoplexy and rarely in cases of epilepsy.

Epileptiform convulsions, or eclampsia, occurring in children, in pregnant women, or in connection with Bright's disease, are to be discriminated by means of the antecedent and co-existing symptoms. Judging from the convulsions and associated nervous phenomena, uræmia and epilepsy might easily be confounded. Uræmic convulsions, however, are rarely of as brief duration as an attack of epilepsy. Examinations of the urine will suffice for this differential diagnosis; it is, however, to be borne in mind that directly after a paroxysm of epilepsy the urine contains a trace of albumen. A paroxysm of convulsions in an infant or child often, with good reason, occasions anxiety lest it may prove the beginning of epilepsy. It is not always practicable to determine this point at once. There is more reason to apprehend epilepsy in proportion as the convulsions are not otherwise to be accounted for. Their non-recurrence affords the only positive proof that they are not epileptic.

It is desirable to determine whether epileptic paroxysms are connected with lesions affecting the cerebro-spinal system, or whether they are idiopathic. With reference to this point, symptoms denoting lesions are to be sought for in the intervals between the paroxysms. Persisting pain in the head, paralysis, and disturbance of the intellect greater than the epileptic paroxysms will account for, are symptoms pointing to cerebral lesions. Lesions are to be inferred if the epileptic paroxysm succeed an injury of the head.

Epilepsy is one of the affections which are sometimes simulated by malingerers. More or less of the appearances which are presented in epileptic paroxysms may be voluntarily produced, but a malingerer must be very well acquainted with the disease to represent accurately the phenomena in the order in which they succeed each other, and certain of the phenomena are

beyond the power of the will. To determine a case of deception, let it be observed if the face become at first pale and afterward deeply congested and livid, if a cry be uttered, if the fall be forward on the face, if the convulsions be at first tonic and afterwards clonic, if foamy saliva be ejected from the mouth, and if the tongue or cheek be wounded by the teeth. Let the pupils be examined; these cannot be voluntarily dilated, nor their mobility on the approach of light prevented. Let the duration of the fit be noted; the convulsions will be likely to be unduly prolonged. Let it be ascertained if, accompanying and succeeding the convulsions, there be insensibility to pricking, burning, or pinching the skin. Let the attention be directed to the time and place in which the paroxysms take place. Malingerers will not select the night, nor a situation in which they will not be observed. They are not likely to fall in a way or in a position to receive injury. The aspect of confusion and shame which is manifested on recovering consciousness after an attack of epilepsy is not easily feigned.

Epilepsy may exist for a long time before its existence is ascertained if the paroxysms occur only at night. The disease is to be suspected when patients complain of awakening from time to time with headache, lassitude, and a wounded tongue. Under these circumstances, the diagnosis is to be settled by causing the patient to be watched during the night.

Owing to the terrible nature of the malady, and the apprehension felt by those in company with an epileptic lest a paroxysm may occur, persons are naturally sensitive with respect to themselves or their relatives being said to have epilepsy. For this reason there is sometimes a disposition to conceal the nature of the paroxysms even from the physician. To avoid the depressing effect upon the mind of the patient which a knowledge of the disease is likely to produce, it is sometimes judicious to refrain from calling it epilepsy. In the case of a lady who was under my observation for many years, the nature of the disease was never communicated to her. The paroxysms, which were often frequent and severe, were always called nervous attacks, and she finally died of an intercurrent affection, without knowing that she had been an epileptic. In this case, ignorance of her disease enabled her to participate in many of the enjoyments of life from which, owing to her sensitive nature, she would have shrunk had she been aware that she was affected with epilepsy.

The prognosis, in cases of epilepsy, as regards immediate danger from the paroxysms, is always favorable. Nor does epilepsy tend to give rise to any particular disease or diseases of a dangerous character. Epileptics, as a rule, are not short-lived, and, in the majority of cases, death arises from other diseases, to the development of which the epileptic paroxysms have not contributed. In another point of view, however, the prognosis is most unfavorable, namely, as regards the persistence of the malady. In the vast majority of cases, the disease tends to become confirmed, and, as a rule, the intrinsic tendency is to increasing frequency of the paroxysms.

In another point of view the prognosis is unfavorable, namely, as regards the mental condition. To a certain extent, the disease tends intrinsically to impairment or disorder of the faculties of the mind. Many epileptics, especially if the paroxysms recur at short intervals, sooner or later fall into imbecility. To a greater or less extent this is due to causes other than the intrinsic tendency of the disease. If epilepsy occur in early life, the mental faculties are not developed by education and those occupations which involve their exercise; and, in the cases in which the disease occurs at a later period, the mental faculties progressively fail from disuse. The unhappy sufferer from this terrible disease is apt to lose interest in those objects or pursuits in life which incite to the exercise of the mental faculties. This explanation, in

part, of the apparent effect of epilepsy on the mind, has an important practical bearing.

Reference has been already made to mild attacks having an evident relationship to ordinary epilepsy, which may be called *epileptoid attacks*. It is important for the practitioner to recognize and appreciate the significance of these attacks. They are considered by French writers as belonging to a variety of epilepsy which they call *petit mal*, in contradistinction from the ordinary form which they call the *grand* or *haut mal*. These attacks sometimes precede the development of ordinary epilepsy, and they sometimes occur intercurrently, in persons who are confirmed epileptics.

The epileptoid attacks are multiform. A sudden loss of consciousness for a few seconds occurs in some cases, during which the body may remain fixed, the person apparently being lost in deep abstraction, the mental faculties resuming their operation, as if nothing had taken place, directly the attack passes off. In a case of confirmed epilepsy under my observation, the patient, at one time, in the intervals between the paroxysms, was subject to frequent attacks of the kind just described. During the attacks she remained fixed in the position in which she happened to be when they occurred. For example, if standing and arranging her hair, the hands were fixed precisely as they were at the instant of the seizure. On some days these attacks took place a great number of times, and the patient did not appear to be conscious of their occurrence. In the fixation of the body and limbs these attacks resemble catalepsy. In the case just referred to, the only convulsive movements were of the muscles of mastication. Similar attacks are sometimes accompanied by convulsive movements of other of the facial muscles, of the muscles of the neck, and slight laryngeal spasm. In some cases the patient falls, but recovers and rises in a few seconds. Loss of consciousness and falling, in some cases, are unattended by any convulsive movements. Trousseau relates examples of this kind. Of course, in such cases, epileptoid attacks are to be discriminated from syncope.

In other epileptoid attacks, sudden delirium occurs, continues for a few seconds, and passes off, leaving the mind in the condition in which it was at the instant of the seizure. The delirium is manifested in different ways. Trousseau cites a case in which the patient uttered a burst of laughter, and when asked why he laughed, he looked surprised, having no knowledge of what he had done. The same author cites examples of persons engaged in conversation, debate, or other occupations, abruptly, as if struck by a sudden thought, going into the street bareheaded, and walking until they recovered themselves, when they were able to return and proceed with the matter in which they were engaged, as if nothing had happened.[1] The following example came under my observation in one of the wards of Bellevue Hospital: A female patient quietly standing in the ward, suddenly uttered a cry, and ran from one end of the ward to the other. The urine was at the same time expelled, leaving on the floor traces of her course. Having reached the end of the ward, she stopped, looked confused, and quietly returned. The following is another example: A young man, who had been subject to ordinary epilepsy for twelve years, came to see me accompanied by his attending physician. On the previous evening, from time to time, he had paroxysms of jumping up and down with violence for a few seconds. In walking to my residence, now and then he stopped and performed his jumping movements in the street. After sitting down and replying quietly to my questions, he began to jump violently in the chair for a few seconds, and continued to do so at short intervals. He was desired to go into an adjoining room during

[1] *Vide* Clinique Médicale, tome ii.

the consultation, and while there we could hear him jumping from time to time with much noise. This case has been already referred to in connection with "anomalous muscular movements."

The following example of an epileptoid attack is interesting from its presenting very distinctly the *aura epileptica*. A man, thirty years of age, had been for ten months in disordered health, suffering from palpitation and mental depression. He described paroxysms of frequent occurrence during the time just stated, in which he felt a flash, as he termed it, originating sometimes in the chest, sometimes in the abdomen, and sometimes in one of the lower extremities, rising upward, giving rise to a sense of suffocation, and, on reaching the head, followed by momentary confusion of mind. He had never fallen. In some of these attacks he had felt stiffness of the muscles of the jaws and of the forehead. The attacks were irregular, but had recurred more or less frequently every week for the preceding ten months. On being questioned, he said that the "flash" gave the sensation of a stream of air or gas. He had never read or heard aught of the epileptic aura. Nine months afterward, this patient had recovered his former health, and no longer had the paroxysms above described.

Other attacks consist of convulsive movements of certain muscles without loss of consciousness or delirium. In a case under my observation, the patient, a young man apparently in perfect health, first consulted me for the occasional occurrence of convulsive movements of the upper extremities. From time to time, the hands were violently jerked, and whatever he might happen to hold at the time was thrown with great force. It was unsafe for him to hold fragile articles. A careful examination in this case revealed nothing abnormal save these convulsive movements. They became more and more frequent, and, shortly, they extended to the lower limbs, so that he was repeatedly thrown down for an instant, still without loss of consciousness. At length, after the lapse of several weeks, he had a severe paroxysm of epilepsy, and the malady afterward became established. In a case under observation in 1864, paroxysms occurred daily, more or less frequently, in which the head was forcibly drawn toward the right shoulder, and retained there for a few seconds. This affection had existed for five years, without eventuating in epilepsy. The paroxysms, however, had increased in frequency and severity, and he appeared to have loss of consciousness for a few seconds, although he did not fall. In other respects the patient was apparently well. Being a young physician, he suffered from the anxiety incident to a knowledge of the fact that these attacks might be premonitory of the graver epileptic paroxysms. Three years afterward he wrote to me that the paroxysms were not more frequent, but more severe, causing him to fall. He stated that they were controlled by large doses of the bromide of potassium. Subsequently he had some paroxysms of well-marked epilepsy. In 1879 he reported to me that neither epilepsy nor the epileptoid attacks had occurred for several years.

In the case of a girl, aged 12 years, the attacks presented the following features: Almost daily, often at the breakfast table, she suddenly manifested a changed expression of countenance, appearing as if frightened, sometimes uttered some exclamation as if surprised, and her consciousness was lost for a few seconds. Sometimes the face was distorted. When consciousness returned, she almost invariably asked "what time is it?" There had never been any convulsive movements of the limbs, but they were sometimes rigid. There was never any spasm of the glottis.

Epileptoid attacks, occurring in persons who have never had well-marked epileptic paroxysms, are to be considered as denoting a pathological condition which is essentially that of epilepsy. Hence, the obvious importance of not

overlooking their significance, in order to prevent, if possible, the fully developed malady which is foreshadowed. Facts showing how frequently epileptoid attacks occur without being followed by the graver form of the disease are wanting, but it is certain that the latter by no means invariably follows. The physician, therefore, should not excite unduly the fears of the patient or friends, by predicting that these minor forms are necessarily the precursors of the graver form.

The treatment of epilepsy relates to the management of the paroxysms and to measures for effecting a cure. The latter are to be employed in the intervals. Curative treatment, as in other of the neuroses, may be conveniently considered as rational and empirical.

The rational treatment consists in deriving, as far as possible, indications from an investigation of each case with regard to the state of the system, co-existing disorders, and circumstances which may be suspected of standing in a causative relation to the malady. If the patient be of a full habit or plethoric, dietetic and other measures addressed to this state, are rationally indicated. If, on the other hand, the patient be anæmic, measures of an opposite character are indicated. Disorders of the digestive system, uterine affections, and, in short, morbid disturbances anywhere in the economy, should receive appropriate treatment; they may, possibly, be in some way concerned in the development or perpetuation of the malady. The presence or otherwise of tænia is to be ascertained. Inquiries with respect to syphilis are not to be forgotten. Phimosis calls for appropriate surgical treatment. Habits of life, with respect to the probable or possible causation, are to be scrutinized. Overtasking of mind or body, undue exposure, on the one hand, and sedentary habits on the other hand, the facts with regard to mental and moral influences, the abuse of alcoholic stimulants, the immoderate use of tobacco, and especially over-indulgence in venery or the practice of masturbation, are to be inquired into. In brief, an important part of the rational treatment consists in enforcing observance, in all respects, of the laws of health. It is unnecessary to consider the many and varied details which this part of the treatment involves.

The empirical treatment consists in the employment of remedies or therapeutical measures which experience has shown to be sometimes curative. The number of these is large. It would require many pages simply to enumerate the drugs, the curative efficacy of which, in certain cases, has been attested by honest and competent observers. The list is so extensive, the testimony with respect to particular remedies is so conflicting, and the instances of incurable epilepsy are so many, that practitioners are apt to enter upon the treatment of a case without much expectation of success. For the reasons just stated, the disease is not infrequently allowed to continue without persevering efforts to effect a cure, and this fact may in a measure account for the number of cases in which patients remain hopelessly epileptics. Of the host of remedies which have been employed, many have doubtless proved successful in a certain proportion of cases. But without any disposition to deceive either themselves or others, practitioners have often been led to overestimate the success of different remedies by not making allowance for the following facts: Any active remedy will frequently prevent recurrence of the paroxysms for a considerable period. Under the use of a certain remedy, a patient passes weeks or months without a paroxysm; he is ready to believe himself cured, and the physician is happy to participate in the belief. Now, sooner or later, the paroxysms, in most cases, return, the patient despairs of benefit from treatment, or consults another physician. The return of the malady may not be known to the physician who had supposed that a cure

was effected, and, in the mean time, he may have reported the case as one cured by the remedy employed. Again, the paroxysms cease, in some cases, to recur for weeks or months or years, without any treatment. I have notes of a case in which paroxysms more or less in number every month, and sometimes fifteen or twenty in twenty-four hours, had occurred for sixteen years, a great variety of remedies having been tried without avail; at length, after all treatment had been discontinued, the paroxysms ceased to recur for ten or twelve years, when they again returned, but at long intervals. Making, however, due allowance for the temporary interruption of the malady either by the treatment or spontaneously, there remain a certain number of undoubted cures effected by different remedies. In view of this fact, cases should not be abandoned without the faithful trial of many remedies. Of the various remedies which have been considered as curative, those within late years and at the present time, in most repute, are the following: The nitrate and other preparations of silver, preparations of zinc, digitalis, opium, the narcotic extracts, more especially belladonna, and, above all, the bromide of potassium.

The nitrate of silver has long been a remedy for epilepsy, and its occasional efficacy rests on abundant testimony. That it will not effect a cure in the majority of cases, is not a sufficient reason for failing to make trial of it in cases which resist other remedies. Commencing with a fraction of a grain three times daily, the dose may be gradually increased to three or four grains. An effect of the prolonged use of this remedy, in some cases, is to be borne in mind, namely, permanent blueness of the skin. To avoid this effect, the remedy should be suspended for a time, after having been continued for two or three months. The oxide of silver is less likely to produce discoloration of the skin, but is less powerful as a remedy.

Of the preparations of zinc, the oxide has been found curative by different observers, and was advocated especially by Herpin, who claimed that, in his hands, a cure was effected by this remedy in 26 of 42 cases. The mode of administration advised by Herpin, is to give at first from six to eight grains daily in divided doses an hour after each meal. The quantity given daily is to be increased by two grains each week, until it reaches forty-five grains, this quantity to be continued for three months. The remedy is not to be discontinued after the cessation of the fits.

The prospect of effecting a cure according to Herpin, by this or any remedy, other things being equal, is proportionate to the small number of fits which have occurred. If there have been more than five hundred fits, the probability of a cure is extremely small. In a few cases, under my observation, in which the treatment as laid down by Herpin was faithfully carried out, the remedy proved unsuccessful. The cases reported by this author, however, afford indubitable evidence of a certain amount of curative power; and with reference to any remedy for this disease, there is no known means of determining beforehand whether it will be likely to prove successful in any particular case. In the cases in which I have tried this remedy, it has been difficult to continue it long after the maximum of quantity is reached, on account of the strong antipathy to it which the patient acquires. In a paper published after his prize essay, Herpin advised the lactate, in preference to the oxide, of zinc. Babington advocated the sulphate of zinc, and carried the quantity given *per diem*, for several weeks in succession, to 36 grains without producing nausea. The phosphate and the valerianate of zinc have been recommended.

The ammoniated copper has been found curative. Of twelve cases treated exclusively with this remedy by Herpin, four were cured. The dose is half a grain, increased gradually to four or five grains. The sulphate of copper has also been employed successfully.

Digitalis is said to have been long a remedy of much repute in Ireland for epilepsy, and its efficacy was attested by Sharkey, Crampton, McCormack, and Corrigan. The infusion is the preparation to be preferred. The quantity given daily is to be increased to the amount which is tolerated, and continued steadily for several months.

Opium is among the remedies recommended as sometimes curative, and, perhaps, it deserves a trial more extended than appears as yet to have been given to it. The evils of the habitual use of opium are to be considered, but, with a fair probability of effecting a cure of the epilepsy, the physician would be warranted in exposing his patient to this danger.

Of the different narcotic extracts, belladonna has the strongest claims, based on the testimony of different observers. Trousseau was an ardent advocate of this remedy, as capable of effecting a cure in a certain proportion of cases, and frequently ameliorating the condition of epileptics when it fails to prove curative. Trousseau insists that a fair test of this remedy requires its continuance for a period not limited to months, but embracing several years. His mode of administration was to begin with a small dose of the extract (gr. $\frac{1}{5}$) once daily, to be continued for a month without increase. At the end of each month the dose is to be doubled, until as large a dose as can be conveniently borne is reached. The tolerance of the remedy differs in different cases. After the disease is perceptibly modified, the doses are diminished in the same manner as they were increased. Atropine may be employed in lieu of belladonna, the mode of administration being similar. With the use of belladonna or atropine, Trousseau frequently combined the employment of the nitrate of silver, the sulphate of copper, and the lactate of zinc.[1]

Of all the remedies at the present time known to have any controlling influence over this disease, the bromide of potassium justly takes the lead. This remedy has not proved as successful in effecting permanent cures as was anticipated twenty years ago, when it was first employed in this disease; but in a considerable proportion of cases paroxysms do not recur while the remedy is in use, and, when this result is not obtained, the recurrence of the paroxysms is often rendered less frequent and their severity is diminished. It has effected permanent cures, making due allowance for occasional spontaneous recoveries, but probably the number of instances is not large. The remedy may be carried to the extent of producing distinct bromism. The doses required differ considerably in different cases owing to difference of tolerance. For an adult, a scruple of the salt may be given, at first, twice or thrice daily. These doses are to be increased until the desired effect upon the disease is produced, unless bromism be induced, even if 40, 50, or 60 grains, in each dose, be reached. Whenever bromism is produced, the remedy should be discontinued for a few days and then resumed. If no effect upon the paroxysms be produced within two or three months, it is useless to continue the remedy longer. Having ascertained the effect produced upon the disease and the tolerance of the remedy, it should not be discontinued, except at intervals, for one, two, or more years, that is, provided the paroxysms are prevented or rendered infrequent. It does not seem to be as yet ascertained how far the other bromide salts share in the efficacy of the bromide of potassium. They should be substituted for the latter if it be not well tolerated. The hydrobromic acid appears not to have the same effect as the bromide of potassium, and it has even been thought to increase the frequency of the paroxysms. It is, of course, important not to carry the use of the bromide of potassium to the extent of causing an alarming degree of bromism; and the fact that, given too largely or continued in large doses too long, it is a dangerous toxical agent,

[1] Clinique Médicale.

is not to be lost sight of. The following case is of interest as showing the value of the remedy and the tolerance of large doses for a long time: An epileptic patient came to me about six years ago, and was placed upon the bromide of potassium, which was given pretty steadily for a couple of years, the quantity *per diem* being about a drachm. During this period the paroxysms were infrequent and light. The quantity *per diem* was increased to two drachms, and continued steadily for about two years. During this period he had but a few paroxysms, and they were not severe. Of his own accord, from some misapprehension, he increased the quantity *per diem* to three drachms, which he took for about two years. During this period he was exempt from paroxysms. At the end of the two years he came to see me, and I was struck at once by his appearance. His face had a vacant, idiotic expression, and he walked with a staggering gait like that of a drunken man. Recognizing bromism, I then ascertained the quantity which he had been taking for the past two years. I directed him at once to suspend the remedy. He did so for a week or two, but, from inability to sleep, he resumed the dose of a drachm at night. Meanwhile, he had a severe paroxysm. After a few weeks the bromism had entirely disappeared. He has continued the remedy in the dose of a drachm at night, and for two months there has been no recurrence of the paroxysms.

The fact of syphilis having existed at a period even remote, should lead to the employment of the antisyphilitic medication, namely, the iodide of potassium and the bichloride of mercury.

It will suffice to mention some other remedies which are worthy of trial, in the cases in which the bromides fail, as follows: Strychnia, or nux vomica, recommended in small doses, especially by Marshall Hall; cotyledon umbilicus, an ounce of the fresh juice or half a drachm of the inspissated juice to be given twice daily; indigo, commencing with moderate doses and increasing to the amount which the stomach will bear; valerian, in large doses, continued for a long period; musk, camphor, cimicifuga, and the oil of turpentine.

Van der Kolk asserted that counter-irritation over the nucha by means of wet cupping, setons, and issues, proved in his hands successful. Others have claimed for these measures success.

Under the supposition that the paroxysm depends upon a morbid agency springing from some part more or less remote from the nervous centres, and that the *aura* indicates the point of departure of this agency, it has been proposed to interrupt the nervous communications with the part by means of ligatures, section of nerves, the actual cautery, and even amputation of an extremity. But in the great majority of cases paroxysms are not preceded by an *aura*, and when this exists there is no ground for the conjecture that it denotes a causative agency. It is claimed that in some instances in which an aura starts from an extremity, a counter-irritant applied between the starting point and trunk has succeeded in arresting the paroxysm.

Surgical measures for the cure of epilepsy, in addition to those just alluded to, are, ligation of the carotids, tracheotomy, and, after injuries of the head, trephining. Ligation of one or both of the carotids has been repeatedly tried, but the results do not warrant its being recommended. The same is true of tracheotomy which was warmly advocated by Marshall Hall. Trephining, when there is reason to believe that the epilepsy may depend on depressed fracture of the internal table of the skull, spicula of bone, or a collection of blood or pus, is a warrantable operation. In 35 cases collected and analyzed by Prof. Stephen Smith, the results of this operation were as follows: "Relieved, but not cured, 3. Immediate relief after operation and no further note of result, 2. Relieved for one month or under, when last seen, 3; between one and six months, 3; between six months and one year,

6; between one and five years, 3; Set down *cured*, but lapse of time from date of operation to time last seen not given, 7."[1]

It remains to consider the treatment called for during the paroxysms. These are rarely witnessed by the physician, save when a series of paroxysms occur in rapid succession. The duration of a single paroxysm is so short that, if the physician do not happen to be present, it ends before he reaches the patient. The instructions to friends or attendants should be, to place the patient on a bed, if practicable, and not to attempt to restrain by force the convulsive movements. All articles of dress which constrict the neck or chest should be removed or loosened. To prevent wounding of the tongue, a roll of linen or a piece of soft wood may be introduced between the teeth. A congregation of spectators around the patient should be prevented, and free ventilation provided for. The patient should be kept quiet after the paroxysm has ceased, and soothed by cooling lotions to the head.

Epileptics should sleep in beds with raised sides to prevent injury from being thrown upon the floor by the convulsive movements, if a paroxysm occur during the night. They should be under observation, as far as practicable, during the night, for death from suffocation has resulted from the face being pressed into the pillow during the paroxysm.

When a series of paroxysms occur, measures may be employed to prevent their recurrence. Ether, valerian, belladonna, and opium may be given for this object. The most effective measure is the inhalation of four or five drops of the nitrite of amyl at the instant of a premonition or of the occurrence of a paroxysm. This drug arrests the paroxysm by relieving the spasm of cerebral arteries. Patients may be provided with this remedy, for the purpose of warding off a paroxysm. A paroxysm may perhaps be postponed, but it is doubtful if it be preventable by any measures resorted to when premonitions are experienced. In a case under my observation, a friend sat by the side of a patient the whole of an afternoon, and, when the premonition was felt, dashed a little water into the face. The paroxysm was apparently prevented for the time, but it occurred as soon as the effort to prevent it was discontinued.

A highly important point connected with the management of epileptics relates to measures to prevent deterioration of the mental faculties. In so far as impairment of mind proceeds from disuse of the mental faculties, it may be obviated or retarded by taking pains to secure as much exercise of these faculties as practicable. It conduces greatly to an alleviation of the unhappy condition of epileptics for them to participate, as far as practicable, in the interests and social enjoyments of life; and, if practicable, it is sometimes desirable to conceal from them the nature or the extent of the malady with which they are afflicted. I have known marriage to be advised by the physician in the case of a young woman. Such advice cannot be too strongly censured. There is no ground to expect that the malady will be favorably affected by marriage. With reference to this step, it is the duty of the physician to explain fully to the family of the patient, if not to the patient, the nature of the malady.

The existence of epilepsy is an important fact in certain medico-legal cases. In the transient delirium which sometimes succeeds epileptic paroxysms, and which may be incident to epileptoid attacks, violence to others, and even homicide, may be committed. The occasional occurrence of delirium, lasting

[1] *Vide* article on the Surgical Treatment of Epilepsy, etc., New York Journal of Medicine, March, 1852. Prof. Smith, in this article, gives a summary of facts with respect to setons, issues, cauterizations, and moxas, operations on the scalp, tracheotomy, amputation, operations on the nerves, operations on the arteries, and trephining.

for hours or days, in connection with the disease, is to be borne in mind in giving medical testimony. An epileptic under my observation, a quiet, docile man, has repeatedly said to me, with an appearance of much concern, that he had fears that he might kill some one. He stated that he was conscious at the moment of an intense desire to kill any one who irritated him.

The treatment of cases in which epileptoid attacks occur, either with or without the occurrence of epilepsia gravior, is essentially the same as in cases of the latter form of the disease.

CHAPTER VIII.

THE NEUROSES—(Continued.)

Hysteria. Hystero-epilepsy. Catalepsy. Ecstasy. Somnambulism. Tetanus.

Hysteria.

THE name hysteria, as commonly used, embraces a multiplicity of morbid phenomena. It is used to denote an abnormal condition of the nervous system and of the mind, entering largely, as a morbid element, into a variety of affections. The hysterical condition, as regards the mind, involves a morbid susceptibility to emotions and a defective power of the will to restrain their manifestations. A person, whether male or female, is said to be hysterical who weeps or laughs irrepressibly on inadequate occasions, and when these emotional acts are incongruous. Frequently these manifestations of opposite emotions occur in alternation, and with an abrupt transition. Weeping and laughter are physiological acts when they represent emotions which are natural, that is, excited by adequate causes, and not exceeding the bounds which observation shows to be consistent with health. These acts are pathological when they do not represent corresponding emotions, or when they proceed from emotions which are unnatural in view of the circumstances under which they occur. The emotions may be real, but morbidly excited or in morbid excess. On the other hand, the hysterical manifestations, in some cases, simulate emotions which do not exist. Patients sometimes weep violently without experiencing mental anguish, and laugh immoderately without enjoyment. An intelligent and estimable lady, in advanced life, who was under my observation for many years, was subject to spells of uttering loud explosive sounds resembling those of laughter, from which she declared she was unable to refrain. They were called, in the family, her laughing or screaming fits. These were the only hysterical phenomena in the case, and it was frequently necessary to administer a full opiate to arrest them.

A tendency to exaggerate subjective symptoms of disease often enters into the hysterical condition, proceeding sometimes from an exaggerated sense of existing symptoms, and sometimes from a morbid desire to excite interest or sympathy. It is an important part of the knowledge and tact of the practitioner to make due allowance for this tendency in his investigation of symptoms. In some cases a morbid perversion of the mind leads patients to undertake to practise gross frauds as regards their ailments. They pretend to have extraordinary disorders, and resort to ingenious and persevering efforts of deception. Here, too, the knowledge and tact of the physician are called into requisition. He meets not infrequently with hysterical malinger-

ing as well as hysterical self-deception. Owing to the facts just stated, hysteria is associated in the minds of many with either imaginary complaints or imposition; hence, many are loath to consider themselves as affected with hysteria, and the physician learns reserve in the use of this term in his intercourse with his patients.

Other symptoms of the hysterical condition are, a painful sense of constriction in the epigastrium, and the sensation of a foreign body in the throat, known as the *globus hystericus*. To these a great number and variety of morbid sensations might be added, such as cephalalgia, *tinnitus aurium*, eructations, abdominal tympanites, irregular chills with yawning and stretching, diuresis, twitching of muscles, cramps, etc. etc. Now, the nervous and mental disorder which constitutes what is commonly called the hysterical condition, may be associated with a host of affections. This condition may enter more or less as an element into almost any disease. There are certain affections often found associated with symptoms denoting this condition. It will suffice to enumerate the more important of these, as follows: 1. Neuralgia, especially supra-orbital, cervico-occipital, and dorso-intercostal. A form of neuralgia almost pathognomonic is that in which the patient describes the pain as if produced by driving a nail into the head (clavus hystericus). 2. Hyperæsthesia of the surface, either limited to certain situations or diffused over the body. Affecting the abdominal walls, it simulates, in some cases, peritonitis. 3. Anæsthesia, local or general. This is sometimes unilateral (hemi-anæsthesia), and generally of the left side. Not infrequently the sensibility to tact remains, while the sensibility to pain is lost (analgesia). 4. Different varieties of functional paralysis, more especially paraplegia, and nervous aphonia. 5. The so-called hysterical cough (*vide* page 306). 6. Hyperæsthesia of the joints simulating grave articular disease. 7. Pain and tenderness over one or both of the ovaries—oftenest on the left side. 8. Retention of urine. 9. Notable diminution or suppression of urine (ischuria).

What I have called the hysterical condition embraces the milder manifestations of hysteria. Severer forms of the affection are hysterical paroxysms characterized by either convulsive movements, or coma more or less complete, or delirium. In some cases convulsions constitute the most prominent feature of the paroxysms, coma, in these cases, usually co-existing; in other cases coma occurs without convulsions, but the coma may precede or follow convulsions, and in some cases delirium is the prominent feature. The severer forms of hysteria, therefore, may be considered as threefold, namely, hysterical convulsions, hysterical coma, and hysterical delirium.

Hysterical convulsions occur in persons subject to the milder manifestations of hysteria, and the latter are frequently premonitions of the former. The development of the paroxysm is generally gradual; the convulsions are preceded by notable distress referred to the epigastrium, by a sense of choking or suffocation, and sometimes by a feeling as if a solid body, or ball, ascended from the abdomen to the throat (*globus hystericus*). The convulsive movements are often first manifested in the muscles of the eyelids and eyeballs. Other of the muscles of the face are rarely affected, and, hence, movements more or less rapid of the eyes and constant nictation are highly distinctive of an hysterical paroxysm, if the movements be limited to these facial muscles. These muscles may be alone affected, but frequently the convulsive movements extend to the extremities and trunk.

A distinctive feature of the convulsive movements of the body and limbs is, they are not purely automatic. Patients throw their limbs in various directions, they tumble about the bed with violence, rolling from the bed to the floor, and striking with force against solid substances, if not prevented; they struggle with those who attempt to restrain them, and sometimes show

a prodigious degree of strength. After making active movements for several minutes, they remain comparatively quiet for a time, and the convulsions are then renewed. At times they grasp the throat as if to remove an obstruction, strike the breast, or tear the hair. These movements are in great measure voluntary; they are directed by a delirious volition, in this respect differing essentially from the convulsions of epilepsy, or eclampsia, which are purely automatic or involuntary. Automatic movements, however, in certain cases, enter, more or less, into hysterical convulsions. Tonic spasm of the posterior muscles of the trunk, bending the body backward so that the trunk, head, and lower limbs form the arc of a circle, constituting what is known as *opisthotonos*, occurs in some cases of hysteria. The jaws are sometimes firmly closed, as in trismus. In the intervals between the active movements the muscles are often rigid.

Consciousness during the convulsive movements, and in the intervals, appears to be lost, but generally the patient has more or less cognizance of what is said and done, a fact which the practitioner may often turn to good account in the management. The face is sometimes flushed and sometimes pale. Respiration is often notably disturbed, in some cases being extremely rapid and irregular, in other cases slow and suspirious. It is extremely rare for foamy saliva to be ejected from the mouth, or for the tongue to be bitten. The spasm of the larynx and muscles of respiration, which characterizes epilepsy, is wanting, the nostrils are usually dilated, nictation and movements of the eyes generally continue. The pulse is frequently but little, or not at all, affected. The heart, however, sometimes acts with violence and irregularity. The tranquillity of the circulation, in some cases, is a striking feature. The duration of the paroxysm varies much in different cases. It very rarely, if ever, is limited to a few moments; it may continue for a period varying from half an hour to several hours. The convulsive movements gradually go off, and the disappearance of the paroxysm is frequently accompanied by cries, groans, sighs, loud weeping, or spasmodic laughter. Copious diuresis is apt to occur at the termination of the paroxysm.

It is important to discriminate hysterical convulsions from epileptic paroxysms and epileptiform convulsions or eclampsia. The foregoing sketch presents certain points which, in general, suffice for the differential diagnosis, namely, the evidence of volition in the character of the movements, the gradual development of the attack, absence of convulsive movements of the muscles of the face, excepting those of the eyes, absence of foamy saliva and blood upon the lips, the respiration disordered, but not suspended by spasm of the larynx and respiratory muscles, the long duration of the paroxysms, the incomplete loss of consciousness, and the occurrence of symptoms denoting the hysterical condition prior to and following the paroxysm. It is a fact, however, not to be lost sight of, that epilepsy or eclampsia may be conjoined with hysterical convulsions.

Hysterical coma enters more or less into the paroxysms just described. It may precede and follow them. It is sometimes accompanied by convulsive movements limited to the eyelids or eyes, but it occurs without any convulsions. In a case of simple, ordinary hysterical coma, the patient lies apparently in a state of profound, tranquil sleep. The countenance presents a natural appearance; the respiration is quiet, with perhaps occasional sighs. The pulse is regular, and is neither accelerated nor retarded; there is frequently more or less rigidity of the muscles. Attempts to rouse the patient from this state are either ineffectual, or answers to questions are obtained with much difficulty in feeble whispers. The muscles offer resistance to efforts to separate the jaws. The *quasi*-comatose state continues for a variable period, often for hours and sometimes for days, if not successfully treated.

Patients in this state are not completely unconscious; they are cognizant of what is said and done. Sensibility to pain is blunted, but not abolished; pinching or pricking the skin may be borne without flinching, but stronger impressions, such as are produced by the application of a heated hammer or the prolonged cold douche, occasion suffering.

Attacks of this kind occasion great alarm, and the physician will naturally participate in the apprehensions of friends if he fail to determine the nature of the affection. It is to be discriminated from apoplexy, and the diagnostic points are as follows: The attacks do not present the stertor of apoplexy, and hemiplegia is wanting; the pupils respond readily to light; the patient is perhaps known to be subject to hysteria. The symptoms of the hysterical condition precede the coma. The age of the patient will be likely to be under the period when apoplexy is most apt to occur; and in ordinary hysterical coma the nature of the affection is generally speedily declared by the efficacy of certain measures of treatment to be presently mentioned.

Uræmic coma is to excluded. Antecedent and co-existing symptoms relating to the urine, general dropsy, in some cases, and the absence of hysterical premonitions, will suffice for this differential diagnosis. Abercrombie related cases of fatal coma, occurring in women, which are liable to be mistaken for hysteria, nothing being found after death to account for the coma except cerebral congestion. Williams described these cases in the following terms: "A young female becomes anæmic, and after exhibiting various symptoms of feeble general circulation, with headache, drowsiness, and impaired sensorial functions, suddenly becomes worse, passes into a state of stupor, with dilated pupils, sometimes varied by slight manifestations of delirium, throbbing of the carotids and partial heat of the head, and dies comatose. On opening the head, a small quantity of serum is found under the arachnoid and in the ventricles, sometimes with a little lymph (in one case there was none). The vascularity of the membranes is remarkable, but the vessels most distended are the veins, and in the larger of these and in the longitudinal sinus there is a firm coagulum."[1] I had met with cases answering to this description many years ago, before uræmia was as well understood as now. The existence of uræmia in such cases would seem now to afford a rational interpretation of the phenomena; yet I have recently met with a case in which repeated careful examinations of the urine gave no evidence of renal disease.

There is a possibility of confounding the coma dependent on meningitis for hysterical coma. Meningitis is to be excluded by the fact of the coma not having been preceded by the diagnostic symptoms of that disease, namely, pain in the head, intolerance of light, suffusion of the eyes, throbbing of the carotids, etc. The thermometer will aid in the exclusion of meningeal or any other acute inflammation. If an acute inflammation exist, the heat of the body is more or less raised; whereas, hysteria, existing alone, does not give rise to any increase of heat. By this, also, meningitis may be excluded in cases of hysterical delirium.

Under the head of hysterical coma may be embraced certain extraordinary cases, in which the mental faculties, the senses, and sensibility are suspended more completely and for a longer period than in ordinary cases. These cases are likely to occasion much embarrassment in the mind of the young practitioner. As an illustration, in the previous editions of this work, I have given with considerable detail, an account of a hospital case, of which a synopsis is as follows: The patient, a man 25 years of age, was admitted in a state of unconsciousness, the previous history not having been ascertained.

[1] Principles of Medicine.

He remained most of the time in an unconscious state for seven days. The eyes were sometimes open and sometimes closed. He appeared to take no notice. The pupils were mobile, and neither contracted nor dilated. Flies creeping over the face and even over the conjunctiva did not disturb him. Drinks introduced into the mouth were retained there for some time, and mostly escaped. The respirations were perfectly normal; the pulse 76, and regular; the skin was natural, and there was neither distension nor tenderness of the abdomen. He lay motionless, not changing his position, and giving no manifestation of suffering.

The treatment consisted of the cold douche, which had no effect, enemata of turpentine and assafœtida, and fluid nourishment by the mouth. The urine was withdrawn with the catheter. On the fourth day there was marked improvement. The eyes were open, and denoted intelligence, but he did not speak nor give heed to questions. He took nutriment freely and with apparent relish. On this day he had a paroxysm of violent weeping.

He relapsed into the former condition on the fifth day. Castor oil was prescribed on this day, no dejection having taken place since his admission. He urinated voluntarily, while preparations were making to introduce the catheter. The bowels were moved freely after four minims of croton oil had been given. He resisted the administration of the oil, as well as of drink and nourishment. The dejections were not passed in bed, but he disposed his body so that they were passed upon the floor. On the seventh day, there being no material change, "firing" was resorted to by means of a hammer heated by boiling water. He bore the heated iron for some time without manifesting pain, but, on continuing the application, he made vigorous resistance, and, at length, protruded the tongue when requested, and took brandy and water freely.

On the eighth day the improvement was marked. He took, however, but little notice, and replied to questions slowly in a feeble whisper. On the eleventh day he was dressed, without any effort on his part, and made to sit up. He remained sitting in one position, the eyes fixed in one direction. He protruded the tongue slowly and partially, when requested, but did not reply to questions. On the twelfth day there was a marked change. He greeted me with a smile, and offered his hand. He walked of his own accord.

He relapsed on the fourteenth day into the former state of unconsciousness, and "firing" was again resorted to. By this measure he was roused sufficiently to take nutriment. He continued in this state until the seventeenth day. On that day he was made to walk about the ward with assistance, and the experiment was tried of leaving him unsupported. After remaining motionless for several minutes, he dropped down, but in a way not to receive any injury.

On the eighteenth day he talked and walked about of his own accord. On the nineteenth day he again relapsed into silence and unwillingness to take food. "Firing" was resumed, and, by means of this measure, he was made to walk into the open air. On the twentieth day he walked about, etc., and talked freely. After this date he progressively improved and was discharged well at the end of three weeks.

Nothing could be ascertained respecting the cause of this attack. The patient stated, after his recovery, that he recollected what had occurred during his illness. I did not discover that the mind was exclusively occupied by any dominant idea, as in ecstasy. Consciousness was not lost, but the exercise of the faculties dependent on the cerebro-spinal system was, in a great measure, suspended. A morbid moral perverseness appeared to be an element in the case, as in most cases of hysteria, but it was certain that the patient was not a malingerer.

The diagnosis of hysterical coma, in this case, was based on the symptoms which have been stated, together with the absence of fever, as well as of the evidence of disease of the kidneys or of any other organ. I have met with a few other cases presenting the same characteristic features, and in two of these instances the patients were of the male sex. In one of the cases catalepsy existed. In each case the termination was in recovery.

Hysterical delirium occurs generally subsequent to, or in alternation with, the paroxysms of convulsions or of coma which have been described; but it also occurs alone. It is preceded and followed by symptoms characteristic of the hysterical condition. The delirium is active, and is manifested, in some cases, by wild, excited talking, the mind passing rapidly from one topic to another. The mind may run on either gay or grave topics, or there may be an incongruous union of both. Patients are sometimes violent. Occasionally they use vulgar and obscene language. In some cases the mind acts under the influence of insane delusions, and these sometimes involve spectral illusions.

Of the pathology of hysteria in the severer forms just described, all that can be said, with our present knowledge, is, it involves a functional morbid condition affecting the nervous system, especially in its relations with the mental faculties. An important element of the affection is disorder and weakness of the will; the affection, however, is by no means purely mental, but proceeds from a pathological state of the cerebral organs with which the perceptive and emotional faculties, together with the will, are connected. The three forms of hysteria which have been described differ considerably as regards the morbid manifestations, but that they are different forms of one affection is shown by their co-existence or occurrence in alternation, by certain symptoms, characteristic of the hysterical condition, which occur alike in connection with each form, and by the fact that what we know of the causation applies equally to the three forms.

Hysteria may occur at any period of life, but in the majority of cases, patients are between fifteen and twenty years of age. I have known it to be well marked in a girl ten years old. It is of rare occurrence either before the evolution of the sexual instinct, or after the period when it may be supposed that venereal desires have ceased; but it sometimes continues into advanced age. The symptoms which characterize the hysterical condition are not very uncommon in males. The name hysteria, therefore, which, in its etymology, signifies the uterus, is a misnomer.

The causation appears to require a peculiarity of constitution. There are some persons who are constitutionally prone to hysteria, and there are many who are incapable of having it. The hysterical diathesis is apt to exist in members of the same family. A great variety of causes may contribute to the development of the affection, among the more frequent being anæmia, overtasking of mind and body, mental anxiety or grief, and the prostration incident to various diseases. The influence of causes pertaining to the sexual system has doubtless been much exaggerated; but the agency of excessive venereal indulgence, or of masturbation, on the one hand, and of continence on the other hand, in certain cases, is not to be doubted. Sudden disappointment, affliction from loss of friends, violent anger, jealousy, and other kinds of strong mental excitement, often act as the exciting causes of an hysterical paroxysm. A desire to excite in the minds of friends or others anxiety or alarm, and to furnish occasions for interest or sympathy, contributes to that abandonment or perversion of the power of the will, which enters into the paroxysms. The hysterical constitution may be developed, and is often fostered, by the absence of wholesome restraint and discipline in the management of youth, and by an unfortunate habit to which women, more than

men, are apt to become addicted, namely, of concentrating unduly the attention on personal sensations and sentiments.

As regards prognosis, hysterical attacks are proverbially devoid of danger. The practitioner, however, is not to lose sight of the fact that hysteria may be associated with affections which are serious. He should not be too ready to set down morbid phenomena to the account of hysteria. It behooves him to be careful not to confound hysteria with other affections.

The treatment of hysteria is to be considered with reference, *first*, to the hysterical condition, and, *second*, to the paroxysms which have been described.

The hysterical condition calls for remedies to soothe the nervous system, but opiates are to be avoided. Valerian, assafœtida, lactucarium, ether, belladonna, hyoscyamus, and the valerianate of ammonia are appropriate remedies. Of these, the first two are the most efficient. The bromide of potassium has, in some cases, a remarkably soothing effect. Alcoholic stimulants should be recommended, if at all, with great reserve, lest the patient take advantage of the sanction of the physician, and resort to them more frequently and freely than prudence warrants. The most important part of the treatment is hygienic. The object is to invigorate both body and mind. With regard to bodily vigor, good diet, abundant exercise in the open air, and regular habits as regards sleep are important. With regard to mental vigor, healthful occupation of mind, and avoidance, as far as possible, of everything calculated to produce undue development of the sentiments and passions, or to excite the imagination, are to be enjoined. The causes which may be suspected, in individual cases, are to be removed as far as practicable. The patient should be encouraged to endeavor to increase the power of the will to resist a tendency to give way to emotional disturbance. For this purpose, the discreditable character of the affection may sometimes be referred to with advantage. The moral management will involve details suited to individual cases, which must be left to the discretion, delicacy, and tact of the practitioner. Cases in which ailments are exaggerated or simulated with a view to excite attention, curiosity, or commiseration, are unhappily not infrequent. As the determination of the patients, in these cases, is not to get well, the varied measures of treatment which are adopted prove, of course, ineffectual. These cases sometimes tax severely the patience and temper of the physician.

In treating cases of hysterical convulsions, it is to be borne in mind that, if left to pursue their course, simply preventing the patient from the self-infliction of wounds or bruises, they would end of their own accord, and it would perhaps be as well for the patient if the paroxysm were allowed to exhaust itself. But the anxiety and alarm of friends generally require a resort to measures to arrest the convulsive movements. The prolonged application of the cold douche to the head is generally successful. The head of the patient is to be held over a tub, and cold water poured upon it continuously until the convulsions cease, and the patient admits being relieved and begs that the measure may be discontinued. Recollecting that consciousness is not usually abolished, and that the convulsions depend upon a delirious volition, the physician should take care to state repeatedly that the douche is to be persisted in until the patient is able to express relief, and is to be repeated if the relief be not permanent. It is unquestionable that the efficiency of this measure depends, considerably if not chiefly, on its moral effect. The physician should also give to the friends, within the hearing of the patient, positive assurances that there is no danger, and that the paroxysm will certainly be arrested. After the convulsions cease, if the patient be much distresed, an opiate may be given, either by the mouth or by the hypodermic method, but if valerian, assafœtida, or ether will suffice, they are to be preferred.

In an ordinary paroxysm of hysterical coma, the douche, as just described, will almost invariably succeed in restoring consciousness. The same course is to be pursued, with respect to moral management, as in paroxysms of hysterical convulsions. The treatment, after consciousness is restored, is the same as in cases of convulsions after these have ceased. In cases of prolonged hysterical coma, "firing," repeated from time to time, is the most effective measure. Nourishment should be given, forcibly if necessary, and as sensibility and consciousness return, the exercise of the will in taking food, sitting up, and performing other voluntary acts, should be enforced.

In hysterical delirium, if mild, the remedies which have been mentioned, valerian, assafœtida, etc., with soothing management, may suffice. If the delirium be violent, the tartrate of antimony carried to the point of nausea, will be likely to tranquillize the patient.

After the paroxysms have ceased, in each of the three forms, the treatment resolves itself into that called for by the hysterical condition.

Hystero-Epilepsy.

Hysteria and epilepsy are distinct affections, but they are not antagonistic to, nor incompatible with, each other. A person may be subject to both, and it may happen that hysterical phenomena may precede or follow an epileptic paroxysm. The term hystero-epilepsy, as used by Charcot and others, however, is applied to cases in which hysteria simulates more or less of the phenomena of epilepsy. In an hystero-epileptic paroxysm, hysteria is the primary and essential malady; but, in addition, there are tonic or clonic convulsions which are automatic; the tongue or cheek may be wounded, and foamy saliva escape from the mouth. There may be an aura which, according to Charcot, often has its source in one of the ovaries. Pressure upon a tender ovary sometimes excites, and methodic compression sometimes averts, a paroxysm. An important point of distinction between a combination of the two affections, and the simulation of epilepsy, is that the latter does not involve a tendency to the recurrence of epileptic, distinct from hysterical, paroxysms. Cases of hystero-epilepsy, as thus defined, must involve the morbid condition of the medulla oblongata and the pons, which gives rise to epilepsy when distinct from hysteria; this condition existing, in these cases, only as incident to the latter affection.

The prognosis is more favorable than in cases of epilepsy existing independently of this etiological connection, and the treatment has relation chiefly to the hysteria.

Catalepsy.

The affection called catalepsy, as this term is now commonly used, is evidently allied to one of the forms of hysteria, namely, hysterical coma. In the cataleptic state, the sensory functions, volition and consciousness, are mostly or entirely suspended. So far, the state is essentially the same as in some cases of hysterical coma; but superadded is a peculiar wax-like rigidity of the voluntary muscles, retaining the limbs and trunk in a fixed position, the different parts of the body preserving the positions in which they may be placed by the hands of another. This superadded feature is characteristic of catalepsy.

The cataleptic state is generally preceded by symptoms of the hysterical condition, but it is sometimes developed suddenly, that is, without premonitions. The patient, while in this state, remains immovable, preserving the position in which the body happened to be at the time of the attack. In

some cases the rigidity of the muscles is such that they offer considerable resistance when efforts are made to alter the position of any part, but in other cases the different parts are easily moved. The trunk or limbs are retained in positions which, in health, would require a strong exertion of the will, and for a longer period than would be possible in health. Thus, the limbs are sometimes kept for a long time extended, or, the patient lying on the back, the lower limbs may be raised and the trunk elevated, so that the body rests only on the sacrum, and this position, which, voluntarily assumed would soon become insupportable, is preserved for a considerable period. This remarkable feature is more or less marked in different cases—in other words, the catalepsy may be complete or incomplete.

As in cases of hysterical coma, the vital functions may be but little, or not at all, disturbed. The circulation may be regular, respiration natural, the temperature normal, and, if food be ingested, the processes involved in nutrition may be well performed.

The affection is paroxysmal, but different cases differ widely as regards the frequency and the duration of the paroxysms. They are sometimes short, lasting but a few moments; not infrequently they continue for several days, and they may extend to weeks and even months. In the majority of cases the duration is three or four hours. A single paroxysm only may occur, and, on the other hand, paroxysms have been known to be repeated daily for a long period. A case is cited by Puel, in which 1200 paroxysms occurred within twenty-eight months.

Catalepsy, in this country, exclusive of cases of so-called Mesmerism or animal magnetism, must be extremely rare. With pretty large opportunities for clinical observation for more than forty years, I have met with but two well-marked cases. The statistical researches of Puel, embracing results of an analysis of 148 cases, show that it is not peculiar to females. Of these 148 cases, 80 were in females and 68 in males.[1] In one of the cases which I have seen the patient was of the male sex. A large majority of cases are between 10 and 30 years of age. The affection, however, may occur under 10 years, and at an advanced period of life. It appears to be induced especially by mental causes. Melancholy, over-taxing of the intellect, and violent excitement of the passions, favor its development, and causes frequently determining an attack are, hatred, jealousy, fright, domestic affliction, reverses of fortune, etc.

The prognosis is always favorable, as regards danger to life. It has, however, been observed to precede the occurrence of insanity, paralysis, and epilepsy.

The principles of treatment are essentially the same as in cases of hysterical coma. The condition of the muscles calls for the use of friction with stimulating liniments. Forcible alimentation may be required if the cataleptic paroxysm be prolonged.

An abnormal state, analogous to that of catalepsy, is among the curious phenomena of hypnotism, formerly known as Mesmerism or animal magnetism. The consideration of these phenomena does not come within the scope of this work.

I shall content myself with a bare allusion to certain abnormal conditions which properly belong to the domain of psychology. One of these is the condition known as *ecstasy*. In this condition, the mind, absorbed in a dominant idea, becomes insensible to surrounding objects. In some cases, during the ecstatic state, the body remains immovably fixed, as in catalepsy. Extraordinary visual hallucinations occur in some cases. The mental condi-

[1] Mém. de l'Acad. de Méd., Paris, 1856, *vide* Valleix *op. cit.*

tion differs from that of catalepsy in this, the mind is active, and thoughts or visions which occur are recollected afterward, whereas in catalepsy the action of the mind is suspended and the period passed in the paroxysm is a blank in the patient's memory. Another name for the ecstatic state is *trance*. As in some cases of catalepsy, the respiration and circulation may become so feeble that, without close examination, life may be supposed to be extinct. If the breathing be not readily ascertained, and the pulse be inappreciable, auscultation with the binaural stethoscope can hardly fail to reveal the heart-sounds in such cases.

Another condition is that called *somnambulism*. This condition is incident to sleep. It embraces the mental and physical performances, sometimes very extraordinary, which are observed in sleep-walkers. Similar phenomena are observed in the condition known as the *Mesmeric or magnetic sleep*.

Tetanus.

The term tetanus is applied to an affection characterized by persisting rigidity of the muscles of the jaw, and frequently of the greater part of the voluntary muscular system, with paroxysms of tonic spasms, the intelligence being preserved. In the great majority of cases, this affection follows a wound or local injury of some kind. It is then distinguished as *traumatic tetanus*, and when not traumatic it is distinguished as *idiopathic tetanus*. Its symptomatic characters are essentially the same whether traumatic or idiopathic. From the large preponderance of traumatic cases, it belongs among the surgical affections, and is treated of at length in comprehensive works on surgery. I shall consider it as an idiopathic affection.

Idiopathic tetanus is everywhere rare, and in cold or temperate climates is one of the rarest of affections. It is less rare in tropical climates. It is one of the affections to which newly-born children are subject, especially in tropical climates, but occasionally everywhere. In adults it seems sometimes attributable to exposure to cold, and, with this apparent causation, it is called by some writers *Tetanus a frigore*. It has been conjectured that the disease is sometimes a manifestation of rheumatism.

In many cases idiopathic tetanus is developed abruptly, without premonitions; but in a certain proportion of cases it is preceded by indefinite ailments, such as chilly sensations, sense of fatigue, etc. The muscles first affected are those of the neck and lower jaw. The affection is sometimes limited to these muscles, and it is then distinguished as *trismus*. The jaws are firmly shut by the rigid contraction of the muscles, and hence the affection is known as *lock-jaw*. The mouth in some cases cannot be opened by any force which it would be prudent to employ; and drink, nourishment, or remedies can only be taken through the spaces between the teeth. The muscles of the face are frequently involved, giving rise to distortions of the features which are sometimes terrific. The angles of the mouth are drawn backward and upward, giving rise to the expression called *risus sardonicus*. The tongue is sometimes severely bitten by being caught between the teeth. The pharyngeal muscles are not infrequently involved, preventing deglutition.

If the affection extend to the muscles of the trunk, the abdomen becomes retracted and rigid, and the respiratory movements of the chest are restrained. The limbs become rigidly extended. The entire body is sometimes immovable and stiff, so that it may be raised by the head or feet, as if it were a statue.

Rigidity of the muscles is persistent. But, at intervals, spasm is added to the persisting contraction. In the paroxysms of spasm or convulsions, the body is frequently bent backward by the predominant force of the posterior

muscles of the trunk; and, in extreme cases, the body forms the arc of a circle, resting on the head and sacrum, and sometimes on the head and heels. This is called *opisthotonos*. A much less frequent form of curvature is produced by the predominant contraction of the muscles on the anterior portion of the trunk. This is called *emprosthotonos*. A lateral curvature, still more rare, is called *pleurosthotonos*. The paroxysms vary in duration, and occur at intervals which vary much in different cases. They are attended with severe pain. The paroxysms are apt to be excited by any mental emotion, and by impressions transmitted from the surface of the body. In this respect, as also in the character of the convulsions, they resemble those which take place in cases of poisoning by strychnia.

As already stated in the enumeration of the characters distinctive of tetanus, the intelligence is preserved; delirium and coma are wanting. In general, the paroxysms are more frequent during the day than during the night. If deglutition be prevented by pharyngeal spasm, the patient suffers from thirst and hunger. Foamy saliva, under these circumstances, collects and escapes from the mouth. The bowels are usually constipated, but, in some cases, involuntary dejections occur. Retention of urine may occur, or, on the other hand, it may be passed involuntarily. The circulation may be but little, or not at all, disturbed, save as an effect of disturbance of the respiration. Respiration is embarrassed in proportion as the respiratory muscles are affected. The embarrassment is usually great during the paroxysms, and fatal apnœa may be induced. The temperature of the body varies much in different cases. In a certain proportion of cases there is moderate or slight fever. In other cases there is notable pyrexia, the thermometer in the axilla sometimes showing a rise to 110° F. The temperature is measurably an effect of the muscular spasms. The temperature is always raised during exacerbations in which the muscular contractions are increased. Profuse sweating occurs in the exacerbations, and more or less perspiration exists in the intervals. Contraction of the pupil to the size of a pin's point during the exacerbations is often observed, the contraction going off in the intervals. A frequent symptom is pain at the pit of the stomach, piercing through to the back.

The disease sometimes destroys life within twenty-four hours. On the other hand, in rare cases, it continues for several weeks; when it is called chronic tetanus.

In a large proportion of cases the affection ends fatally after a duration varying from twenty-four hours to twenty days, the average duration being not far from ten days. The fatality is somewhat less from idiopathic than from traumatic tetanus. The mode of dying may be by apnœa or by asthenia. The danger of apnœa is in proportion to the amount of embarrassment of respiration. Death by asthenia is caused by the exhaustion incident to long continuance of the rigidity and spasms, together with the difficulty, in some cases, of alimentation. It has been noticed, that in some cases rigor mortis succeeds the spasms during life, without any appreciable interval of muscular relaxation.

The distinctive characters of the affection render the diagnosis sufficiently easy. It is to be distinguished from spinal meningitis and from cerebro-spinal meningits, by the absence of local symptoms denoting inflammation, and from the latter of these affections by the absence of cephalalgia, delirium, and coma. Absence of coma distinguishes it from epilepsy. Moreover, the latter is purely paroxysmal, the muscles not being contracted in the intervals. Absence of characters distinctive of hysteria sufficiently distinguish it from that affection. It is, however, to be recollected that trismus, with or without convulsions, is an occasional manifestation of hysteria, and, under these cir-

cumstances, is unattended with danger. The phenomena produced by strychnia in poisonous doses bear the closest resemblance to those of tetanus, and to discriminate between them is of great importance in a medico-legal point of view. Within late years strychnia has been repeatedly employed for homicidal and suicidal purposes. The following differential symptoms are quoted from Todd:—[1]

"*As regards the tetanoid state from strychnine.—a.* The *rapid* supervention of tetanoid convulsions affecting chiefly, and with most intensity, the muscles of the trunk and spine, causing an active and violent opisthotonos rarely met with in tetanus. *b.* A rigid and tetanoid state of the muscles of the lower extremities, with somewhat less intensity than those of the trunk; the limbs extended and the feet drawn powerfully inward by the action of the tibialis postici muscles. The upper extremities affected also, but in a less degree, and the hands generally semiflexed. *c.* The trismus existing only imperfectly, and the *facies tetanica* very slightly or not at all; swallowing perfect, but the mode of deglutition peculiar, the patient snapping at the liquid offered, and gulping it down with an effort, in a manner very similar to that in which hydrophobic patients swallow. *d.* The attacks of opisthotonos very frequent, seemingly exquisitely painful, and ushered in by a cry more or less loud.

"*As regards tetanus.—a.* The symptoms coming on *gradually*, and the trismus the earliest, the most prominent, and most important one. *b.* The *facies tetanica* a very characteristic symptom. *c.* The attacks of opisthotonos less frequent, less extensive, and less severe than in poisoning by strychnine. *d.* The extremities the last parts affected and suffering much less from the tonic spasms than other parts. *e.* Deglutition slow and difficult, and sometimes impossible, owing to the spasmodic closure of the mouth."

To these differential points it is to be added, that a fatal dose of strychnia kills quickly, usually within an hour, whereas, in fatal cases of tetanus life is prolonged generally for two or three days.

Rokitansky, Lockhart Clarke, Dickinson, Michaud, and others have found in examinations after death, morbid appearances of the gray matter of the spinal cord. Others have failed to find any lesions. In the present state of our knowledge, therefore, the disease is to be considered as functional, the changes which may be found after death being secondary or associated by coincidence. With respect to the pathology, the close analogy of the symptomatic phenomena to those produced by strychnia is a strong point in favor of the supposition that the disease involves the presence in the blood of a toxical agent acting upon the spinal cord and the medulla oblongata. The symptoms show an exaggerated reflex excitabily of the medulla and the cord to be a marked pathological feature of the disease.

The treatment of tetanus, by different methods, has proved unsuccessful in a large proportion of cases. Among the measures which have seemed to be sometimes successful are, opium given in large doses, aconite, alcoholic stimulants carried to the extent of producing intoxication, and the inhalation of chloroform. Other remedies advocated as sometimes successful, are belladonna, cannabis Indica, and quinia, in large doses. Bloodletting and counter-irritation over the spine have been largely tried, but are not to be recommended. Ice applied to the spine has been found useful. Cold affusion has been employed with success. The high temperature of the body, in some cases, indicates antipyretic measures of treatment.

In addition to the remedies already named, others more recently employed are the hydrate of chloral, the Calabar bean, curare, and the nitrite of amyl.

[1] Clinical Lectures on the Nervous System.

Cases which have ended favorably under treatment by these remedies have been reported; but clinical facts do not, as yet, warrant positive conclusions respecting the remedial power which they respectively exert over the disease. The great number of remedies which have been advocated as possessing curative efficacy in tetanus, suggests a reflection which has been suggested in other connections. It is, when cases of a disease have ended favorably under a host of remedies, it may be reasonably conjectured that the ending, in these cases, was due more to an intrinsic tendency of the disease than to the remedies used. It remains to be determined in how large a proportion of cases tetanus would end in recovery without any actual medicinal interference.

In the following case, improvement and recovery took place after all treatment had been discontinued: A boy, 7 years of age, the son of a poor washerwoman, came under my observation about a fortnight after the commencement of the disease. He then had, every few minutes, paroxysms of opisthotonic spasms, with rigidity of the limbs, pronation of the thumbs, erection of the penis, and firm closure of the jaws. The paroxysms lasted two or three minutes; they were accompanied by great embarrassment of breathing; they occurred spontaneously, but were brought about whenever the body was moved. During the paroxysms the body could be lifted, like a statue, by raising one leg. The angles of the mouth were depressed, and the features expressed great distress. A certain amount of trismus was constant; the mouth could not be opened sufficiently for the patient to take food freely or to protrude the tongue. The pain was severe during the paroxysms. The mind was clear. He obtained but little sleep. The pulse was not accelerated. The disease could not be referred to any cause.

The case had been treated with morphia, quinia, and the valerianate of zinc. He was kept under the influence of chloroform for several hours. The effect was to relax the muscles of the jaw and to lessen the frequency of the paroxysms. From a misapprehension, this patient had no subsequent treatment. At the end of ten days he was found to have notably improved, and he shortly recovered. After the trial of the chloroform, nothing was done but to give nutritious food. The improvement was very gradual; slight spasms occurring, from time to time, after he had convalesced sufficiently to be up and about.

A highly important part of the treatment relates to the quietude of the patient. The body should be moved as little as possible, and all excitement of the mind should, as far as practicable, be avoided. Light, currents of air, and noise should be excluded. Nutritious alimentation is an important part of the treatment. If deglutition be impossible, food should be introduced by means of a stomach-tube which may be passed through the nostril.

CHAPTER IX.

THE NEUROSES—(Concluded.)

Rabies. Delirium Tremens, Alcoholism. Hypochondriasis, Pathophobia.

THE affections known as *rabies canina*, or *hydrophobia*, and *delirium tremens*, are to be included among the neuroses. The consideration of these, and of hypochondriasis or pathophobia, will conclude the section of this work devoted to diseases affecting the nervous system.

Rabies.

The affection called *rabies canina*, and more commonly known as *hydrophobia*, is due to the action of a special poison, a virus derived from the mouth of some animal of the canine or feline race, namely, the dog, cat, fox, or wolf. The virus is communicated by inoculation, that is, by the bite of an animal affected with the disease. An animal affected with the disease in this way communicates it to other animals, herbivorous as well as carnivorous. The former rarely communicate it, because they rarely bite other animals or man. That it may be communicated by herbivorous to carnivorous animals appears to be proven. The virus is contained exclusively in the fluids of the mouth; there is no proof that other fluids of the body are capable of communicating the disease. It would appear, also, that the virus enters the body only by inoculation; it is not absorbed from the healthy cutaneous or mucous surface. It has been repeatedly communicated from man to inferior animals by inoculation. The disease in man is much oftener derived from the dog than from any other animal; hence the name, *rabies canina*. Owing to the pains taken to confine or to destroy animals suspected of having the disease, it is rarely seen in man. A few cases have come under my observation.

The disease does not make its appearance for some time after the bite. The usual period of incubation is stated to be from thirty to forty days. There is considerable variation in this period in different cases. In one of the cases which I have observed, the patient was bitten seven weeks, and in another case eight weeks, before the disease appeared. There is ground for distrusting the accuracy of statements as regards cases in which the disease is said to follow very quickly after the bite, and, also, when several years have been supposed to elapse. The error in the first of these cases probably consists in confounding the disease with tetanus. The utmost possible duration of the period of incubation cannot be stated, and this is a point in the natural history of the disease of no little consequence with reference to the anxiety of persons after having been bitten by an animal known to be, or suspected of being, rabid. It is probable that the period is very rarely, if ever, under eight or ten days, and that it very rarely exceeds a year.

The development of the disease is gradual. It is stated that certain morbid sensations emanating from the cicatrized wound precede other symptoms; but, if this be true of some, it is certainly not of all cases. There were no such premonitions in the cases which I have observed. The premonitions are, notable depression of spirits, so that this premonitory period has been

called the *stadium melancholicum*, change of disposition, restlessness, mental agitation, vigilance or disturbed sleep, cephalalgia, chilly sensations, loss of appetite, a sense of distress referred to the epigastrium, and sometimes nausea and vomiting. Two or three days elapse before the distinctive characters of the disease are fully declared.

When the disease is developed, the most prominent feature is laryngeal spasm excited by the effort to swallow water. The patient has a dread of water because efforts to swallow it occasion violent paroxysms of suffocation and are generally unsuccessful. The association with these paroxysms gives rise to the fear of water, or hydrophobia. After they have repeatedly been thus produced, the mere sight of water may be sufficient to provoke them; but this is not always the case. In the cases which I observed the patients did not suffer any inconvenience from seeing, or hearing the sound of, water. Patients are sometimes able to swallow other liquids than water; in one of the cases which I have noted, spirit was taken without much inconvenience, and in another case, at times, water was taken from a teaspoon without exciting spasm. Pieces of ice were taken without any inconvenience. The paroxysms excited by attempting to swallow water are extremely violent. The patient, with a nervous determination, drinks precipitantly, and instantly respiration is arrested, the whole frame is agitated, terror and distress are depicted on the countenance, and the water is forcibly ejected from the mouth and nostrils. In some cases, paroxysms of laryngismus occur spontaneously; in one of the cases which I have noted, they were repeated forty or fifty times in an hour, the patient suddenly and quickly raising himself in bed, the spasm lasting a few seconds, and in the intervals the respiration was hurried and panting. In other cases, the patient is free from paroxysms if he do not attempt to swallow liquids. A current of air is apt to excite laryngeal spasm; the patient complains that it takes away his breath. A bright light, the reflection from a mirror or any polished surface, and any mental excitement, have the same effect. The countenance expresses excitement, anxiety, and terror.

An abundant secretion of tenacious mucus from the fauces, together with an increased flow of saliva, leading to frequent and sometimes almost constant expuition, is a distinctive feature. An examination of the throat shows the fauces to be more or less reddened. At first, the mind is simply excited, but, in the course of the disease, delirium becomes developed. The patient talks wildly and incoherently. Sometimes the delirium assumes the form of mania; the mind acts under the influence of hallucinations, and forcible restraint in some cases becomes necessary. There is no foundation for the vulgar notion that patients assume the character of the animal from which the virus was received, and attempt to bite persons around them. In some cases delirium is manifested by excessive tenderness and affection. *Satyriasis* has been observed in males, and *nymphomania* in females.

Convulsions occur in a large proportion of cases. These are sometimes clonic, extending more or less over the voluntary muscular system, and they are sometimes tonic, as in tetanus. The pulse becomes frequent and small. Febrile movement does not belong to the history of the disease; the temperature of the body is increased but little, or not at all. The surface presents capillary congestion and is sometimes covered with clammy perspiration. The vital forces progressively fail; the patient is worn out with continued vigilance, the paroxysms of laryngismus, the convulsions, and innutrition, the mode of dying being by asthenia.

Of all the diseases in the nosology, there is no one in which the intrinsic tendency to death is greater than in this. The disease runs a brief career, death usually taking place on the second or third day, and always within five

days after it has become fully developed. The disease has no anatomical characters which can be considered as primary. Congestion of the meninges of the brain and cord, and small hemorrhages in the medulla oblongata and elsewhere in the central nervous system, are probably secondary alterations.

The diagnostic features of rabies are highly distinctive. It is distinguished from tetanus by the absence of trismus, and the occurrence of delirium. In some cases of tetanus, the deglutition of liquids is impossible; but the difficulty arises from spasm of the pharyngeal, not involving the laryngeal, muscles, the latter being affected in rabies. Moreover, convulsions occur at a late period in rabies, and the convulsions are tetanoid only in a certain proportion of cases. The only difficulty of diagnosis relates to the discrimination of cases of true rabies from those in which, to a greater or less extent, hydrophobic phenomena are simulated. Notable repugnance to liquids, susceptibility to currents of air and to light reflected from a mirror or some polished surface, frequent sputation, together with delirium and convulsions, are occasionally incident to various acute diseases. But the hydrophobic phenomena are especially simulated under intense apprehension of rabies after a bite has been inflicted by an animal suspected of being rabid. Excessive fear leads to the belief, in the mind of the patient, that the disease exists, and this belief leads to the production of certain of the phenomena, especially horror of liquids, delirium, and sometimes a fancied disposition to bite others. Among the points to be considered in this discrimination is the time which has elapsed after the bite. If the morbid phenomena occur immediately or quickly afterward, or, on the other hand, after a very long period, the reality of the disease is very doubtful. If it be evident that the horror of liquids is purely mental, or dependent entirely on spasm of the pharynx, as in some cases of hysteria; in other words, if laryngeal spasm be excluded, the affection is not true rabies. The continuance of the hydrophobic phenomena is another point. If they continue for many days or weeks, the affection is not true rabies, for the latter affection ends fatally within five days. The opinion, which some have entertained, that rabies may be developed in man spontaneously, probably has no foundation other than the cases in which hydrophobic phenomena have been incidental to other diseases. The disease, however, is spontaneously developed in the dog and other animals.

Of the great number and variety of remedies which have been tried for the cure of rabies, one only at the present time claims consideration. This remedy is curare. A few cases have been reported of the successful employment of this remedy administered by subcutaneous injection. There is room for doubt, in these cases, concerning the diagnosis, and, hence, other cases must be observed before it can be asserted positively that the remedy has proved in any instance successful. One of the cases reported as cured by this remedy came under my observation. The patient had been bitten by a dog undoubtedly rabid. A servant in the family was bitten by the same dog, and died with rabies. Many of the symptoms in the case which ended in recovery pointed to rabies, but hydrophobia was wanting.[1] In a case reported by Dr. Offenberg, of Wickrath (Rhein-preussen), all the diagnostic symptoms, inclusive of hydrophobia, were apparently well marked. The patient, a maid servant, had been bitten by a dog evidently rabid, and a member of the family in which she lived, having been bitten by the same dog, died with rabies. The curare was given in successive doses, as follows: two doses of 0.02 gramme (gr. $\frac{1}{3}$) after an interval of fifteen minutes; an hour after the last dose, 0.03 gramme (gr. $\frac{6}{13}$), the latter repeated twice after an hour's

[1] *Vide* report of this case, by Dr. B. A. Watson, in Am. Journ. of Med. Sciences, July, 1876.

interval, once after an interval of two hours and thirty minutes, and again after two hours and twenty minutes. Temporary general paresis was produced by the remedy.[1] This drug is of uncertain strength, and it must therefore be used with caution.

There is no prophylactic treatment to be relied upon, save excision or effectual cauterization of the wound as quickly as possible after it has been inflicted. Amputation of fingers or toes, and even of larger members, is advisable, if the extent or character of the wound be such that the excision and cauterization cannot be effectually employed.

It is desirable, of course, to know whether an animal which has inflicted a wound be really rabid. Dogs and cats are often supposed to be rabid when they are affected with epilepsy or some disease other than rabies. It is a popular error that dogs are especially apt to become rabid during the so-called dog-days, that is, the hot months of summer. Cases are quite as likely to occur at other periods of the year. When rabies is suspected, the animal should be confined and not killed until the character of the disease is fully declared. Rabies in the dog is to be suspected when the animal manifests a notable change of habits, becoming shy and irritable, eating straw, bits of paper, etc., and refusing food. When the disease becomes developed, the appearance is much changed; the look is depressed and haggard, the ears and tail droop, the quality of the bark is altered, the eyes are watery, the fauces are reddened, saliva flows from the mouth, and there is febrile movement. Dread of water is no test of the malady in the dog and other animals. They frequently lap water without difficulty. Delirium supervenes, and then the dog snaps at his master as well as others, and at any animal which comes in his way. He seldom becomes ferocious, but bites and runs away. He appears sometimes to have hallucinations, and snaps at invisible objects. Convulsions may or may not occur. Death takes place usually within five days.

Persons bitten by an animal known to be rabid are by no means invariably affected with rabies, even if no preventive measures be resorted to. The chances of escape are a little more than three to one. The exemption may proceed from an insusceptibility to the poisonous action of the virus, but probably often, in those who escape, the inoculation does not take place. Of 100 inoculations made by Herting, only 23 were successful. If the bite be inflicted through clothing, the virus will be likely to be wiped away from the teeth before they penetrate the skin. The inoculation is more likely to take place from the bite of the wolf than from that of the dog. Of 250 cases, collected by Renault, of persons bitten by the wolf, 164, about two-thirds, became affected by rabies.[2]

Delirium Tremens. Alcoholism.

This affection proceeds from the abuse of alcohol. The various pathological effects of alcohol are considered as incident to a toxical condition, called *alcoholismus* or *alcoholism*. These effects enter directly into the causation of many affections, such as cirrhosis of the liver, fatty liver, epilepsy, muscular tremor, gastritis, pyrosis, and various dyspeptic disorders. Indirectly, alcoholism favors the production of nearly all diseases by lessening the power of resisting their causes; and it contributes to their fatality by impairing the ability to tolerate and overcome them. Taken

[1] For a translation of the history of this case, by Dr. S. W. Williams, with full details, *vide* New York Med. Record, Aug. 9, 1879.

[2] Jaccoud, *op. cit.*

in sufficiently large quantity, alcohol produces certain immediate effects which belong to the state commonly known as intoxication or drunkenness. The opportunities of observing these effects are, unhappily, but too common. The coma which exists when a person is profoundly intoxicated, or, in common parlance, dead drunk, is liable to be mistaken for apoplexy. The differential points have been presented in treating of the latter. Intoxication falling short of coma sometimes comes under the cognizance of the physician under circumstances in which the nature of the difficulty is not suspected by friends, as in women and children. Knowledge of the characteristic phenomena is then brought into exercise. The physician, in these cases, is sometimes bound by delicacy and prudential considerations to withhold an enunciation of the diagnosis.

The habitual use of alcohol, beyond certain limits, produces a deleterious influence on the whole economy. In cases of chronic alcoholism, the digestive powers are weakened, the appetite is impaired, the muscular system is enfeebled, the generative function decays. The blood is impoverished, nutrition is imperfect and disordered, as shown by flabbiness of the skin and muscles, emaciation, or an abnormal accumulation of fat. Pain in the limbs and back is a symptom of frequent occurrence. The breath and emanations from the skin have a characteristic odor. The deleterious influence on the mental, is not less marked than on the physical, powers. The perceptions are blunted, the intellectual and moral faculties progressively deteriorate, until, at length, the confirmed inebriate, miserably cachectic in body and imbruted in mind, has but one object in life, namely, to gratify the morbid craving for alcohol. He exemplifies a variety of the form of mental derangement called dipsomania, from which recovery is extremely rare.

Delirium tremens, called, also, *mania à potu*, is an affection incidental to alcoholism. It has been a mooted question whether the affection ordinarily known by these names, is due to the sudden withdrawal of an habitual amount of alcoholic stimulation, or whether it is a direct consequence of the long-continued action of alcohol on the brain. Both explanations are correct. In a large proportion of cases, its development is evidently owing to the use of alcohol being suspended or much diminished. Thus, it occurs in persons who voluntarily undertake to abandon intemperate habits, or who are unable to obtain liquor, or who are prevented from drinking by the occurrence of some disease or accident. It is notoriously common among inebriates who are thrown into prison, and among those admitted into hospitals. It is apt to follow paroxysms of intemperance, in periodical drinkers, when the stomach refuses further alcoholic libations. On the other hand, it is sometimes developed notwithstanding the continued use of the habitual amount of alcohol.

The symptoms attending the access are anorexia, insomnia, muscular tremor, more especially tremulousness of the tongue, and notable dejection. This state is known among drunkards as "the horrors." The mental depression is so great as not infrequently to lead to suicide. There is no pain in the head nor febrile movement; the pulse is generally feeble, and the surface cool. This stage continues for one, two, or three days.

The development of the disease is characterized by mental aberration of a peculiar character. The derangement is characteristic, although presenting considerable diversity in different cases. The expression becomes wild, the eyes either vacant or staring. The movements are quick. The patient is constantly in motion. He talks incoherently. His mind wanders from one subject to another. He fancies that he has important business to attend to, wishes to go out, and requires to be constantly watched. To these manifestations of mental disorder are added illusions of the senses, phantasms and

hallucinations of various kinds. He sees imaginary objects, such as mice, dogs, cats, lice, snakes, and ferocious animals. He hears noises of animals or men, answers imaginary questions, and is apt to fancy the proximity of persons who are bent on insulting or ridiculing him, or from whom he apprehends personal violence. Uncouth and unnatural representations appear to him to be going on. At first, he may be able to appreciate the unreality of what he sees, hears, and imagines; but, after a time, his morbid perceptions become delusions, and, however extraordinary and absurd, they are real to the sufferer. They are sometimes of a character to inspire the greatest possible terror. Thus, patients not infrequently leap from windows and are dashed in pieces, believing that they are pursued by wild beasts or by men who seek their lives. A patient who escaped in his night-clothes, under a sense of personal danger, ran barefooted over frozen ground for fifteen miles before he was overtaken by men on horses who followed in pursuit. The degree of terror must be fearful to lead to such an amount of physical effort and endurance. In some cases the delusions are ludicrous. Thus, a patient declared that he should be able to sleep, but whenever he fell into a doze there were persons under his bed who tickled his fundament with straws. Under the apprehensions which the delusions excite, patients are sometimes violent and dangerous, and they are usually controlled without much difficulty.

The insomnia continues. The patient gets no sleep for two, three, or four days, and sometimes for a still longer period after the development of the affection. The delirium is always much worse during the night. Tremulousness of the muscles continues, but this is not always a marked symptom, although it enters into the name. Vigilance being a more constant symptom, it has been proposed to call the affection *delirium vigilans*, instead of *delirium tremens*. Anorexia continues, the bowels are usually constipated, the skin is cool, the pulse is feeble and, except under mental excitement, may be but little, or not at all, accelerated; the patient makes no complaint of pain in the head or elsewhere, and generally declares that he is well.

If the affection end favorably, sleep at length occurs. If the patient once become soundly asleep, he will be likely to remain so for many hours, or, if he awake, the speedy return of sleep may be counted upon. After a protracted sleep, generally the delirium is found to have disappeared; occasionally it continues, but is diminished, and disappears after renewal of sleep. Sleep appears to be, not merely a criterion, but a means of convalescence. After sleeping much of the time for one or two days, convalescence is established, and the patient recovers more or less slowly or rapidly according to the duration of the affection and his physical condition at the time of the attack. If the affection pursue an unfavorable course, the insomnia persists and notable prostration ensues. The condition is not unlike that in an advanced stage of typhus; the delirium continues, with efforts to get out of bed; subsultus tendinum occurs; the pulse becomes more and more frequent and feeble; the skin is sometimes bathed in perspiration, and death takes place by asthenia, although the fatal termination is usually preceded by coma.

The prognosis is generally favorable. When not associated with other affections, a fatal termination is rare. The affection destroys life *per se*, chiefly in cases in which repeated attacks have occurred, and the constitution is broken by a long-existing alcoholic cachexia. Occurring after wounds, surgical operations, or accidents, and associated with other affections, as, for example, with pneumonitis, it adds much to the gravity of the prognosis.

The symptomatic phenomena show the affection to be cerebral, but the nature of the morbid condition, as in the other neuroses, is unknown. It is important to bear in mind that inflammation is not involved, nor is there ground to believe that congestion is an essential element. There is usually

some increase of the cerebro-spinal fluid, and the ventricles of the brain may contain an abnormal quantity of serum. The substance of the brain may be œdematous. This condition is sometimes called the wet brain of drunkards. All that can be said of the pathological character with our present knowledge is, that the prolonged toxical action of alcohol on the brain induces a peculiar morbid condition giving rise to those manifestations of disorder which are characteristic of this affection, especially when the use of alcohol is from any cause suspended. There is reason to believe that the morbid phenomena relating to the mind, as well as the progressive impairment of the vital forces, are to a considerable extent due to the insomnia. This is to be inferred from the fact that the delirium generally ceases after sleep has continued for several hours. Inability to sleep is an essential feature of the affection, and the chief obstacle in the way of a favorable termination.

In general, the diagnosis is not attended with difficulty. The characteristics of the delirium render the affection easily recognizable when fully developed; moreover, the known habits of patients generally lead the practitioner to expect it. Tremulousness of the tongue and limbs, with vigilance, if the patient be a drunkard, denote an impending attack. If now the patient complain of having remarkable visions or manifest illusions of the senses, the development is progressing. The cases in which the practitioner hesitates in coming to a diagnosis are those in which the habits are unknown. The affection may be developed in secret drinkers, and in persons who are supposed to be perfectly temperate. I have known a person to be attacked who was supposed by his friends never to taste any alcoholic beverage. As the diagnosis implies intemperance, caution in forming an opinion in some cases is advisable, and prudence in expressing the opinion when formed. Of course, it is a breach of medical ethics to reveal the character of the affection save to the patient, and, under certain circumstances, to his friends.

Excesses in drinking sometimes occasion a form of delirium, differing, pathologically, from delirium tremens, but apt to be confounded with it. The delirium now referred to is an active delirium, characterized sometimes by violence or fury, and sometimes by hilarity. It is a form of acute mania due to active cerebral congestion, conjoined with the immediate effect of alcohol on the brain. It is occasioned by a protracted paroxysm of drinking rather than by the habitual use of alcohol. This form of delirium has been distinguished as *delirium ebriosum*. It is accompanied by pain in the head, increased heat, throbbing of the carotids, febrile movement; in short, by the symptoms of active cerebral congestion. It is of brief duration, ceasing when alcoholic stimulants are discontinued; it thus ceases under the circumstances which are apt to occasion delirium tremens. It may be followed by delirium tremens. Aside from the discontinuance of stimulants, it claims the treatment indicated by active congestion of the brain, namely, bloodletting, purgatives, etc., measures not suited to the treatment of delirium tremens.

Finally, with respect to the diagnosis of delirium tremens, meningitis is excluded by the absence of cephalalgia, intolerance of light and sounds, throbbing of the carotids, febrile movement, etc. Acute gastritis, which may present some of the phenomena of impending delirium tremens, is to be excluded by the absence of vomiting, gastric pain, tenderness over the stomach, etc. Gastritis, however, is often present in delirium tremens. Typhoid and typhus fever are excluded by the absence of the diagnostic symptoms, other than delirium, of these diseases.

Delirium tremens was formerly treated by bloodletting and other of the so-called antiphlogistic measures, under the belief that it involved either inflammation or cerebral congestion. These measures are now abandoned as

not only uncalled for, but injurious. Within late years, various curative methods of treatment have been advocated on the grounds of success; and, in endeavoring to judge of their respective merits, it is to be borne in mind that, under favorable circumstances, the intrinsic tendency of this affection is to recovery. It may be said of this affection, as of others tending in like manner to recovery, that a large proportion of recoveries cannot be cited in evidence of the curative efficacy of any particular method of treatment, but that a large proportion of fatal cases favors the presumption that the treatment was injurious. Excluding cases in which the affection occurs in connection with wounds, surgical operations, and accidents, or with other affections, and the cases in which it occurs in persons whose constitutions are shattered by intemperance, judicious management without therapeutical measures would, in the great majority of cases, prove successful. It does not follow, from this statement, that remedial measures are not often useful.

The great object of treatment is to procure sleep. Opium has been employed largely for this object. The statistical researches of John Ware showed that the fatality was greater under the opiate plan of treatment than when an expectant or eclectic plan was adopted, and that the fatality is proportionate to the excessive use of opium. Opium used indiscriminately and largely is undoubtedly injurious, but that its moderate employment is useful in certain cases, is not to be doubted. The use of opium as advised by Stillé may be safely adopted. This author says: "The best mode of exhibiting the medicine (opium) is undoubtedly to begin with a quarter of a grain, or its equivalent, and progressively to augment the dose by small and hourly additions until sleep is produced, or a sufficient degree of tranquillity obtained." I have not infrequently found a full dose, repeated, if required, after intervals of several hours, to act very favorably. The remedy should never be pushed to the extent of inducing narcotism, and if, on a fair trial, it be not found to tranquillize, it should be discontinued.

Cases have been treated satisfactorily by simply continuing the use of alcoholic stimulants in moderate quantity. In general, it is injudicious to discontinue entirely the use of stimulants so long as the affection continues. The time for breaking off the habitual use is after sleep has taken place and the patient is convalescent. Stimulants are to be given freely in cases in which the symptoms denote failure of the vital powers.

Tartar emetic, in nauseating doses, is useful in certain cases. This remedy, if not pushed too far, exerts a sedative influence, diminishes delirium, and disposes to sleep. It is suited to cases in which there is considerable constitutional vigor, and it should be very cautiously given to patients much enfeebled, or in cases in which there is a tendency to prostration. Emetics have been advocated as curative, but the evidence of this is unsatisfactory, and they are now very rarely employed. They are objectionable on the score of perturbation. Cathartics are objectionable on the same score. These evacuant remedies have been employed under the idea that they eliminate the alcohol from the system. But the affection is due to the toxical effects of alcohol, not to its actual presence in the system; indeed, the attack often appears to proceed from a diminution of the amount of alcohol habitually present.

Cold affusions, the cold douche to the head, and the shower-bath are useful in some cases. They are of doubtful expediency if employed against the will of the patient; he should be induced to concur in the propriety of making trial of them. They may do harm to feeble subjects, or if the powers of life be much depressed.

Digitalis has been advocated as a curative remedy. It was introduced by Dr. G. M. Jones, of Jersey, England, who was led to ascertain its efficacy

by a patient affected with delirium tremens having taken an ounce of the tincture by mistake. Subsequently he employed it in seventy cases with the loss of only one case. No practitioner would have ventured to give this remedy in the doses which experience has abundantly shown may be given without any unpleasant consequences in this disease. The dose advised by Dr. Jones is half an ounce of the tincture, which may be repeated, if required, after an interval of four hours. Many cases in which this plan of treatment has apparently proved efficacious have been reported. I have tried it in a few cases, in one of which it appeared to act like a charm, but in the others no curative effect was apparent.

The inhalation of chloroform, in some cases, tranquillizes the patient and induces sleep. This is a remedy to be employed with great circumspection. Its effect has been happy in several instances under my observation. In one case the effort to employ it excited such a degree of mania that I was led to desist. The hydrate of chloral may be employed. The use of this remedy calls for circumspection. The bromide of potassium, given in large doses, is a valuable remedy in this disease. This remedy is chiefly relied upon in a large majority of the great number of cases treated at Bellevue Hospital. Hyoscyamin has lately been employed with much success as an hypnotic in this disease.

As regards the measures which have been referred to, and others, they are to be employed according to circumstances proper to individual cases. Each of the measures is suited to some cases and not to other cases. They are to be employed tentatively, the practitioner being guided by the effect in deciding whether to continue or discontinue them. Not infrequently they may be tried successively in the same case. In short, the appropriate treatment, as regards these measures, is expectant and eclectic, and they will be employed judiciously or otherwise according to the judgment of the practitioner.

The management in other respects is important. Quietude is to be enforced. Visitors, who are often actuated by curiosity, are to be excluded. The circumstances surrounding the patient should, as far as possible, be regulated with a view of promoting sleep. Much may be done by the exercise of tact in soothing the patient, combing the hair, bathing the face, resorting to warm pediluvia, etc. I have known muscular exercise, carried to the point of fatigue, useful. Alimentation is highly important. The patient should be encouraged, as much as possible, to take nutritious and easily digested food.

It is the duty of the physician, after recovery from this disease, to inform the patient of its character, and to point out the inevitable consequences of the habits which have induced it. And the patient will be aided in an effort to emancipate himself from the slavery of intemperance, by remedies and hygienic measures which tend to invigorate the body, thereby strengthening the mental powers.

A craving for alcoholic excitation is a result of habit. It is sometimes induced by dyspeptic disorders, mental depression, or a sense of prostration incident to various diseases, and it is sometimes a constitutional idiosyncrasy. The power to resist it is impaired in proportion as the faculties of the mind are weakened by indulgence. It can only be overcome by sufficiently long-continued total abstinence, together with measures to remove disorders, and to promote mental occupation and invigoration of body and mind. There is no drug which has a special curative efficacy. Persuasion, the fear of consequences, and moral considerations are often unavailing. The unhappy slaves of intemperance should be considered as suffering from disease, and should be treated as patients until the morbid craving is extinguished by prolonged

abstinence. In many instances effective treatment is only practicable in institutions established for this purpose.

The "opium habit" is to be regarded in the same light. Generally, instant and complete withdrawal of every form of opiate is perfectly safe and the preferable course. Under judicious medical treatment and encouragement, patients will be more likely to endure the intense suffering from the sudden disuse of opium, than to persevere in a gradual diminution of doses during a period of weeks or months.

Hypochondriasis. Pathophobia.

Although hypochondriasis belongs in the list of disorders of the mind, the mental aberration is not regarded as amounting to insanity, and patients with this affection are not proper subjects for treatment at lunatic asylums. Cases are not infrequent, and they claim the services of the general practitioner. In view of these facts, it is appropriate to consider the affection as one of the neuroses. The name hypochondriasis, which from its derivation is supposed to have reference to morbid sensations sometimes felt in the hypochondriac regions, has very little significance as indicating the character and seat of the affection. The name pathophobia is much more expressive of the malady.

The characteristic feature of the affection is a morbid apprehension of either the existence of, or a liability to, some serious disease. In its mildest form it consists of a feeling of extreme delicacy of constitution, or of a peculiar susceptibility to the causes of disease. Existing in this form, it leads to an anxiety concerning health, and over-precautions for its preservation. In the severest form of the affection, patients suffer from the conviction that they have an incurable malady, and that life is in imminent danger. Different cases represent gradations between these extremes. The mental depression or despair which may be produced by a knowledge of the fact that a serious or fatal disease actually exists, does not constitute hypochondriasis. The hypochondriac is the victim of a delusion with respect to his condition; and the mental suffering arising from this error of belief often exceeds that which would be likely to be experienced if the fancied diseases really existed. Generally the hypochondriacal delusion is accompanied by more or less mental depression, and often by marked melancholia; but in some cases, patients are resigned and cheerful. Fancied diseases are sometimes the occasion of profound religious sentiment, calling forth the manifestations of pious resignation.

The affection is presented to the practitioner in different phases. In some cases the imagination becomes fixed upon a particular disease, and the patient's belief in the existence of the disease defies all efforts to remove it. Disease of the heart, pulmonary consumption, cancer, syphilis, tapeworm, softening of the brain, and diabetes are among the diseases which, in different cases, are supposed to exist. The physician may strive in vain by assurances and arguments to dispossess the mind of his patient of the delusion. In support of his conviction the patient sometimes not only exaggerates ailments which are present, but insists on the presence of symptoms which are wanting. The pertinacity and ingenuity with which, in some cases, patients hold to their faith and strive to convince the physician of its truth, is remarkable. Not infrequently the conflict between the physician and patient continues until it becomes intolerable, and each is well pleased to break off the professional relation. Hypochondriacs are apt to consult many physicians in suc-

cession, finding, for a time, greater attention and apparent interest in a new medical adviser; naturally enough, in their mental condition, they become dissatisfied when the patience of the physician becomes exhausted, and they have given up all expectation of converting him to their belief. The absurdity of the delusion in some instances is truly surprising. I have known two cases in which the patients, women of intelligence and good sense, for a long time could not be persuaded that they were not affected with cancer of the breast, although nothing was to be seen or felt to give color to the delusion. It is a noteworthy fact that hypochondriasis is not confined to the weak-minded. Persons of education and strong mental powers are as liable to the affection as those who are ignorant and of feeble intellectual capacity.

In another phase of the affection there is not a fixed belief in the existence of a particular disease, but a shifting of the delusion from one disease to another. The physician may succeed in convincing the patient of the non-existence of an imagined disease, but no sooner is this done than the patient's imagination runs upon another disease, and so divers diseases are in turn imagined, until, at length, the physician is discouraged and is apt to give up the contest. Again, patients sometimes keep the house and take to the bed, complaining of ill health, prostration, and various morbid sensations, without selecting any particular disease. With cases of bedridden patients who have no definite malady, but a host of subjective symptoms, all practitioners of much experience are familiar. Such cases occur much oftener among women than among men, and the phenomena embraced under the name hysteria are generally more or less involved.

The causes of hypochondriasis are physical and mental. Some persons are constitutionally prone to morbid apprehensions in this direction. Whenever they are ill with any affection, their mental constitution leads to a sense of danger and to despondency as regards recovery. Not infrequently this state of mind exerts a depressing influence which may interfere seriously with the favorable progress of disease. Persons thus unhappily constituted are apt to exaggerate the permanent consequences of dissipated habits in early life, and more especially of abuses of the sexual function. Delusions with respect to the latter are fostered by publications and lectures designed by unprincipled persons to produce this effect. Apprehensions on this score, often with little or no foundation, are a source of nefarious profit to a host of charlatans. If a person with a hypochondriacal predisposition either have had or imagines that he may have had syphilis, he is liable to fall into the belief of supposing that his system is irretrievably ruined. This delusion also is encouraged by empirics whose business is to prey upon the fears which they foster and excite. There is a class of wretched hypochondriacs whose minds are absorbed with the idea that they are the hopeless victims of the thoughtless errors of youth, and patients of this class, much as they are to be pitied, often tax severely the temper of the physician. It is to be added that the practice of masturbation, excessive sexual indulgence, and the intemperate use of alcoholic stimulants, are undoubtedly sometimes involved in the causation, not merely by an effect upon the imagination, but by aiding to produce a morbid condition of the nervous system.

The reading of legitimate medical works is to be mentioned among the causes of hypochondriasis. Want of mental occupation contributes indirectly to the affection. Persons who have relinquished active pursuits are apt to become hypochondriacs. Success in the acquisition of wealth, when it leads to a determination to forego labor and to enjoy leisure, may thus engender a far greater evil than poverty. On the other hand, the loss of fortune, or

want of success in the pursuits of life, and severe affliction of any kind, are sometimes concerned in the causation of this affection. These various causes may produce the affection in those who are not, as well as in those who are, constitutionally predisposed to it; but, of course, their efficiency will be marked in proportion as the predisposition is strong.

The morbid physical conditions often existing in cases of hypochondriasis, and more or less concerned in its causation, are various. Among these may be mentioned anæmia, neurasthenia, and dyspeptic disorders. The latter, there is reason to believe, are frequently, to a considerable extent, effects of the morbid condition of the mind.

The diagnosis of hypochondriasis must rest on an exclusion of the maladies which are apprehended or imagined, and of any serious disease. The different organs of the body are to be interrogated by means of symptoms and signs; and it is obvious that the accuracy of the diagnosis will depend on the ability of the physician to exclude the affections to which the different organs are subject. Subjective symptoms are to be admitted with circumspection, and a certain amount of distrust. The incongruity of the previous history and the present condition, as described by the patient, with the laws of any definite disease, exclusive of mental disorder, is often at once significant of the affection under consideration; or the subjective symptoms are incongruous with the physical disorders which may be associated with the hypochondriasis. From want of sufficient knowledge or skill to reach the diagnosis by exclusion, practitioners are sometimes misled by the statements of patients, and thus contribute unwittingly to establish more firmly existing delusions.

In a certain proportion of the cases in which some serious disease is either apprehended or imagined, the positive assurances of the physician suffice to dispel the delusion. In this way the physician who is confident in his ability to interrogate accurately the different organs of the body has the power of doing much good. The fear of the existence of some grave disease oppresses especially those who are dependent for the means of living upon a certain measure of health; and a decided opinion, in which they have confidence, is a great blessing to patients of this class.

In cases of confirmed hypochondriasis, the first object with reference to management is the removal of any supposed causes. Over-exertion, mental or physical, if possible, is to be avoided; sexual abuses, intemperance, and any violation to the laws of health, are to be inquired into and reformed. Aside from the causal indications, the measures of treatment relate to both body and mind. Any co-existing physical disorders are to be remedied as far as practicable. Anæmia and dyspeptic ailments often claim remedial measures. In addition to the physical operation of remedies, they undoubtedly have a useful moral effect within certain limits. Patients are apt to crave remedies, and it is important not to encourage this disposition; but it is often not judicious to withhold remedies altogether, even when the medicinal part of the treatment is comparatively unimportant. Alcoholic stimulants and opiates should not be prescribed, or, if indicated for a temporary object, they should be given with great circumspection.

The most important part of the treatment is that which relates to the mind. Arguments, assurances, and combined medical opinions may be brought to bear upon the delusions with more or less effect. It is, however, not always judicious to act upon a determination that the patient shall be at once reasoned out of the affection. It is not wise to attempt to dispel the delusions by ridicule or indifference. A fundamental part of the moral management is to direct the patient's attention from himself. This is to be effected by inducing occupation, if the patient has been living a life of indolence, and by well selected recreations, if the patient be of industrious habits. It is more

difficult to effect this in cases of hypochondriasis among women than among men. Change of scene and new associations are often effectual, and, wherever practicable, should be advised. With respect to the particular plans to be pursued in different cases, the habits, intelligence, education, and social position are to be considered in each case, and the success of the treatment will depend much on the judgment and tact of the physician.

SECTION SIXTH.

DISEASES AFFECTING THE GENITO-URINARY SYSTEM.

CHAPTER I.

HYPERÆMIA AND ANÆMIA OF THE KIDNEYS. ACUTE AND CHRONIC BRIGHT'S DISEASE.

Active Congestion of the Kidneys. Passive Congestion of the Kidneys. Anæmia of the Kidneys. Parenchymatous Degeneration of the Kidneys. Fatty Degeneration of the Kidneys. Acute Bright's Disease. Chronic Bright's Disease.

A LARGE proportion of the affections of the genito-urinary system do not fall within the scope of this work. Excluding the affections peculiar to females, diseases of the male generative organs and of the bladder are to be excluded as belonging to surgical, rather than to medical, practice. The diseases which remain are chiefly those affecting the kidneys. Abnormal changes in the urine are highly important as denoting morbid conditions relating to the kidneys and the blood. These changes constitute important symptoms in various diseases; they are not to be considered as individual affections, and in general it suffices to notice them in connection with other symptomatic events which make up the clinical history of different diseases. In an important disease which, in the present state of our knowledge, it is convenient to regard as a urinary affection, it is certain that the abnormal change in the urine expressed by the name of the disease is merely a symptom. The disease referred to is *glycosuria* or *diabetes mellitus*. This disease will be included among the diseases to be considered in this section. The same statement may, probably, be applied to the disease distinguished as *diabetes insipidus;* also to *endemic hæmaturia* and *hæmoglobinuria.*

Active Congestion of the Kidneys.

Active congestion of the kidneys may be due: *first*, to the action of irritants; *second*, to vaso-motor paralysis. These two forms of active congestion are widely different from each other. The former, when of sufficient intensity to give clinical evidence of its existence, is almost invariably accompanied by inflammatory or degenerative changes in the kidneys; the latter has no tendency to lead to inflammation: the former is accompanied by the excretion of urine similar to that of certain forms of acute nephritis, the urine being albuminous, bloody, and usually diminished in quantity; in the latter, the urine is abundant in quantity, non-albuminous, and of low specific gravity.

In the inflammatory variety of active congestion the kidneys are enlarged, of a dark red color, engorged with blood, and ecchymosed. Certain drugs which exert an irritant effect upon the kidneys are usually assigned as the most important causes of this form of active congestion. Such drugs are cantharides, turpentine, oil of mustard, cubebs, copaiba, nitrate of potash,

carbolic acid. Of these drugs, cantharides, taken either internally or applied externally in the form of a blister, provokes the most marked urinary symptoms. In cantharides-poisoning the urine is diminished in quantity and may be suppressed; it is usually, but not always, stained with blood; it is albuminous, and may contain hyaline and blood-casts, as well as epithelial cells. A peculiarity noted in some cases has been the spontaneous coagulation of the urine. Gelatinous fibrinous clots, either pale or red, may form in the bladder and interfere with micturition; or similar coagula may form in the vessel after the urine is voided. It has been shown by the experiments of Browicz,[1] and also by Cornil,[2] that a true diffuse nephritis is produced by cantharides. It is probable that an inflammatory condition likewise exists when similar symptoms follow the ingestion of the other drugs named. The treatment consists in removal of the cause, rest, and the administration of diluent and of mucilaginous drinks. Camphor in doses of two to five grains will often afford relief.

The existence of vaso-motor nerves of the renal arteries has been demonstrated by physiological experiment. These nerves are contained in the splanchnics. Paralysis of these nerves causes dilatation of the arteries in the kidneys and consequent afflux of a larger amount of blood to these organs. Some also assume the existence of vaso-dilator nerves of the kidneys. It is fully in harmony with the results of physiological experiment that this increased flow of blood through the kidneys is attended by the excretion of a large quantity of pale urine. We may assume that renal hyperæmia due to vaso-motor influence may be produced in man by causes acting upon the peripheral nerves as well as by those acting on the nerve-centres. We possess little positive knowledge as to this variety of renal hyperæmia in man. It has been inferred to exist, from the characters of the urine, in certain diseases of the brain. Hyperæmia of the kidneys from vaso-motor influence is assumed to exist in many cases of diabetes insipidus, of hysteria, and of emotional disturbance.

Passive Congestion of the Kidneys.

Passive or venous congestion of the kidneys is one of the characteristic events in the general venous congestion which attends certain pulmonary and cardiac diseases. Passive congestion of the kidneys may also be caused by thrombosis of the vena cava ascendens, but this occurrence is so rare that it does not demand further consideration here. Thrombosis of one of the renal veins has been observed more frequently, but in the cases hitherto recorded no notable congestion of the kidney has been observed. Passive congestion of the kidney, therefore, may be considered as almost invariably accompanied by general venous stasis.

Pulmonary affections are less important in the etiology than cardiac diseases. Advanced emphysema and certain cases of fibrous phthisis are attended by chronic congestion of the kidneys. The various diseases of the heart which lead to general venous congestion—valvular lesions, fatty degeneration, myocarditis—are the most frequent and important of the causes. Mitral lesions may be especially emphasized in this connection. It will be remembered that the symptoms of venous stasis do not appear until the stage of non-compensation, and are intense in proportion to the failure of heart-power. It is also important to bear in mind that in proportion as the tension in the veins increases, the blood-pressure in the arteries sinks.

[1] Browicz, Centralbl. f. d. Med. Wiss., No. 9, 1879.
[2] Cornil, Comp. rend., Jan. 26, 1880.

The appearances presented by the kidneys after prolonged passive congestion are quite characteristic. The condition is sometimes called cyanotic induration of the kidneys. These organs are enlarged, their consistence extremely firm, the capsule non-adherent, the surface smooth; upon section both the cortical and the medullary substance presents a dark bluish-red color, the pyramids being darker than the cortex. The dark red color and the firm, almost stony hard, consistence of the kidneys are the most distinctive features. Upon microscopical examination the parenchyma and the interstitial tissue are usually unchanged. Fatty degeneration of the epithelium and increase of the interstitial tissue are found sometimes, but not as a rule.

Chronic passive congestion of the kidneys is accompanied by the symptoms of the primary disease. There are generally evidences of venous congestion in other parts of the body. Œdema of the lower extremities is usually present. The only symptoms which can be referred, with any certainty, to the condition of the kidneys, are changes in the urine. The quantity of urine is diminished; its specific gravity is increased; its color is darker than normal; it contains a moderate quantity of albumen, and usually some red blood-corpuscles, a few small hyaline casts, and a few epithelial cells. The urine upon standing often throws down an abundant sediment of the urates. According to Bartels, the excretion of uric acid is greater than in health. The amount of albumen is not great, rarely reaching two parts in a thousand. The quantity of blood does not generally suffice to color perceptibly the urine. The small quantity of urine may be referred to the diminished rapidity with which the blood flows through the glomeruli. The albuminuria is attributed, by some writers, to increased blood-pressure in the glomeruli; by others, to changes either in the capillary walls or in the epithelium of the glomeruli in consequence of an insufficient supply of arterial blood. Passive congestion of the kidneys is never a cause of uræmia. The diminished excretion of urine may perhaps increase the general dropsy. The treatment is directed to the primary condition, and not immediately to the kidneys. The indication is to strengthen the force of the heart, thereby increasing the arterial tension and relieving the venous stasis. By the administration of digitalis the urinary symptoms often improve, and may entirely disappear, as the power of the cardiac contraction increases. The reader is referred to the article on Valvular Diseases of the Heart for a consideration of the treatment applicable to the disturbances of the circulation which cause the manifestations of venous congestion.

Anæmia of the Kidneys.

Anæmia of the kidneys may be due either to general anæmia or to local causes. The renal anæmia which is present in pernicious anæmia, leucocythæmia, cancer, tuberculosis, and other diseases attended by general anæmia, is of little clinical importance. The most important cause of renal anæmia is epidemic cholera. In consequence of the sluggish circulation and the diminished volume of blood in the asphyctic stage of cholera, the kidneys are insufficiently nourished, and, therefore, undergo important alterations in function and in structure. It has been shown, both by experimentation and by pathological observation, that the renal parenchyma is extremely intolerant of even temporary interruption of the supply of arterial blood. Max Herrmann proved that narrowing the calibre of the renal artery in an animal causes diminution in the urinary secretion which entirely ceases before the artery is completely occluded. If the renal artery be closed by a ligature or by a clamp for a few minutes to half an hour, and then the obstruction be removed, it is found that a perceptible interval (sometimes three-quarters of an hour) intervenes before

the secretion of urine is re-established, and that after this interval the urine for a time is albuminous, and contains casts with some red blood-corpuscles. It has been shown by Litten that, if the renal artery be closed by ligature for one and a half to two hours and the ligature be then removed, many of the epithelial cells of the convoluted tubes in the course of the next twenty-four hours undergo coagulation-necrosis (*vide* page 53). Fatty degeneration of the renal epithelium is an effect of less complete interruption of the circulation through the kidney. The bearing of these experimental results upon human pathology is obvious. The anæmia of the asphyctic stage of cholera is explained by the slow circulation, amounting almost to stagnation of the blood, in this stage. As the circulation becomes re-established in the stage of reaction, the appearance of a scanty, albuminous urine containing casts and blood is in harmony with the results of Herrmann's experiments. It is, however, not proven that all of the changes in the kidneys, in cases of epidemic cholera, are referable to the anæmia of the asphyctic stage. It is possible that they are in part attributable to the infectious character of the disease.

Of the causes of local anæmia (ischæmia) of the kidneys, spasm of the branches of the renal arteries is the only one which requires special consideration. Thrombosis and embolism of the renal arteries will be considered in another connection. Spasmodic contraction of the arteries in the kidneys may be due to excitation of the vaso-motor nerves or centres, possibly also to direct irritation of the muscular coat of these arteries. While spasm of the small arteries of the kidneys has not been actually demonstrated as a pathological occurrence in man, it is assumed to exist in a variety of conditions which are attended or followed by a slight temporary albuminuria. The most important of these conditions in which vaso-motor spasm of the renal arteries is believed to be present are, epileptic convulsions, lead colic, strychnia poisoning, tetanus, extreme dyspnœa. A temporary albuminuria frequently occurs either during or shortly after these affections. The first urine voided after an epileptic convulsion is always albuminous. It is a reasonable supposition that the excitation of the vaso-constrictor nerves which is known to attend most of these conditions, involves those supplying the arteries in the kidneys. That the renal ischæmia thus produced should be followed by transitory albuminuria is in conformity with the results obtained by the production of temporary anæmia of the kidneys in animals. Cohnheim is inclined to refer the albuminuria and other symptoms in many cases of puerperal eclampsia to spasm of the renal arteries, but this view is less substantiated.

Anæmic kidneys are pale in color, especially the cortical portions, and are dry and somewhat shrunken. They are apt to be in greater or less degree fatty, in which case they may be swollen. It is not always easy to distinguish by the naked eye anæmic from fatty portions of the kidney.

Parenchymatous Degeneration of the Kidneys. Fatty Degeneration of the Kidneys.

These degenerations occur in the different forms of diffuse nephritis, in connection with which they will be again mentioned. Many of the slighter grades of so-called catarrhal nephritis and of parenchymatous nephritis belong, in reality, to the category of these degenerations. The degenerations may occur independently of any inflammation of the kidney, in which case they are generally without much clinical importance. It is desirable not to include under the heading of Bright's disease these degenerations when they are unattended by any inflammation.

The cortical substance of kidneys in the condition of parenchymatous de-

generation or cloudy swelling is somewhat swollen, and of an opaque, grayish color. The striæ are less distinct than normal. The surface of the organ is smooth, and the capsule easily detached. The consistence of the kidney is diminished. Upon microscopical examination the epithelial cells of the convoluted tubes are swollen and filled with albuminous granules which, in considerable part, dissolve in acetic acid. As these cells are normally very granular, it is not easy to detect with the microscope the slighter grades of this form of degeneration. The macroscopical appearances are often more distinctive than the microscopical (*vide* Part I. page 54). Excluding inflammation of the kidney, the most important causes of parenchymatous degeneration are infectious and febrile diseases, and certain mineral poisons. Of the first group of causes may be mentioned pyæmia, septicæmia, diphtheria, the exanthematous and the continued fevers; of the second group, phosphorus, arsenic, antimony, and the mineral acids. Parenchymatous degeneration also follows extensive burns, and irritating applications to a large surface of the skin.

Fatty degeneration is often combined with parenchymatous degeneration (granulo-fatty degeneration). It is a usual sequence when the action of the causes named is long continued or intense. In well-marked cases of fatty degeneration the cortical substance is more swollen than in the preceding degeneration. The enlarged and pale cortex presents yellowish streaks and patches. Hemorrhages are usually present in the fatty degeneration of phosphorus poisoning. The microscope shows in the epithelial cells of the convoluted tubes an accumulation of fatty molecules larger and more refractive than the albuminous granules of parenchymatous degeneration, from which they furthermore differ by their insolubility in acetic acid, and their solubility in ether after treating the specimen previously with alcohol. Both in parenchymatous and in fatty degeneration the glomeruli are unchanged. The causes of fatty degeneration, in addition to those of parenchymatous degeneration, are anæmic conditions, especially pernicious anæmia and leucocythæmia; cachexiæ, especially chronic pulmonary tuberculosis; chronic alcoholism, and, according to Wilks and Moxon, diabetes. In old age and in general obesity a moderate fatty degeneration may be met with. Jaundiced kidneys are apt to be fatty. No attempt is made to discriminate between fatty infiltration and fatty degeneration of the kidney. Many of the causes of these degenerations are also causes of nephritis.

Parenchymatous degeneration of the kidneys is usually attended by a moderate albuminuria. As already remarked, this condition is held by some pathologists to be a mild form of acute Bright's disease or to be the first stage of some of the varieties of that disease. This form of degeneration is generally transitory, and readily subsides as its causes disappear. It is not certain that the slight albuminuria so often present in simple parenchymatous and fatty degenerations of the kidney, in reality, depends upon these degenerative changes in the renal epithelium. It is, perhaps, referable in some other way to the primary condition which causes the degeneration. It is certain that extensive fatty degeneration of the kidney may exist, as in some cases of phosphorus poisoning, without any albuminuria or other appreciable urinary symptoms. These observations justify us in separating from Bright's disease proper these non-inflammatory degenerative changes.

In all forms of jaundice, of sufficient intensity, hyaline casts are present in the urine, often without any albuminuria. Whether the production of these casts has anything to do with changes in the renal epithelium, is a matter of uncertainty.

Acute Bright's Disease. Acute Diffuse Nephritis.

Since the memorable researches of Richard Bright, published in 1827, diseases of the kidney characterized by albuminuria and general dropsy have been called Bright's disease. It will be seen that the renal changes which belong to the different forms of this disease are various, although, as has been remarked, not so many as the names which have been proposed for them. Not every case of albuminuria is to be considered as one of Bright's disease. We do not include under this name the renal changes which have already been considered in this section, namely, simple parenchymatous degeneration, fatty degeneration, hyperæmia, and anæmia of the kidneys, although each of these alterations may form an important element in Bright's disease. These changes are attended either by moderate albuminuria or by none whatever; and if any dropsy be present, this is not referable, as a rule, to the alteration in the kidneys. By almost universal consent Bright's disease is regarded as a nephritis, that is, as an inflammation of the kidneys. This nephritis affects both organs, and is, therefore, described as diffuse, in distinction from the circumscribed renal inflammations, such as suppurative nephritis. The great majority of cases of Bright's disease are furthermore appropriately called diffuse nephritis, on the ground that all the constituents of the kidney, namely, the interstitial tissue, the uriniferous tubes, and the bloodvessels, are involved in the inflammatory process. But the epithet diffuse must not be understood as implying that the morbid process affects uniformly the kidney tissue. Some parts of the kidney are always more diseased than others. Bright's disease is divided into an acute and a chronic form.

Acute Bright's disease has received various names, such as parenchymatous nephritis, acute tubal nephritis, acute desquamative nephritis, catarrhal nephritis, croupous nephritis. These names are all objectionable, as they embody theories concerning the nature of the disease which are either unproven or erroneous. The designation acute Bright's disease is the simplest, and involves no doubtful hypotheses. If it be desired to employ an anatomical term, acute diffuse nephritis is the one least objectionable.

Anatomical Characters.—The morbid appearances in acute Bright's disease vary considerably in different cases, although less than in the chronic form. The kidneys may present so little variation from their normal aspect that the disease can be recognized only by microscopical examination. As a rule, however, these organs are enlarged and somewhat softened. The surface is smooth, and presents red patches mingled with opaque grayish or yellowish-white portions. The red parts correspond to hemorrhages, or to spots of congestion; the pale parts are either relatively or absolutely anæmic. Upon section, the swelling is seen to involve the cortical portion, which presents the same mixture of colors. Red points corresponding to congested Malpighian bodies or more frequently to hemorrhages, are observed. The red and pale portions usually present more or less of a striated appearance, but the normal markings of the cortex are obscured. In some kidneys the hyperæmic and hemorrhagic portions are more prominent than the anæmic; in others the pale opaque appearance predominates. It is thus possible to distinguish red kidneys and pale kidneys of acute Bright's disease; but between these types there is every possible transition, and we are not to consider them as representing different varieties of the disease. The pale kidneys, doubtless, often belong to a later stage of the disease than the red, but this interpretation is not in all cases admissible. Even the pale kidneys usually present small hemorrhages, and, upon the surface, dilated stars of Verheyen. The medullary substance is either normal in color or congested, and, in either

case, offers in the pale kidneys a marked contrast to the color of the cortex. In the majority of cases of acute Bright's disease the kidneys are hyperæmic, but not uniformly congested; if the disease approach a chronic stage, the hyperæmia gradually gives place to a whitish or yellowish color, but some hemorrhages usually remain. In the acute Bright's disease following scarlet fever, diphtheria, and septicæmia, the whitish or yellowish color may predominate in an early stage of the affection.

Upon microscopical examination the alterations are sometimes found to be astonishingly slight, even when during life the urine was quite albuminous and contained blood and casts. In these cases, which are generally mild and do not terminate fatally from the kidney disease, the inflammatory alteration is supposed to affect chiefly the capillaries of the glomeruli. These altered capillaries allow the escape of an albuminous fluid, and the passage of white and red corpuscles through their walls. These inflammatory products are exuded into the tubes and pass out with the urine. In these mild cases we find, therefore, in the tubes some red and white corpuscles, hyaline casts chiefly in the straight tubes, and a moderate cloudy swelling of the epithelium of the convoluted tubes. The interstitial tissue presents no inflammatory changes.[1]

When death occurs from the renal affection itself, the changes are generally more marked. In most of these cases hemorrhages are present, partly in the intertubular tissue, partly within the capsules of Bowman, but chiefly within the convoluted tubes. In some instances these extravasations are so many that the name hemorrhagic nephritis, employed many years ago by Traube, is appropriate. It is in these cases that the urine during life contains a large quantity of red corpuscles. The epithelium of the convoluted tubes is swollen, and filled with an abnormally large number of albuminous, mixed with some fatty, granules. It must not be supposed that these epithelial changes are present throughout the cortical portion, or, when present, exist in the same degree everywhere. In some places the epithelial cells are flattened by blood or other abnormal contents in the tubes, in others they are swollen as described, and again in other places they are normal in appearance. The epithelial cells may be desquamated and fill the tubes. Hyaline casts are found here and there in the convoluted tubes, and in still larger numbers in the loops of Henle and the collecting tubes. Emigrated white blood-corpuscles are found not only in the tubes, but also in the interstitial tissue. In the latter situation they are collected in groups either about the Malpighian bodies or between the tubes. These collections of lymphoid cells are scattered throughout the cortex, but may not be sufficient in number to appear in each microscopical section. The changes in the epithelium are usually most marked in the neighborhood of these clumps of lymphoid cells.[2] In the pale

[1] This mild form of acute Bright's disease is the glomerulo-nephritis of Cohnheim, and the hemorrhagic-catarrhal nephritis of Wagner. The glomerulo-nephritis of Klebs is entirely different. In the latter there is an increase of nuclei in the glomeruli, and no marked changes elsewhere. This form of glomerulo-nephritis occurs, according to Klebs, chiefly in scarlatina, but it is not common.

[2] There are some details concerning the changes in the epithelial cells, which are not introduced into the text lest the description should become too complicated. The epithelium lining the capsule of Bowman and that covering the glomeruli may swell up and undergo granulo-fatty degeneration. Between the capsule and the compressed glomerulus there may be an accumulation of new cells which, according to Langhans, are partly emigrant corpuscles and partly proliferated epithelial cells. The glomerulus, on the other hand, may be swollen by an increase of nuclei in or between its capillaries. Cornil has described (1879) the appearance of spheres resembling colloid drops, but of an albuminous nature, in the epithelial cells from which they may be extruded. He ascribes to these an important role in the formation of hyaline

kidneys the parenchymatous and the fatty degeneration with the attendant anæmia exceed in extent the similar changes in the hyperæmic kidneys. The hemorrhages, too, are not so many as in the red kidneys. Corresponding to these differences the urine in life is paler, as it contains less blood. In the more severe forms of acute Bright's disease it is not uncommon to find colonies of micrococci in the bloodvessels of the kidney.

Anasarca and serous accumulations in the pleural, pericardial, and peritoneal cavities, are usually met with to a greater or less degree in the bodies of those dead of acute Bright's disease. Sero-fibrinous pleuritis and pericarditis are not infrequent. Pneumonitis, both in the lobar and in the lobular form, is one of the recognized complications. Increase of the cerebro-spinal fluid with cerebral œdema, or even with meningitis, is likewise to be mentioned in this enumeration of complications.

Clinical History.—Subcutaneous œdema is a very frequent but not a constant symptom. It is usually the first symptom pointing to the existence of this affection. The œdema is generally first observed on the face, particularly on the eyelids and around the eyes, but it is speedily apparent in the lower extremities, and sometimes occurs first in the latter situation. Coincident with the appearance of the dropsy is more or less febrile movement, frequently preceded by chills or shiverings, together with thirst, anorexia, pain and tenderness in the loins. Pain and tenderness over the kidneys are, however, rarely marked and are often wanting. Vomiting is a frequent symptom at the commencement of the affection. The skin is dry, and the countenance becomes pallid. The dropsy increases and becomes general, varying considerably in amount in different cases. In some cases the anasarca is great, the limbs, scrotum, penis, or external labia, becoming enormously swollen. In other cases it does not exceed a moderate amount. More or less dropsical effusion usually takes place into the peritoneal and the pleural cavity. Hydrothorax sometimes occurs to such an extent as to occasion great suffering from dyspnœa, and endanger life.

The examination of the urine is essential for the diagnosis of acute Bright's disease. The quantity is usually diminished and may be very scanty. Suppression sometimes occurs. The specific gravity generally exceeds that of health. The total quantity of urea excreted in twenty-four hours is much diminished. The urine contains albumen in considerable, and frequently in great, abundance. The amount of albumen is usually between $\frac{1}{4}$ and 1 per cent., but may exceed this proportion. In some cases the urine has a reddish-brown, smoky appearance from the presence of blood. A certain number of red blood-corpuscles are present in nearly all cases, although not always in sufficient number to color the urine. Wagner distinguishes two types of urine in Bright's disease, the one bloody and the other free from blood. As a rule in this disease a considerable sediment forms in the urine. The microscopical examination of this sediment shows red and white corpuscles in varying proportion; the one variety may be abundant in the absence of the

casts, but this view is far from proven. The epithelial cells may undergo the transformation described by Weigert as coagulation-necrosis. This change has been observed in nephritis produced artificially in animals by means of chromic acid, of cantharides, of croton oil, of petroleum. It also follows temporary ligation of the renal artery. It is probable that it occurs in some cases of toxic nephritis in man, but further observations in this direction are needed. Both Cohnheim and Weigert assign to cells which have undergone this transformation a share in the production of hyaline casts. The epithelial cells may proliferate and produce cells to replace those destroyed by degenerative changes. Sometimes simple atrophy of the epithelial cells occurs.

other. The red corpuscles may appear normal, or as clear pale rings, or they may be shrunken. Disintegrated red corpuscles and granules of hæmatoidin may be observed. Epithelium of the urinary passages, less frequently of the kidneys, may be present. Granular matter and micrococci are also among the frequent constituents of the sediment. The most characteristic objects are cylindrical bodies known as casts. These are formed in the uriniferous tubes of the kidney. Those which escape with the urine are derived from the straight tubes (Henle's loops and collecting tubes), as casts formed in the convoluted tubes cannot well make their way through the narrow loops of Henle. Casts vary from $\frac{1}{1000}$ to $\frac{1}{500}$ of an inch in diameter. A number of varieties are distinguished. Those which belong to acute Bright's disease are blood-casts, epithelial casts, and hyaline casts. Granular casts and fatty casts indicate a more advanced change in the kidneys than usually belongs to acute Bright's disease. But in some cases of the acute disease, many fatty granules are attached to the hyaline casts. Hyaline casts are pale cylinders with delicate contours, and are so transparent that an inexperienced observer readily overlooks them. The addition of some coloring agent, such as iodine or eosine, is of assistance in searching for them, as they readily stain with most coloring matters. Their chemical composition is not known. They are often described as fibrinous, but they do not conform to the reactions of fibrin. They are probably of an albuminous nature. They vary in size. Small hyaline casts are those most frequently met with in this form of disease. Blood-corpuscles, epithelial cells, and granular material are often attached to these casts. Epithelial casts are composed of desquamated epithelial cells of the renal tubes. Some of the so-called epithelial casts are composed of white blood-corpuscles. Blood-casts are made up of red blood-corpuscles. These last two forms of casts often possess a hyaline basement substance to which the cells and corpuscles are attached. There may be some oil-globules in the sediment free, or attached to the casts, or contained in cells. In most cases there are many casts, but sometimes they are so scanty as to require careful search for their detection.

Coma and convulsions occur in a certain proportion of cases. These are symptoms of uræmia. Owing to an insufficient elimination of urinary constituents by the kidneys, these may accumulate in the blood to an extent sufficient for the manifestations of their toxical effects upon the brain. Vomiting and purging may precede, or occur without the cerebral symptoms of uræmia, being due to a vicarious elimination of urea through the gastro-intestinal mucous membrane. Impaired vision and amaurosis are among the effects of uræmia occasionally observed. Blindness, which may be complete, when it occurs in acute albuminuria, is generally sudden; it is often of temporary duration, and recovery is complete. The ophthalmoscope, under these circumstances, shows no morbid appearances within the eye. The morbid condition is central. It is otherwise, as will be seen, in amaurosis occurring sometimes in the acute affection, but oftener in cases of chronic Bright's disease. The amaurosis which is not associated with changes appreciable with the ophthalmoscope, is called uræmic amaurosis. It occurs especially in cases of acute albuminuria developed in connection with scarlatina and pregnancy.

Complications considered as occurring sufficiently often to show, not merely coincidence, but a pathological connection with the affection, are bronchitis, and inflammation of serous membranes, especially pleuritis and pericarditis. Pulmonary œdema is an occasional complication.

In the course of the affection, the symptoms are apt to present considerable variation on different days. The quantity of urine, the amount of albumen, etc., vary, and so with respect to the œdema, the effusion into the cavities, and the febrile movement. If uræmic effects and important complications

do not occur, the affection continues for a period varying between a few days and a couple of months, the average duration being about four weeks. The approach of convalescence is denoted by a notable diminution or disappearance of the dropsy, cessation of febrile movement, return of appetite, and an abundant secretion of urine. Albuminuria usually continues, but in a lessened degree, after the dropsy has disappeared. At length the urine becomes normal and casts disappear from the sediment. The latter sometimes continue to be found for some time after the albumen has disappeared. The affection may end in complete recovery, or it may eventuate in a chronic affection. The latter is rare. As a rule, if the patient be not cut off by uræmic poisoning or the complications which are liable to occur, the recovery is complete and permanent.

Pathological Character.—As both kidneys are diffusely inflamed in acute Bright's disease, it is to be inferred that the irritant which excites the inflammation is contained in the circulating blood. In many cases, as in the acute Bright's disease secondary to toxic influences (cantharides, turpentine, etc.) and to infectious diseases, the relation between morbid blood-changes and the local affection is clear. In other cases, as when the disease follows exposure to cold, this relation is obscure. The kidneys are peculiarly exposed to the action of noxious substances, as it is mainly through these organs that these substances are excreted from the body. As it is through the glomeruli that the water, and, doubtless, many of the solid constituents of the urine are excreted, it is believed that inflammatory irritants act first of all upon these structures, and, in the mildest cases of the disease, only upon them and the renal epithelium, with which, also, irritants contained in the urine must come into intimate contact. In more severe cases all of the constituent elements of the kidney share in the inflammatory process. The diminished quantity of urine in acute Bright's disease, may be explained by the lessened blood-pressure and slow circulation in the glomeruli, these changes in the vascular system being incident to all acute inflammations. The red and white corpuscles found in the kidney and in the urine are the natural products of inflammation. The red corpuscles doubtless escape, at least in part, by diapedesis (p. 27). The albuminuria may be referred partly to inflammatory alterations in the walls of the renal capillaries, partly to changes in the epithelium, particularly of that covering the glomeruli. Changes in the blood-pressure may also be concerned in the causation of albuminuria.[1] As to the mode of production of hyaline casts there is discrepancy of opinion. According to one view, they are formed from altered epithelial cells which

[1] Writers are far from agreed as to the causation of albuminuria. Increased blood-pressure in the glomeruli has usually been considered an important cause. Runeberg has recently advocated with skill the view that the cause is, in all cases, diminished pressure. The truth seems to be that the blood-pressure is not an important factor in the production of albuminuria. Diminished rapidity of the circulation in the glomeruli is considered by many to be an efficient cause. The view advocated by Cohnheim is, that the usual cause of albuminuria is to be found in changes in the epithelium covering the glomeruli. This view is consistent with the preceding, for slow circulation produces alterations in these cells by depriving them of their proper supply of nutriment. The real difficulty is to explain why albumen is not present normally in the urine. All other capillaries in the body, so far as known, allow an albuminous fluid to transude under normal circumstances. Are the capillaries of the glomeruli differently constituted, or do they also allow an albuminous transudation which, however, is unable to penetrate the epithelium covering the glomeruli? If the latter hypothesis be correct, Cohnheim's doctrine seems plausible. The fact that in albuminuria the albumen, at least in great part, escapes from the vessels of the glomeruli, has been proven by the investigations of Posner (Virchow's Archiv, Bd. 79, p. 311, 1880).

have coalesced with each other; according to a second, they are produced by secretion of hyaline material from the epithelial cells; according to a third, and the most probable view, they result from a coagulation of albuminous material which has escaped from the bloodvessels into the tubes.

The most important of the effects produced by the renal disease upon the general system are dropsy and uræmia. The dropsy is usually referred to the hydræmia which results from the withdrawal of albumen from the blood and the diminished excretion of water. The relation between hydræmia and general dropsy has been discussed in Part First, page 65. This explanation of the dropsy is not in all cases satisfactory. There is reason to believe that in some cases the anasarca is best explained upon the assumption that some alteration exists in the walls of the cutaneous and subcutaneous vessels, which renders them more permeable to the passage of albuminous fluids. Cohnheim assumes this alteration to be of an inflammatory nature, and to be produced often by the same causes which excite the nephritis.[1] The uræmia is the result of the accumulation in the blood of urinary constituents. This subject has been considered in Part First, p. 76.

Causation.—This affection may occur at any period of life; young infants are not exempt from it. It occurs oftener in males than in females. As already stated, in the majority of cases it is a sequel of scarlatina. It may occur during the progress of scarlatina, or follow directly the stage of desquamation, but it is most apt to occur in the second or third week after the date of convalescence. It is an important question whether this sequel proceed exclusively or chiefly from an agency pertaining intrinsically to scarlatina, or whether it depends on extrinsic causes, such as the action of cold. It occurs in cases in which the utmost care is taken to place the patient beyond the agency of extrinsic causes, but it is probable that the latter are frequently involved. It may be developed in a person much exposed to the scarlatinous infection, without any affection of the throat or an eruption, the person having already experienced an attack of scarlatina many years previously. I have notes of several cases exemplifying the facts in this statement.

Exclusive of the cases in which it is a sequel of scarlatina, it occurs in various pathological connections; it is an occasional sequel of diphtheria, and of epidemic cholera. It sometimes occurs during the development of pulmonary tuberculosis, in the course of articular rheumatism, in cases of typhoid and typhus fever, erysipelas, relapsing fever, acute lobar pneumonia, pyæmia, septicæmia, endocarditis, dysentery, carbuncles, and suppurative processes in different situations, and in measles. Albuminuria and general dropsy occurring in pregnancy depend, in a certain proportion of cases, on this affection. As a primary affection it occurs especially in persons addicted to intemperance. In these cases it is sometimes difficult to say how much causative agency is to be attributed directly to the action of alcohol, and how much to the exposure incidental to intemperance. It is observed not infrequently to become developed after lying on the ground in a state of intoxication. In a case which came under my observation, it followed excessive indulgence in beer without any exposure to cold. It is sometimes attributable to exposure to cold irrespective of alcoholic indulgence. It may be caused by extensive burns. Other causes are cantharides, turpentine, phosphorus, the mineral acids, arsenic, the nitrate of silver, lead, and mercury, taken internally. It is thus seen that with regard to etiology, most cases may be distributed into three groups, namely, 1st, those in which the disease

[1] This view must be considered hypothetical. It is elaborated by Cohnheim in the second volume of his Allgemeine Pathologie, Berlin, 1880.

is caused by toxic agents; 2d, cases in which it is incident to infectious diseases; and 3d, cases in which it is referable to causes acting on the skin, as cold and burns.

Diagnosis.—The existence of albuminuria is not, in itself, adequate proof of either the affection under consideration, or of the chronic affections of the kidneys which remain to be considered. Albumen may be present in the urine in a small or moderate quantity, and, for a brief period, in the course of a great number of diseases. It is found not infrequently in the urine of persons who are apparently in perfect health. Munn found albuminuria in the proportion of eleven per cent. of persons applying for life insurance, this being the only evidence of any disease.[1] In general, the diagnosis is easily made, being based on the occurrence of anasarca, developed rapidly, accompanied with febrile symptoms, and an examination of the urine generally showing albumen in abundance. Dropsy is an early symptom in the great majority of cases, but it is sometimes wanting. The diagnosis is then to be based on symptoms pertaining to the urine, in conjunction with general symptoms. In addition to the presence of albumen in the urine, the quantity is usually notably lessened; it frequently has a smoky or sooty appearance from the presence of red blood-corpuscles, and it is sometimes distinctly bloody. The sediment of the urine, examined microscopically, is found to contain, in greater or less abundance, the casts which have been described. The presence of these, in conjunction with other characters pertaining to the urine, and the general symptoms, render the diagnosis positive. Etiological connections are also to be taken into account in the diagnosis.

Prognosis.—The danger in cases of this affection is from uræmia and the complications which are liable to occur. Coma and convulsions always denote imminent and great danger to life, but recovery may take place notwithstanding these effects of uræmia. Pleuritis, pericarditis, peritonitis, meningitis, and pneumonitis, developed in the course of the affection, are apt to prove fatal. Œdema of the lungs may prove a cause of death. Dropsical effusion into both pleural cavities may take place to such an extent as to destroy life. An instance of death from this cause has not fallen under my observation, but I have repeatedly met with cases in which the dyspnœa seemed to denote imminent danger to life.

Exclusive of uræmia and serious complications, the prognosis is favorable. The affection does not tend to disorganize the kidneys. It is a self-limited affection, seldom continuing more than two months, and in some cases ending in from one to two weeks. It very rarely assumes a chronic form. Cases of the chronic affections which remain to be considered, as a rule, do not originate in an acute attack.

Uræmic poisoning is to be apprehended when the urine is scanty; in other words, when the quantity of urea eliminated by the kidneys is small. Suppression of urine lasting twenty-four or forty-eight hours places the patient in imminent danger, and, if it continue, is a fatal symptom. Danger from uræmia is not passed, although the albumen may have disappeared from the urine, if the sediment still contain casts. I have known fatal uræmic convulsions to occur under these circumstances.

Treatment.—The treatment embraces the following leading objects: 1. Diminution of the intensity of the renal inflammation, promotion of resolution, and restoration of the secretory function of the kidneys. 2. Diminu-

[1] *Vide* article by Dr. John Munn in the N. Y. Med. Record, March, 1879.

tion or removal of dropsical effusion. 3. Elimination of urea through the skin and gastro-intestinal mucous membrane, if uræmia exist or be threatened.

With reference to the first of these objects, rest and warmth of the surface are important. The patient should keep the bed in order to maintain both warmth and rest. The diet should be unstimulating. Water and other bland liquids should be allowed as freely as the thirst dictates. Dry-cupping over the loins is the best method of revulsion or counter-irritation, and, if the patient be not feeble or anæmic, the scarificator may be employed. General bloodletting is advisable only in cases in which patients are full-blooded and attacked when in good health. As a rule, after scarlatina, in intemperate persons, and whenever the system is enfeebled from any cause, this measure is inadmissible. Fomentations over the region of the kidneys by means of moistened cloths covered with oiled muslin and several thicknesses of flannel, or the spongio-piline, are useful. Saline laxatives are useful by way of depletion.

With reference to the dropsy, either saline cathartics or the more active hydragogues are indicated in proportion to the amount and situation of the dropsical effusion. In cases in which suffering and danger are incident to hydrothorax, the elaterium is the most prompt and reliable hydragogue. I have repeatedly obtained, by means of this remedy, effectual relief in a few hours, when the pleuritic effusion was sufficient to occasion alarming dyspnœa. Gamboge, podophyllin, and jalap with the bitartrate of potassa, are efficient hydragogues. Diuretics are not to be relied upon; the kidneys will not be likely to respond to them. Moreover, they are considered by some as inadmissible because their action on the kidneys may increase the inflammation. They are, however, recommended as safe and frequently useful by others. A rational indication for their use is afforded by the fact that the renal tubes are obstructed; a free secretion of urine will be likely to remove the obstruction by washing away the contents of the tubes. So far as my experience goes, digitalis and the saline diuretics do no harm and are often useful.

Measures for the vicarious elimination of urea are indicated whenever the diminished quantity of urine and its low specific gravity show the elimination by the kidneys to be greatly deficient. By timely meeting this indication, uræmic poisoning may perhaps be forestalled. Of course, measures for this object are urgently indicated when uræmic poisoning has taken place. Hydragogue cathartics are the most efficient, and next to these the hot-air bath. The pilocarpin, given hypodermically, in some cases produces profuse perspiration, and is a potential eliminative remedy. It may be conjoined with the use of the hot-air bath. Both hydragogues and sudorifics are to be employed in alternation if uræmic coma or convulsions have occurred. If the indication be not urgent, salines and sudorific remedies may suffice. An eligible sudorific remedy is the liquor ammoniæ acetatis in half-ounce doses thrice daily. The statement concerning the use of diuretics with reference to dropsy, of course, is equally applicable to their use for the elimination of urea. They are not to be relied upon for the elimination of urea when uræmia exists or is threatened. Under other circumstances diuretics may be employed, selecting those which do not act as irritants of the kidneys. The bitartrate of potassa, the infusion of digitalis, and the decoction of broom are eligible diuretics. With reference to a diuretic effect, pure or distilled water should be taken as a drink as freely as can be done without inconvenience. Dickinson says: "Of all diuretics water is the best," and my own experience has led me to think that this statement is not too strong.

Uræmic coma and convulsions call for measures of treatment in addition to those which are eliminative in their operation. Venesection may be employed, if not contra-indicated by the condition of the patient, exclusive of

the uræmic symptoms. For the arrest of convulsions, either chloroform inhalation, or the chloral hydrate given by the mouth or rectum, is indicated. Morphia may be administered by subcutaneous injection, but not in toxic doses. These are palliative measures to be pursued until elimination has been effected by hydragogues and sudorifics, or as long as the coma and convulsions continue.

During convalescence, carefulness as regards diet, exercise, and exposure to cold, is important. Tonic remedies, and especially preparations of iron, are generally indicated.

My clinical records furnish illustrations of complete recovery from this affection when the dropsy was excessive, when life was threatened by hydrothorax and œdema of the lungs, and also after the occurrence of uræmic coma and convulsions.

Chronic Bright's Disease. Chronic Diffuse Nephritis.

It is not easy to make a convenient and correct classification of the different forms of chronic Bright's disease. In different cases of this disease, the kidneys present a great variety of morbid appearances as regards size, color, character of the surface, etc. Kidneys affected with chronic Bright's disease may be small, of normal size, or enlarged; they may be red, yellow, white, or mottled; their surface may be smooth or granular; waxy degeneration exists in some and not in other cases. The large kidneys are usually pale in color and of smooth surface, and the small kidneys are generally red or mottled and of granular surface; but the exceptions to these rules are many. There are three modes of classification which deserve especial mention. There is first the classification of Frerichs, adopted in its leading features by Grainger Stewart. This divides Bright's disease into three stages: *first*, a stage of inflammation; *second*, a stage of degeneration; *third*, a stage of atrophy. This classification is founded on theory, and is opposed by clinical and pathological observations. It is certain that in the majority of atrophied kidneys the disease is chronic from the start, and there is no reason to suppose that these kidneys are preceded by either of the other stages. Nor are most cases of the so-called second stage ushered in by an acute attack. It may be that there are cases of Bright's disease which pass through the three stages of Frerichs, but this sequence of events is so rare that it cannot serve as a basis of classification. This division of Bright's disease into stages is generally abandoned.

Another classification is based on a view wholly opposed to the preceding. Bright's disease, according to this second view, is a general name for a number of independent diseases. This doctrine is advocated by many English writers, and, since Bartels' important work on diseases of the kidney, it is widely adopted in Germany. It is without doubt more generally accepted at the present time than any other classification. The distinct affections which are thus recognized as included under the name Bright's disease are: 1, acute Bright's disease; 2, chronic parenchymatous nephritis; 3, chronic interstitial nephritis; 4, waxy degeneration of the kidney. It is admitted that these affections are often combined with each other. This classification is in many respects a convenient one. It is certainly proper to separate acute from chronic Bright's disease. But on pathological, as well as on clinical, grounds, there are serious objections to the sharp distinctions drawn in the above classification between parenchymatous nephritis, interstitial nephritis, and waxy degeneration. In the so-called chronic parenchymatous nephritis, there are present interstitial changes of the same nature as those found in chronic interstitial nephritis; in the latter, there are also parenchy-

matous changes. There is no proof of the assertion that the disease begins in one case in the parenchyma and in the other in the interstitial tissue of the kidney. Waxy degeneration of the kidney may occur without inflammatory alterations, but, in that case, the degeneration is not extended, and is of little clinical importance. The waxy kidney is, in the great majority of cases, accompanied by a true nephritis. In many cases usually described as chronic parenchymatous nephritis, there is waxy degeneration in addition to the nephritis.

A third classification is the one adopted in this work. It embraces all of the different forms of chronic Bright's disease under the name chronic diffuse nephritis. This classification recognizes the fact that in all of these forms there are both interstitial and parenchymatous changes. It does not consider the preponderance of parenchymatous alterations in one case and of interstitial alterations in another, as a satisfactory reason for distinguishing a parenchymatous from an interstitial nephritis, especially as there may exist every possible degree of combination between these two changes.

It has been abundantly demonstrated that certain morbid conditions of the kidney in chronic diffuse nephritis, are associated with characteristic clinical phenomena. These different morbid conditions are, perhaps, best designated by indicating the gross appearances of the kidneys in which they are present, as, for example, the small granular kidney, the large waxy kidney, etc. This method of division has disadvantages, but is, perhaps, as good as any which our present knowledge enables us to make. Whether the varieties of chronic Bright's disease are to be regarded as distinct affections, or as different manifestations of one and the same disease, is, in a measure, a matter of individual judgment. If chronic diffuse nephritis embraced only typical cases of large white kidney on the one hand, and typical cases of small granular kidney on the other hand, there would be no impropriety in regarding these as distinct diseases. But there is every grade of transition between the large and the small kidneys; there are large kidneys with the clinical history of the small, and *vice versâ;* and there are large kidneys which, except as regards size, may present all the pathological changes of the small. For these and other reasons which might be adduced, it is better to regard the types of diseased kidney which are to be described, not as independent affections, but as different manifestations or varieties of the same disease, namely, chronic diffuse nephritis.

The two influences of greatest importance in determining the character or type of kidney found after death from chronic Bright's disease are, the duration of the disease and the presence or absence of waxy degeneration. When the disease has lasted for several years, it is almost certain that the small granular kidneys will be found after death. When the affection terminates in less than a year from the onset (a point by no means easy in all cases to determine), some form of large kidney will usually be found on post-mortem examination. The waxy kidney, however, even when of several years' duration, is, as a rule, large and pale. It may, however, be small and granular. It must not be inferred from the fact that the small kidneys run a more prolonged course than the large, that the former represent a late stage of the latter. In the majority of small kidneys, the process of contraction or atrophy is to be considered as at work from the onset of the disease.

The three main forms of chronic diffuse nephritis are: 1. The large kidney (red, mottled, or white); 2. The small, granular kidney; 3. The waxy kidney. The waxy kidney is usually enlarged. It is therefore convenient to consider two forms of large kidney—one with, and the other without, waxy

degeneration. Mention will also be made of the occurrence of waxy degeneration in small kidneys.

I. *The Large Kidney without Waxy Degeneration.*—This form is less frequent than either the large waxy kidney or the small granular kidney. It is the variety met with in the rare instances in which acute Bright's disease passes into the chronic stage. It is not, however, generally preceded by the acute disease. It runs, as a rule, a more rapid course than any other variety of chronic diffuse nephritis, its duration being rarely over a year and a half. It presents two modifications according to the color of the cortical portion of the kidney. In one the cortex is red or, more usually, mottled with red and white (large red or mottled kidney) ; in the other the cortex is pale (large white kidney). The kidneys are enlarged, less frequently of normal size (a normal sized kidney is reckoned among the large, in distinction from the small kidneys). The surface is smooth. The capsule is easily detached. The swelling affects chiefly the cortex, which may present many hemorrhagic and congested portions, mingled with opaque whitish or yellow parts, or may be almost uniformly of a pale yellowish-white color, with only here and there a hemorrhage or a congested patch. In exceptional cases the surface of the kidney is slightly granular, and the capsule is adherent in a few places.

Upon microscopical examination, small hemorrhages are found in abundance in the red or mottled kidneys, and, although diminished in number, they are usually not absent in the pale kidneys. The extravasated blood may be in the intertubular tissue, but is more frequently within Bowman's capsules and in the convoluted tubes. The changes in the interstitial tissue are in the form of more or less circumscribed patches scattered throughout the cortex. In these patches the connective tissue between the tubes and around the Malpighian bodies is increased. This new tissue may be rich in cells and indistinctly fibrillated, or may be poor in cells and fibrous. The epithelium lining the tubes surrounded by the new connective tissue is generally atrophic, and the diameter of these tubes is diminished. In some places the tubes may have entirely disappeared. The glomeruli may be shrunken and fibrous, and the new tissue may be developed especially around the altered glomeruli. In these patches there is often a growth of new connective tissue in the walls of the arteries, presenting itself frequently in the form of an obliterating endarteritis. Besides this development of new connective tissue combined with atrophy of the tubes, the interstitial tissue may present here and there an infiltration with small round cells, and with fatty molecules. Outside of the patches of new connective tissue the convoluted tubes, instead of being atrophic, are frequently dilated. In these dilated tubes the epithelium is generally swollen and contains molecules of fat. In other places no change may be noticeable either in the tubes or in the interstitial tissue. The lumina of the tubes contain beside blood-corpuscles, also hyaline casts, fatty molecules and granular matter.

In the large kidneys, in distinction from the small granular kidneys, the changes in the epithelial cells (that is, the parenchymatous and the fatty degenerations) exceed in extent the interstitial alterations. Whether or not there is a form of chronic Bright's disease in which the parenchymatous and fatty degenerations constitute the sole changes, is a matter of dispute. It is certain that in the great majority of cases there are interstitial alterations as described, mingled with the changes in the tubes. It is important to observe, however, that both the parenchymatous and the interstitial changes are scattered in patches throughout the cortical portions of both kidneys, and are not uniformly diffused ; also that the most extensive swelling and fatty degeneration of the epithelium are found outside of the patches of new con-

nective tissue, in which, on the other hand, the epithelial cells are usually small and atrophied. It is evident from the description that even in large smooth kidneys there may be (microscopically) atrophied portions, resembling those in the small granular kidneys, but not so abundant. This atrophy, with increase of fibrous tissue, is evident to the naked eye in those large kidneys which present a granular surface with adherent capsule. These and other considerations which will appear in the course of this article, render it clear, that, important as it is to distinguish certain general types or varieties of chronic diffuse nephritis, it is not desirable to separate them from each other by sharp boundary lines. The pale kidneys differ from the red or mottled kidneys chiefly in a greater amount of anæmia and of fatty degeneration.

A considerable number of the large, non-waxy kidneys of chronic Bright's disease are accompanied by hypertrophy of the left ventricle, or of the whole heart. These large kidneys, with hypertrophy of the heart, constitute the chronic hemorrhagic nephritis of Weigert.[1] Under this heading come also some of the large white kidneys of the English writers, that is, kidneys with smooth surface, with pale cortex presenting grayish and opaque yellow portions, and with absence of cardiac hypertrophy. Hypertrophy of the heart does not usually develop in connection with the large kidneys when the renal disease occurs in patients already much enfeebled, as by phthisis, syphilis, chronic suppurations, etc. It is in connection with such wasting diseases that the greatest number of the large white kidneys are developed. There is reason to believe that many of the kidneys hitherto described as large white, are affected by a waxy degeneration which has been overlooked, and which therefore places them in the following variety.

II. *The Large Kidney with Waxy Degeneration.*—This form and the small granular kidneys constitute the most frequent forms of Bright's disease. This variety embraces a large proportion of the cases developing in connection with phthisis, syphilis, chronic suppurations, and severe cachexiæ. As already mentioned, a considerable number of the large white kidneys of the English writers belong to this variety.[2] Waxy degeneration of the kidneys is, with very few exceptions, accompanied by waxy degeneration in other parts, especially the spleen and the liver. The kidney is one of the favorite seats of this abnormal deposit. The waxy change in the kidney may be so slight as to be only recognizable upon microscopical examination, or it may be so

[1] Weigert, Volkmann's Sammlung klinischer Vorträge, Nos. 162, 163, 1879.

[2] This is not the view usually held. Most writers regard the large white kidney as characterized especially by fatty degeneration of the epithelium, as free from waxy degeneration, and as unattended by hypertrophy of the heart. This constitutes only one variety of large white kidney. A part of the confusion arises from the fact that there are different forms of diffuse nephritis which may present the appearances of the large white kidney, namely: 1. The pale kidney of acute Bright's disease, especially of scarlatinal nephritis. 2. The pale modification of Weigert's chronic hemorrhagic nephritis, or the large kidney without waxy degeneration and with hypertrophy of the heart. 3. The large pale kidney of chronic Bright's disease, without waxy degeneration and without hypertrophy of the heart (the large white kidney proper). 4. The large pale kidney with waxy degeneration. Certainly in New York most of the large white kidneys of chronic Bright's disease without hypertrophy of the left ventricle, are affected with waxy degeneration. Weigert, with abundant material at his disposal in Breslau and in Leipsic, has never met with the third form, or large white kidney of the English writers, that is, one presenting the gross appearances described, but without waxy degeneration, without hypertrophy of the left ventricle, and with the clinical history of chronic Bright's disease. Its occurrence, however, cannot be doubted, nor does Weigert deny it; but its frequency has certainly been overestimated in consequence of failure to recognize the slighter grades of waxy degeneration, in connection with chronic diffuse nephritis.

extensive as to give a very characteristic aspect to the organ. In nearly all doubtful cases its presence or absence can be determined by means of the simple iodine test (see page 57). For microscopical examination iodine and sulphuric acid, and methyl-violet are to be preferred. A slight or moderate waxy degeneration may occur in the kidney without further parenchymatous or interstitial changes. This simple waxy degeneration, however, is so rare that its occurrence is even denied by Cornil and Ranvier. Waxy degeneration of the kidney, when of clinical importance, may be practically considered as associated always with diffuse nephritis. Whether the waxy change is the cause of the nephritis, or whether both are effects of the same cause, are undecided questions which at present do not admit of profitable discussion.

Kidneys affected with waxy degeneration present a variety of gross appearances according to the degree of degeneration and the extent and character of the parenchymatous and interstitial changes. The waxy change may be so slight as not to influence the appearance of the kidney which then presents some one of the forms of chronic diffuse nephritis. Usually, however, careful inspection will reveal in the glomeruli, and perhaps elsewhere, the characteristic translucent appearance of the waxy material. When a large amount of the waxy deposit exists, we have the characteristic appearance of the waxy kidney. The organ is then enlarged, pale, and anæmic. The consistence is firm. The surface is smooth and glistening. The capsule is not adherent. Upon section the cortex is found to be the part chiefly swollen. It presents the same pale aspect as the surface. The pyramids are bluish-red, as in most forms of diffuse nephritis. The cortical striæ are obscured. The translucent Malpighian tufts are visible. The cortex presents a combination, in irregular patches or in striæ, of translucent gray portions with opaque white or yellow portions. The latter correspond to the parts most affected by fatty degeneration, the former to the waxy districts. The more the translucent gray substance predominates, the greater is the extent of the waxy degeneration and the more characteristic of the waxy kidney is the appearance. The more the yellowish parts predominate, the more closely does the appearance approach that of the large white kidney without waxy degeneration.

By the use of iodine it is evident to the naked eye that the favorite seats for the deposit of the waxy material are the glomeruli and the vasa recta. Microscopical examination shows that the capillaries of the cortex and the membranæ propriæ of the tubes, especially of the straight tubes and the loops of Henle, are also often affected. Waxy degeneration of the epithelium of the tubes is described and doubtless occurs, but it is very rare. The deposit, as a rule, is at first in the middle coat of the arterioles and in the capillary walls of the glomeruli. The walls of the affected vessels become swollen and homogeneous. The lumen of the vessels is gradually diminished and may be obliterated. In a similar way the walls of the tubes may be thickened and homogeneous.[1] The nephritic changes are in most respects the same as those described for the preceding variety, and need not here be repeated. It is only necessary to add that hemorrhages are usually absent in kidneys affected with waxy degeneration. Fatty degeneration of the epithelium and anæmia are prominent features. The waxy glomeruli present a more homogeneous appearance, fewer nuclei, and less shrinkage than those involved in

[1] As a rule, both cortex and medulla are the seats of the waxy deposit, but exceptionally one or the other part may be alone involved. There are curious cases of even extensive waxy degeneration in which the glomeruli are unaffected. Of 29 cases examined by Kyber, in 3 the medullary substance was exclusively or chiefly involved, in 8 the degeneration was confined to the cortex, and in 18 both parts were affected. He distinguishes, therefore, three varieties of waxy degeneration of the kidney.

the other forms of chronic diffuse nephritis. There is nothing characteristic of waxy degeneration in the casts found in the tubes.[1]

Waxy degeneration is not confined to large smooth kidneys. It is not very rare to find large waxy kidneys with irregular surface and partially adherent capsule. Small granular kidneys may also be waxy, as will be described below. Waxy kidneys are not accompanied by hypertrophy of the heart. The coincidence of waxy spleen and of waxy liver with this form of kidney disease is an important element in the diagnosis. There are cases, however, in which the change in the kidney is well marked, while that in the liver and in the spleen is insignificant. It may always be inferred that some degree of waxy degeneration of the kidney exists when this change can be recognized in the liver and in the spleen.

III. *The Small Granular Kidney.*—Many writers consider that there are three varieties of this form of kidney, namely, one representing an atrophic stage of the large kidney without waxy degeneration; a second, representing the same stage of the large waxy kidney; and a third being the genuine contracting kidney, of which no stage of enlargement exists. The first two are called secondary contracting kidneys. There is much controversy as to their occurrence. So excellent an observer as Samuel Wilks, whose investigations in this department are among the most objective and important which we possess, says that he has not met with any small kidneys which he regarded as representing a late stage of the large. There seem, however, to be sufficient grounds for recognizing the existence of these secondary contractions of the kidney. Nothing could be more erroneous than the view which once prevailed, that the large kidneys in the natural order of events, if recovery does not take place, necessarily pass into a stage of contraction, and that the majority of atrophied kidneys are preceded by a stage of enlargement. The secondarily contracted kidneys do not usually reach as small a size as the genuine or primarily contracted. It is not rare to find small kidneys with waxy degeneration. Many, if not most, of the small granular kidneys occurring in gout are waxy. It is probable that in most of these cases the waxy degeneration is superadded to a genuine contracted kidney. Some of the small waxy kidneys, however, are better regarded as representing an atrophic stage of the large waxy.

While, then, the existence of secondarily contracted kidneys is admitted, it is the primarily contracted form which is referred to in the remainder of this article under the name small granular kidney. Other names for this variety of chronic diffuse nephritis are, genuine contracting kidney, small red kidney, granular atrophy of the kidney, cirrhosis or sclerosis of the kidney, chronic interstitial nephritis, and chronic desquamative nephritis (Johnson). There is no serious objection to any of these names except to the last. Of all the forms of chronic diffuse nephritis, this is the one which with most propriety may be regarded as a distinct disease, and this is the view now very generally adopted. There are authorities who hold the opinion that renal cirrhosis is not only to be separated from other forms of chronic Bright's disease, but that it is only one manifestation of a general disease affecting the arteries of the body. This view will receive consideration subsequently.

The kidneys, in this form, are reduced in volume and weight. As in all forms of Bright's disease, both organs are involved, and, as a rule, to nearly equal extent. The size may be a third that of the normal kidney, or even

[1] These casts, often called waxy, may stain red with methyl-violet, but they do not give the characteristic reaction with iodine and sulphuric acid. Formless clumps presenting this reaction have, however, been found in the tubes (Kyber).

less. There is usually a compensatory increase of adipose tissue around the kidneys. The organs are abnormally dense and resisting. The capsule is with difficulty detached, and, when removed, brings away portions of the torn renal substance. The exterior surface presents little irregular elevations or granulations. The granulations usually have a yellowish and the depressions between them a reddish color. In many cases the name small red kidney is appropriate. Sometimes, however, the prevailing color is whitish or yellowish. Upon section it is observed that especially the cortical portion is diminished. This is reduced to a narrow rim over the pyramids. In marked cases the pyramids extend nearly to the exterior surface, and their sides are almost in contact. Little cysts, varying in size from a pin's head to a pea or even larger, and filled with a thin fluid or with colloid contents, are frequently observed both on the surface and in the interior. White lines, due to the deposit of urate of soda in the tubes, are not infrequently seen in the pyramidal portion. They are invariably present when the disease of the kidney is associated with gout. Small kidneys with these deposits were called by Todd gouty kidneys. The same deposit of urates may occur independently of gout.

The microscope shows as the most essential change the production in the cortex of a large amount of fibrillated connective tissue. This new tissue is not uniformly distributed, but is in greater amount in some places than in others, and there are usually parts where no thickening of the interstitial tissue exists. Many of the Malpighian tufts are small and fibrous, and are often placed abnormally close to each other in consequence of atrophy of the intervening tubes and retraction of the new fibrous tissue. The rich development of new connective tissue around the shrunken glomeruli may be especially noticeable. An important change in most cases is the growth of fibrous tissue in the walls of the arteries, both in their adventitia (periarteritis) and in their intima (endarteritis). By the obliteration and partial occlusion thus effected of many small arteries and of capillaries in the glomeruli, the circulation through the kidneys must be much impeded. But the bloodvessels are not the only parts that suffer by this new growth of fibrous tissue. The tubes are also compressed, and may be in part obliterated. By this constriction of the tubes in certain places, the flow of urine through them is obstructed, and, being dammed back, causes the cystic dilatations visible to the naked eye. These cysts consist of dilated tubes and of dilated capsules of Bowman. In the latter form of cyst the glomerulus is compressed or entirely obliterated. Although interstitial changes decidedly predominate in this form of kidney, parenchymatous changes are not usually wanting. The atrophy of the epithelium so constantly met with in tubes enveloped in connective tissue, is generally regarded as an effect of compression by the new tissue.[1] Fatty degeneration of the epithelium, although less extended than in the large kidneys, will usually be found in some places. Fat globules may also appear in the interstitial tissue. The tubes within the new fibrous tissue are small, and may be entirely obliterated. Outside of this they are frequently dilated. Hyaline and granular casts are often discovered in the tubes, especially of the pyramids. There may be some increase of the interstitial tissue of the pyramids, but the changes in these are trifling in comparison with the alterations in the cortex.

One of the most constant accompaniments of the small granular kidney is hypertrophy of the left ventricle, unattended usually by valvular lesion.

[1] Weigert, on the other hand, regards this atrophy of the epithelium as an important, if not the essential, element in all forms of chronic Bright's disease. He believes that the production of connective tissue is the result of this atrophy and not its cause.

There may be hypertrophy of the whole heart. The hypertrophy is usually attended by more or less dilatation, but it may be simple. Buhl has pointed out the frequent coincidence of fibrous or chronic interstitial myocarditis in connection with this hypertrophy. Another complication of great frequency and of diagnostic value, is the form of retinitis called retinitis albuminurica, the ophthalmoscopic appearances of which will be described in connection with the symptoms. Both the retinitis and the cardiac hypertrophy may occur with other forms of chronic Bright's disease, but are rarely, if ever, met with in conjunction with the large, waxy kidney. Cerebral hemorrhage and inflammation of serous membranes are also to be mentioned as important complications. Bartels calls attention to the frequent occurrence of thickening of the skull-cap and adhesion of the dura mater to the same. Dropsical effusions are rather the exception than the rule in this form of Bright's disease.

Gull and Sutton regard renal cirrhosis as only one manifestation of a widespread affection of the whole arterial system, to which they give the name arterio-capillary fibrosis. The essential change, according to these authors, is a thickening of the outer coat of the arteries. The disease they regard as mainly one of old age. The hypertrophy of the heart, they urge, is only to be explained by this general arterial disease. Most observers who have studied the subject have been unable to confirm the results reached by Gull and Sutton. They who have found changes in the arteries, describe them usually either as an endarteritis, or as an hypertrophy of the muscular coat. The subject has not received the careful investigation which its importance merits, but thus far the observations have been opposed to the exclusive applicability of Gull and Sutton's theory. There can be no doubt, however, that extensive atheroma of the arteries (arterio-sclerosis), such as occurs in old age, is usually attended by partial atrophy of the kidney, the portion of the cortex immediately beneath the capsule being often contracted and granular. A relation therefore between extensive arterio-sclerosis and atrophy of the kidney is not to be denied. But this or any similar change in the arteries of the body is by no means constantly present in renal cirrhosis. There is not, therefore, sufficient basis for the doctrine that this form of Bright's disease is in all cases the result of primary arterial changes. Moreover, Gull and Sutton have overestimated the influence of old age in the causation, and seem to have overlooked the well-established instances of cardiac hypertrophy in connection with other forms of Bright's disease.

Clinical History. — Chronic Bright's disease sometimes follows the acute affection. This statement applies chiefly, if not exclusively, to the large kidney without waxy degeneration. But, as a rule, the disease is developed imperceptibly, and is, from the first, subacute. In a large proportion of cases, the event which first directs attention to the existence of renal disease is dropsy. Prior to this event the patient for some time may have been sensible of impaired strength, and the appearance may have denoted anæmia; but not infrequently, up to the time when dropsy is noticed, the patient was not aware of any deterioration of health. The first appearance of dropsy is œdema either around the eyes, or in the lower extremities, or in both situations simultaneously. As regards the amount of dropsy and the rapidity with which it increases and is diffused, cases differ. It may exist and remain in so slight a degree that its existence is only ascertained by close examination, and it may escape the attention of the patient. On the other hand, in certain cases, anasarca occurs either rapidly or slowly, the limbs, body, and especially the genitals, becoming enormously swollen, together with more or less effusion into the serous cavities. A convenient place for determining, by pressure with the finger, a small amount of anasarca, is over the sternum. The dif-

ferent forms of disease do not equally give rise to general dropsy. It occurs most constantly, and is most marked, in connection with the large kidney. It is wanting in a certain proportion of cases, and in these cases the most frequent form of disease is the small granular kidney. It is frequently, also, wanting for a considerable period during the progress of the waxy form of disease. Of 89, out of 102 recorded cases under my observation, in which facts respecting dropsy were noticed, it existed in 74, and was absent in 15 cases. The dropsy was slight or moderate in 21, and considerable in 36 cases. In 17 cases the degree and the extent of the dropsy were not noted.[1] Of 430 cases collected from different authors and analyzed by Frerichs, general dropsy existed in 376 and was wanting in 34. As a rule, general dropsy is marked in the cases in which the albumen in the urine is very abundant, and, *per contra*, general dropsy is either slight or wanting in the cases in which the urine contains but little albumen or none whatever.

The examination of the urine is of great importance as regards diagnosis in the different forms of chronic Bright's disease. In the large kidney without waxy degeneration, the quantity of urine excreted within twenty-four hours is diminished, unless the arterial tension be elevated by hypertrophy of the heart, in which case the quantity is normal or even increased. The diminution is rarely as marked as in acute Bright's disease. The specific gravity, as a rule, is high when the quantity of urine is scanty, and low under opposite circumstances. Generally it does not vary much from the normal. The urine of this form of kidney is usually of a yellow color and turbid. The amount of albumen is considerable, and in some cases very large. The daily excretion of urea is lessened. There is generally an abundant sediment which contains casts, epithelial cells, red and white blood-corpuscles, and granular material. Urates may be deposited in abundance. All varieties of casts are found, but the most common are hyaline casts, either narrow or broad, frequently dotted with oil-globules, and granular casts which may also contain fatty molecules. To both varieties of casts, frequently adhere red corpuscles, pus-cells, and epithelial cells, and casts composed wholly of epithelium may be observed. The pus-cells usually exceed in number the red corpuscles, but there are exceptions to this rule. Cells filled with fatty globules (so-called granular or exudation corpuscles) and free fatty granules are often present.

The urine excreted by kidneys affected with waxy degeneration, presents great variations in its characters, this variation being influenced especially by the degree and the extent of the diffuse nephritis which is present, and by the amount of waxy deposit. When the parenchymatous changes predominate, the urine presents the characters belonging to the preceding form. In consequence of the absence of cardiac hypertrophy, the quantity may be greatly diminished, although rarely in the degree belonging to acute Bright's disease. Red blood-corpuscles are absent or few. In no form of Bright's disease is a larger percentage of albumen met with than in these large waxy kidneys with extensive parenchymatous changes. With the typical waxy kidneys, that is, those containing a large amount of waxy deposit and presenting in most parts a pale translucent appearance, the urine is usually abundant, very pale in color, of low specific gravity, clear, and rich in albumen. The specific gravity may fall as low as 1005 or even lower. The quantity of albumen is usually considerable, but may be slight. The daily excretion of urea is below the normal, but the poor nutrition of the patients

[1] *Vide* "A Clinical Report on an Analysis of One Hundred and Two Cases of Bright's Disease," by Austin Flint, M.D., one of the Attending Physicians of Bellevue Hospital, etc., published in the Bellevue and Charity Hospital Reports, 1870, p. 226.

will in a great measure explain this. There is little or no sediment. Casts are not abundant; they are chiefly hyaline and so-called waxy casts. The term waxy cast is often employed synonymously with hyaline cast. When used in a different sense, it refers to broad homogeneous casts of a yellowish hue, and more distinct and refracting than the hyaline. These waxy casts are probably similar in structure to the hyaline; they are not, as the name would imply, composed of waxy or amyloid substance. Exceptionally, however, casts are found which give the same reaction with iodine as the waxy material. The so-called waxy casts are not confined to the waxy kidney, but may be found in the urine of any form of chronic diffuse nephritis. It is this abundant, clear, albuminous, light urine which is considered most distinctive of waxy degeneration of the kidney, but, as already mentioned, its characters are greatly modified by the intensity and the extent of coincident inflammation and by the degree of waxy change. Litten and others have reported cases of even extensive waxy degeneration of the kidneys without albuminuria. In some of these cases dropsy was present during life. We have no satisfactory explanation of the absence of albuminuria in these cases.

The small granular kidneys (renal cirrhosis) sometimes secrete urine which in no way differs from the normal. It is particularly to be emphasized that albumen and casts may be absent from this urine. This is one of the reasons why this form of chronic diffuse nephritis so often escapes detection. The quantity of urine excreted by the small granular kidneys usually exceeds the normal. The polyuria may be so great as to lead to the suspicion of diabetes. The specific gravity is low. It averages about 1010, but may be less. The color is pale greenish-yellow. The urine is clear, there being little or no sediment. The percentage of urea is lessened, as is likewise in most cases the quantity excreted daily. It is not, however, very exceptional to find this quantity equal to that in health. Albumen is usually present in small amount. Its quantity is in striking contrast to that in most other forms of Bright's disease. It may fail altogether, but this is generally only a temporary occurrence. Bartels, however, mentions a case in which albumen was absent throughout the whole course of the disease. Exceptionally, the quantity of albumen is abundant. When a uræmic attack supervenes, the amount of albumen is usually increased. If waxy degeneration be present, there is an increase in the quantity of albumen. Casts may be absent. Careful search will usually reveal a few hyaline casts. Granular casts are much less frequent. Toward the end of life it will usually be found that the quantity of urine is diminished, the amount of albumen is increased, and a sediment containing casts appears. With small kidneys, due to secondary atrophy, the urine has similar qualities to those described, if hypertrophy of the heart be present.

The characters of the urine belonging to the different varieties of Bright's disease are not sufficiently distinctive to justify a positive diagnosis of the form of kidney in all cases. There is no form of cast which is characteristic of any one variety of the disease. In general, it may be said that hypertrophy of the heart and waxy degeneration tend to increase the quantity of urine, and that low arterial tension and active inflammatory changes diminish the quantity. An abundant sediment containing many casts and blood corpuscles, is indicative of an active inflammatory process, particularly of parenchymatous changes. The smaller in quantity the urine, the richer in sediment and in albumen is it, as a rule. It is of importance to estimate the amount of urea excreted daily, for which purpose it is of course necessary to determine the percentage of urea in the total quantity of urine passed in twenty-four hours. The specific gravity affords an approximate, although far from accurate, estimate of the percentage of urea. The specific gravity of a single specimen of urine is manifestly of no value in forming an idea as to the daily

excretion of urea. It is necessary to take into consideration at the same time the quantity of urine voided in the twenty-four hours. A low specific gravity may be compensated by a large daily excretion of urine.

Pallor of the countenance, due to anæmia, is generally more or less marked. The anæmia is, measurably, if not chiefly, owing to the loss of albumen; it is most marked in cases in which albuminuria and general dropsy are marked. It may be an effect of defective nutrition from anorexia or persistent vomiting. In cases of cirrhotic kidney in which albuminuria and dropsy are slight or wanting, pallor is not usually a marked symptom. Œdema and pallor combined, give to the face an appearance highly characteristic of Bright's disease.

Symptoms referable to the digestive system are more or less prominent. Indigestion or dyspeptic disorder is common. Flatulency of the stomach is a frequent symptom. Vomiting is a prominent and persistent symptom in certain cases. It is referable to the vicarious elimination of urinary principles by the gastric mucous membrane. It may be preceded or accompanied by other symptoms denoting uræmia, but it is sometimes the chief uræmic manifestation. The uræmic vomiting occurs when the stomach is empty, and often early in the morning. The acts of vomiting are apt to occur suddenly and violently without much previous nausea. These circumstances connected with vomiting should always excite suspicion of renal disease, although no other symptoms pointing to the kidneys are apparent. Uræmic vomiting not associated with general dropsy, denotes the small granular kidney. The vomiting is sometimes so persistent as to interfere with alimentation and thus induce alarming prostration.

Diarrhœa is a less frequent symptom. It is, however, a prominent and persistent symptom in some cases, either with or without vomiting, or, like vomiting, it may be a uræmic symptom. It may proceed from uræmic intestinal ulceration. It is especially frequent in cases of the waxy kidney combined with waxy disease of the intestine.

Urea is also eliminated vicariously by the skin. The perspiration emits distinctly the odor of urine, in some cases. An intense characteristic odor is given off from the skin by some patients who do not pay any attention to cleanliness. Crystals of urea are sometimes found on the skin. Bartels observed a case in which the full beard of a patient had a frosted appearance from an abundant deposit of these crystals. An occasional symptom is an intense itching of the skin.

Symptoms referable to the respiratory system may be produced by pleural effusion, or hydrothorax, by pulmonary œdema, and by œdema of the glottis. Pleuritic effusion and œdema of the lungs sufficient to occasion notable embarrassment of respiration, are apt to occur more especially when disease of the heart, involving mitral contraction or regurgitation, or both, co-exists with the renal disease. Under these circumstances, the pleural cavities may become nearly filled with serum; œdema of the lungs, under these circumstances, is sometimes the immediate cause of death. The occurrence of the œdema is sometimes very sudden, and it may prove quickly fatal. Not infrequently, however, the œdema disappears, even when life has been placed in imminent danger. Œdema of the glottis is of rare occurrence (according to statistics of Frerichs and of Rosenstein, in only 4 of 292 cases). It may occur when general dropsy is moderate, or slight, or wanting.

Dyspnœa may exist in a marked degree when it is not referable to any of the conditions just named, but proceeding, apparently, from a toxical effect upon the nervous centre presiding over respiration. In these cases the moist râles incident to pulmonary œdema and the dry râles of asthma are wanting. Auscultation and percussion give no signs denoting any pul-

monary affection. I have met with several cases in which this nervous dyspnœa was the most prominent symptom; and I have known it to exist when no other symptom was present to direct attention to the kidneys as the seat of disease. The patients suffer from a feeling of apprehension of "losing the breath," and are afraid to sleep on this account, the exertion of the will being required for respiration. Disturbance of the rhythm of respiration characterized by the frequent occurrence of a long interval between the respiratory acts, followed by series of rapid respirations (Cheyne-Stokes respiration), is not infrequent, occurring in connection with uræmic stupor and coma.

Symptoms referable to the nervous system are among the most important of those belonging to the clinical history of the disease. Pain in the back is rarely prominent, and is generally wanting in chronic Bright's disease. Cephalalgia is a frequent symptom. It may precede, as well as accompany, the symptoms which point to the existence of renal disease. Neuralgic pains in other parts of the body are common; attacks of vertigo are not infrequent. Troubles relating to vision constitute, in certain cases, important symptoms. Diplopia or double vision, hemeralopia or night blindness, myopia, and presbyopia are attributed, and perhaps fairly attributable, to the disease. Including these forms of disorder, it would appear that vision is more or less affected in a pretty large proportion of cases; but, exclusive of these, either obscurity or loss of sight—that is, amaurosis, complete or incomplete—is not of extremely rare occurrence. The amaurosis affects both eyes. When not complete, and it rarely is so, the degree varies in different cases, and in different periods of the same case. In chronic, as in acute, Bright's disease, the impairment of vision may depend on an intra-cranial morbid condition, the ophthalmoscope showing no morbid appearances within the eye. This condition is called uræmic amaurosis. Under these circumstances, it is temporary, and is liable to recur from time to time. I have known it to occur repeatedly, in the same case, as a precursor of uræmic coma and convulsions. More frequently, however, it is connected with changes within the eye, which, by means of the ophthalmoscope, have been brought under clinical observation. In this so-called *retinitis albuminurica* the optic papilla is swollen, clouded, and indistinctly bounded; the retinal veins are tortuous, and white patches appear in different parts of the retina. The most characteristic appearance, however, is the presence of white dots and streaks in the periphery of the macula lutea. "These fine white dottings and radiating lines give the impression of having been splashed on with a feather." The appearances are so distinctive of renal disease, that a practised ophthalmoscopist is led by the former to suspect the latter. It has happened in several cases which have come under my observation, that disease of the kidney was discovered by means of ophthalmoscopic appearances, the patients having first consulted oculists for defect of vision. Amaurosis dependent on neuro-retinitis may diminish, and recovery is possible; but it is almost always persistent, either progressively increasing or remaining stationary after it has reached a certain degree. The development is usually gradual, whereas, the so-called uræmic amaurosis occurs suddenly. The patient describes the defect of vision as like that of a mist before the eyes. Deafness, hemiplegia, paraplegia, and paralysis limited to a single member, have been observed to follow or accompany uræmic coma and convulsions. Muscular cramps are sometimes a source of suffering, and I have known them to constitute the chief ailment for some time before other symptoms directed attention to the kidneys.

The symptoms just mentioned, namely, coma and convulsions, are the most important of those referable to the nervous system. They occur in a pretty large proportion of cases, and are generally forerunners of a fatal termination.

In chronic Bright's disease, as in the acute affection, they proceed from uræmic poisoning; they are, therefore, among the ulterior effects of interference with the secretory functions of the kidneys. They are consequently most apt to occur when the secretory structure of the organs is extensively destroyed, and, hence, especially in connection with the small granular kidney. In acute Bright's disease they always denote great danger, but in chronic Bright's disease the danger is vastly greater.

Coma may precede or follow convulsions; but it occurs in some cases, and death takes place, without the occurrence of convulsions. Occasionally coma occurs suddenly, but generally it is developed gradually, the patient having been more or less somnolent, dull, or lethargic for several days before becoming profoundly comatose. The coma is sometimes quiet and in some cases accompanied by stertor. Marked dilatation of the pupils is sometimes observed. The face is congested, sometimes becoming livid, and death is preceded by tracheal râles. The convulsions are epileptiform in character, varying much in degree and extent in different cases. They occur in paroxysms which may be repeated at short intervals, the patient in the intervals being completely comatose, the convulsions at length ceasing, and the coma continuing until death; or, after a paroxysm or a series of paroxysms, the patient recovers intelligence, and hours, days, weeks, or months elapse before a recurrence takes place. Convulsions not following coma are generally preceded by symptoms referable to the head, such as cephalalgia, vertigo, and mental excitation sometimes amounting to delirium. Contraction or rigidity of certain muscles has been observed to precede convulsions; but they sometimes occur suddenly without any premonitions. Of 70 cases among those which I have analyzed, selecting those only the histories of which embrace either death or recovery, coma or convulsions were noted in 26.

The uræmic phenomena, if neither an acute inflammation nor an essential fever exist, are not, as a rule, accompanied by notably increased frequency of the pulse; the action of the heart is sometimes diminished in frequency; I have known the pulse to fall to 32 per minute. Pyrexia is wanting except in a certain proportion of the cases in which coma and convulsions occur. In some instances, in connection with these events, there is a considerable rise of temperature (105° F.); in other instances the temperature is lowered and it may fall considerably below the minimum of health. The circumstances which occasion these variations are not as yet ascertained. Further study of the temperature in the different varieties of chronic Bright's disease is a desideratum.[1]

Delirium, which has just been mentioned as sometimes preceding convulsions, is occasionally a prominent feature in cases of uræmic poisoning, occurring in connection with both acute and chronic Bright's disease. It is characterized, in some cases, by remarkable hallucinations. The delirium may be quiet, or gay, or sad, and it is sometimes furious or maniacal. Uræmic poisoning, as manifested by delirium, coma, and convulsions, may occur in cases of Bright's disease with abundant general dropsy; but it often occurs in cases in which dropsy is slight or wanting. Of the 26 cases above referred to, in which coma or convulsions occurred, in 11 there was no dropsy. It may follow copious vomiting and purging, but it occurs oftener in cases in which these symptoms are slight or wanting. The symptoms of uræmic poisoning are sometimes the first to direct attention to the kidneys as the seat of disease.

[1] *Vide* Bourneville, Etudes Clinique et Thermométrique sur les Maladies du Système Nerveux, 1872; also, article by McBride, in the Archives of Medicine, New York, Feb. 1880; also, Bartels in Ziemssen's Cyclopædia, vol. xv.

After an attack of uræmic coma and convulsions, there is sometimes complete absence of the symptoms of renal disease, inclusive of the morbid characters of the urine, the disease remaining completely latent, and another outbreak occurring after an intermission of a greater or less duration. These facts were illustrated by the following case: Mr. D., aged 56, while transacting business in a bank, had an apoplectic seizure, followed by epileptiform convulsions. Leeches were applied to the head, and free hydragogue evacuations were obtained promptly by podophyllin and elaterium. On the following day he had emerged from the coma. The urine was found to be albuminous, and to contain hyaline, fatty, and granular casts. On the fifth day he had recovered sufficiently to be carried to his country house, distant seven miles. Both the albumen and casts had now disappeared from the urine. Examinations of the urine, made repeatedly during several weeks, showed always absence of albumen and casts; and, in the mean time, he had regained his accustomed apparent health. Five months afterward, at the card-table with his family, he was seized with coma and convulsions. He emerged but partially from the comatose state, and died on the fourth day after the attack. Examinations of the urine prior to the last uræmic attack, showed the presence of albumen and casts.[1]

As regards uræmic phenomena, different cases present a striking difference in the amount of lesions with which their occurrence is connected. Coma, convulsions, and death may take place when the kidneys are not greatly diseased, and, *per contra*, the amount of disease sometimes becomes very great before any uræmic phenomena are manifested. So, also, there is a great difference in different cases with respect to the relation between the diminution of the excretion of urea, and the effects of its accumulation in the blood. A rational explanation of this difference is given by Johnson.[2] It is, that the occurrence of uræmic phenomena depends much on the rapidity with which the accumulation of urea in the blood takes place. *Cæteris paribus*, uræmia is quickly induced if the urea accumulate rapidly. On the other hand, if the accumulation take place slowly, the system acquires a tolerance of urea, as of other toxic substances, and hence, fatal uræmic effects may be for a long period postponed. Another explanation has reference to the production of urea in the system. This will vary within wide limits according as the ingestion of nitrogenized food is small or abundant, and also according to the amount of muscular exercise. It is a matter of clinical observation that uræmic manifestations are less frequent with than without dropsy. Bartels finds an explanation of this fact, in a measure, in the amount of urea contained in the dropsical effusions. The elimination of the urea renders the dropsy, to a certain extent, protective against uræmia.

The complications of the disease form an important part of the clinical history. Several affections included among the symptomatic events, might be considered in the light of complications, namely, œdema of the lungs, œdema of the glottis, and amaurosis. Other secondary affections are pericarditis, peritonitis, pleuritis, and cerebral meningitis. Of these, pericarditis and pleuritis occur oftener than other inflammations of serous membranes. They are secondary especially to the small granular kidney.

Hypertrophy of the left ventricle of the heart is developed in connection with the small kidney. It may be a secondary affection in cases of the large kidney, but not in cases of the waxy kidney. If not associated with valvular lesions, hypertrophy of the left ventricle renders extremely probable the

[1] For cases illustrating the latency of renal disease, *vide* Bellevue Hospital Clinical Reports, *op. cit.*

[2] *Vide* London Lancet, Am. ed., Jan. 1857, p. 13.

existence of renal disease. The hypertrophy may not give rise to any subjective symptoms, and will therefore be overlooked if the rule be not adopted of always making a physical examination of the chest. With hypertrophy of the heart is associated a hard, resistant pulse, indicating high arterial tension. In my analysis, out of 26 fatal cases in which the condition of the heart was noted, in 11 there was more or less enlargement without valvular lesions. Cirrhosis of the liver and fatty liver are not infrequently associated with Bright's disease, but they are to be considered as concomitant, not secondary, affections. This statement is applicable to waxy liver and waxy spleen, which, in a very large proportion of cases, accompany the waxy form of disease of the kidneys. Waxy disease of the alimentary canal co-exists in a certain proportion of cases. Cerebral hemorrhage, although not of frequent occurrence, occurs sufficiently often to show a pathological connection. It is a complication of the small granular kidney oftener than of the other forms of renal disease. Pulmonary phthisis is a complication of the waxy kidney sufficiently often to show a pathological connection; this does not hold true of the other forms of renal disease. The researches of Fenwick and Wilson Fox show that the appearances after death denote often gastritis. This may be attributed to the presence of decomposed urea in the stomach. Gastritis occurs especially as a complication in cases of the small granular kidney. Epistaxis and hemorrhages in other situations may be here mentioned as of not infrequent occurrence.

Chronic rheumatism is sometimes associated with chronic Bright's disease. It may, however, be doubted whether it occurs often enough to establish any pathological connection. Todd, and other British writers, have observed the frequent association of gout and the small kidney. This form of Bright's disease was called by Todd the *gouty kidney*. Gout in this country is, comparatively speaking, a rare disease, but the small kidney is by no means extremely rare. The union of these diseases is not of frequent occurrence with us.

Pathological Character.—With the description of the anatomical appearances, the grounds for regarding chronic diffuse inflammation of the kidneys as the basis of all forms of chronic Bright's disease have been given. It has been made apparent that there are no essential pathological differences between the large and the small kidney (that is, between the so-called chronic parenchymatous nephritis or large white kidney, and the chronic interstitial nephritis or contracted granular kidney). In both we have interstitial inflammation, atrophy of the tubes, and parenchymatous and fatty degenerations of the epithelium. But in the small kidney the interstitial processes and the atrophy predominate, and in the large kidneys, while these changes are not absent, swelling of the epithelium from parenchymatous and fatty degenerations is more prominent. Exceptionally, however, there are large kidneys in which the increase of interstitial tissue is apparently as marked as in some small kidneys. It is of great importance to recognize the waxy deposit whenever it is present. Especially, in all cases of chronic diffuse nephritis without hypertrophy of the heart, should careful search be made for the waxy degeneration. A diffuse nephritis is an almost constant accompaniment of this degeneration. The former may, however, be absent, particularly in the slighter grades of the latter. The difficulty of making a useful and correct classification of the different cases of chronic Bright's disease, has been emphasized in view of the facts that every degree of combination of parenchymatous and of interstitial processes may exist, that waxy degeneration may appear in both large and small kidneys, and with marked, or with slight inflammatory changes, and that every grade of transition exists between

the very large and the very small kidney. It is possible, however, to separate certain types of chronic diffuse nephritis, which, when considered by themselves, are sufficiently distinct, and it is upon this basis that the classification adopted in this work has been made. It must not be forgotten that the forms of kidney which have been distinguished merge into each other by intermediate forms which are often difficult to classify. The small kidney, while including atrophic stages of the large, either with or without waxy degeneration, is represented chiefly by the primarily contracted form. The chronic parenchymatous nephritis, or the large white kidney of other authors, corresponds to the large kidney without waxy degeneration. There is reason to believe that not a few of the cases described by the former names are also represented by that modification of the large kidney with waxy degeneration in which the yellowish-white color of the fatty degeneration predominates over the translucent gray color of the waxy material.

Albuminuria, dropsy, and uræmia are common to both acute and chronic Bright's disease. Reference has been made to the mode of their production under the pathological characters of the former disease. Hypertrophy of the heart is a symptom which does not appear in the acute disease. There are many theories and much controversy as to the cause of this hypertrophy. We possess no satisfactory explanation of its production. The majority of those who have treated the subject, regard the hypertrophy as dependent upon the renal disease, although as to how the latter leads to the former there are various hypotheses. But there are authorities who hold the opinion that the cardiac hypertrophy and the kidney disease are co-ordinate results of a common cause, neither being dependent upon the other. The leading theory based upon the latter view is the one advocated by Gull and Sutton, which at present has many adherents. These writers consider hypertrophy of the heart as occurring only in connection with the small granular kidney. The primary disease, according to their doctrine, is an affection of the whole arterial system, and is called arterio-capillary fibrosis. In consequence of thickening of their coats, the calibre of the diseased arteries is diminished; the resistance offered to the circulation is increased; the arterial tension is consequently elevated, and, as a result, the left ventricle hypertrophies. The changes in the kidney are also, they believe, the sequence of similar disease of the branches of the renal artery. The objections to this theory are the following: 1. Gull and Sutton's description of changes in the arteries has not been satisfactorily confirmed, and competent observers have failed to discover in some cases of small kidney with hypertrophied heart any alterations in the general arterial system; 2, this theory does not explain the cardiac hypertrophy sometimes observed with the large kidney, and rarely with double hydronephrosis.[1] There are two leading theories as to the dependence

[1] That general atheroma may lead to atrophied kidneys has already been mentioned. It is not improbable that a similar result may follow a general syphilitic endarteritis. But, as urged by Cohnheim, it is in these cases that hypertrophy of the heart is not infrequently absent in consequence of the poor nutrition of the body. Ewald, who examined a large number of cases with reference to Gull and Sutton's theory, failed to find arterio-capillary fibrosis, but discovered often hypertrophy of the muscular coat of the arteries. To this hypertrophy of the media Johnson had previously called attention. Ewald regards this hypertrophy as consecutive to the cardiac hypertrophy; Johnson attributes it to impurities in the blood from the impairment of the renal functions. Grawitz and Israel claim to have produced hypertrophy of the heart experimentally in animals by extirpation of one kidney. In young animals no hypertrophy follows. A modification of Gull and Sutton's view is that disease of the arteries is present, but that it is not of the character described by these authors. It is either an hypertrophy of the media or a thickening of the intima, according to these modified views.

of the hypertrophy upon the renal disease. According to one, which was advocated by Bright, the urinary constituents (urea especially) which accumulate in the blood in consequence of imperfect performance of the renal functions, render more difficult the circulation of the blood through the small vessels, particularly the capillaries, and by thus raising the blood-pressure cause hypertrophy of the heart. The objection to this view is that cardiac hypertrophy is most frequent and reaches the highest degree in connection with the small granular kidney, with which there may be, for a long time, little or no diminution in the excretion of urea or other constituents of the urine. The other theory was advanced by Traube. According to it the obstruction to the flow of blood through the kidneys causes elevation of the arterial tension and hypertrophy of the heart. That the circulation through kidneys affected with chronic diffuse inflammation is obstructed can hardly be doubted. It is difficult, however, to understand in what way an obstruction, comparatively so small, can raise the general blood-pressure, when it is a matter of experience that the circulation through a much more extensive vascular tract may be obstructed or destroyed without a similar result.[1]

However produced, the hypertrophy of the heart is an important conservative process. It compensates in a remarkable degree the disturbance of the renal functions incident to the small granular kidneys. The fact that notwithstanding the destruction of a large amount of renal parenchyma these kidneys secrete a normal or even increased amount of water, and not infrequently a nearly normal quantity of solids, is explained by the high arterial tension in the diseased organs, and this tension could not be maintained without increased force of the heart. The compensation is, however, less complete for the excretion of the solids, than for that of the water of the urine. The beneficial effects of this compensatory hypertrophy are made evident when from any cause (for example fatty degeneration) the cardiac muscle becomes insufficient. Then the quantity of urine becomes small, the excretion of solids is still further diminished, and the danger of uræmia is great.

Causation. — In a small proportion of cases, chronic Bright's disease follows the acute affection. The causes, in these cases, are those which give rise to the latter. Exclusive of these cases, the causation is often obscure. In a considerable proportion of cases, there are no symptoms denoting impaired health prior to the manifestations of the renal disease, that is, prior to either dropsy or uræmic symptoms. This was true in 30 of 53 cases, among those which I have analyzed, information on this point being contained in the histories of these 53 cases. In 6 of these 30 cases, uræmic coma or convulsions occurred either when the patients were supposed to be in good health, or when these events were preceded by other ailments only for a period not longer than three or four days. In the 23 cases in which ailments

[1] Cohnheim, who accepts Traube's explanation in a modified form, takes the ground that the amount of blood sent to the kidneys depends upon the quantity in it of substances capable of exciting the urinary secretion (harnfähige Substanzen), and that therefore the conditions of the circulation in these organs are different from those in any other part of the body. If the circulation in other parts of the body be obstructed, the superfluous blood is either eliminated or goes to parts which can act vicariously for the obstructed districts; but this compensation, he thinks, does not take place when both kidneys are diseased. No mention is made in the text of that part of Traube's theory, which refers the high arterial tension, in part, to hydræmic plethora, although this view of the causation is urged in a recent paper by Bamberger. This abnormal accumulation of water in the blood is not proven to exist; the conditions for it do not seem to be afforded by the small granular kidneys; the experiments of Cohnheim and Lichtheim have rendered it improbable that hydræmic plethora raises the blood-pressure.

preceded the manifestations of renal disease, excluding the cases in which other diseases existed, the patients had complained of general debility more or less marked for a period ranging from a few weeks to several years. It is probable that, in many of the cases in which the manifestations of renal disease occurred in persons apparently in good health, the urine would have been found for weeks, or months, possibly even for years, to furnish proof that the kidneys were not healthy. The disease occurs very rarely in infancy and childhood. The disease is also infrequent in old age. In the vast majority of cases the patients are either young or in middle life. My analysis of 102 recorded cases showed not a single case under fourteen or over seventy years of age. One patient only was 70 years of age. The mean age was 34 years. A difference relating to age exists between the different forms of renal disease. The large kidney occurs especially in early life, although extremely rare under two years of age. On the other hand, the small kidney is seldom developed in early life. It is most apt to occur in the neighborhood of fifty. Men are much oftener affected than women. Of my 102 cases, 67 were males and 35 females. As regards habits of intemperance, of the 102 cases which I have analyzed, in 38 the histories contained information on this point. In nearly all these cases the patients were males. In 18 cases the habits, as regards the use of alcoholic stimulants, were good; in 13 cases the patients were spirit-drinkers and intemperate; 3 patients were moderate drinkers; 4 drank malt liquors freely, and in one case it was simply noted that the patient was a "free-liver." So far as these facts go, they certainly do not show any special causative influence pertaining to the use of alcoholic stimulants. It is probable that the abuse of alcoholic beverages contributes to the production of the disease, but it is also probable that their direct agency has been much over-estimated. Clinical observation in this country certainly does not warrant the name *spirit-kidney*, as applied to the small kidney by Goodfellow. The disease is much oftener observed in hospitals than in private practice among the better classes of society, a fact going to show that the exposures, hardships, and deprivations incident to the lives of those who seek for hospital relief in illness, are involved in the causation. Persons whose occupations involve exposure to cold and wet are more liable to be affected than those who are protected against the vicissitudes of weather. Cases are more numerous in humid, marshy climates, and on the sea-coast, than in dry, elevated, and inland situations. Malaria is supposed to be a causative agent, but, of 78 cases observed in situations in which intermittent fever was of frequent occurrence, this disease had existed antecedently to the renal affection in only ten. Dickinson shows by statistical data that chronic Bright's disease, more especially the small granular kidney, is of more frequent occurrence in temperate than in either cold or tropical countries, and that variableness, as regards temperature and humidity, favor its production.

It may be developed in the course of various other diseases. It is sometimes developed during the progress of pulmonary tuberculosis, but, exclusive of the waxy kidney, the proportion of the cases in which after death tubercle in the lungs or elsewhere is found to be associated, is perhaps not greater than in fatal cases of other diseases. Of the cases of the waxy kidney, pulmonary tuberculosis exists in a considerable proportion, and it precedes the renal disease sufficiently often to denote a causative influence. The waxy kidney is developed secondarily to syphilis in such a proportion of cases as to show that the latter has a causative agency. Caries and necrosis of bones, ulcers of the intestine and in other situations, and chronic suppuration in any part have a relation of causation to this form of renal disease. Todd, Garrod, and other British authors have observed the frequent occurrence of the small

kidney in persons affected with gout. That the latter affection is often involved in the causation is doubtless true; but the connection is by no means sufficiently constant to warrant, as a distinctive title of this form of renal disease, the name "gouty kidney." Facts show that the absorption of lead into the system may lead to the development of the small kidney.

Chronic Bright's disease not infrequently supervenes in protracted cases of diabetes mellitus. In these cases the latter is probably causative. In some of these cases there is a remarkable tolerance of the disease of the kidneys, but in some cases the renal affection has a rapid course, life being speedily destroyed by uræmic coma.

Diagnosis.—The diagnosis of chronic, as of acute, Bright's disease, is to be based on the evidence afforded by examinations of the urine. It is always to be borne in mind that transient albuminuria is a symptom occurring in the course of many diseases. Albumen in the urine is found in cases of all the essential fevers, inclusive of lobar pneumonia, diphtheria, erysipelas, etc. etc. In these connections it denotes hyperæmia of the kidneys, or parenchymatous degeneration. Generally the amount of albumen is small. On the other hand, it is to be borne in mind that albuminuria is not an invariable symptom in cases of chronic Bright's disease. Nor is the presence of a few casts a sure sign of Bright's disease. These may be found in other conditions both with and without albuminuria. In general, the diagnosis is rendered sufficiently easy and positive by persistent albuminuria and casts of the different kinds which have been described, together with dropsy and other diagnostic symptoms; but the occasional latency of the disease, exclusive of symptoms referable to the urine, is not to be lost sight of. Not very infrequently albuminuria and casts show disease to exist when dropsy and other diagnostic symptoms are wanting. The disease is always to be suspected in cases of coma or convulsions, of cephalalgia, or neuralgia in other situations, of vertigo and other forms of cerebral disorder, of amaurosis and other forms of paralysis, of serous inflammations, of persistent vomiting or purging, of anæmia and impaired muscular strength, whenever the etiology is not otherwise intelligible. In short, it is a good rule in practice to examine the urine in all cases, whether symptoms point to the kidneys or not, and repeated examinations should be made whenever there are any grounds for a suspicion of the existence of renal disease. To determine the co-existence of Bright's disease, or to exclude this disease, in all affections, is of much importance. Of course, the urine is to be examined repeatedly in order to ascertain the persistency of albumen or casts, together with other morbid changes.

A difficulty in the way of determining the particular forms of chronic disease represented in individual cases, is the fact that the different forms are not infrequently combined. In typical cases of each form, however, the diagnostic points are sufficient for the differential diagnosis. These points, which have been already presented in the clinical history and causation, are as follows:—

1. *The Large Kidney without Waxy Degeneration.*—The existence of this form is probable whenever the chronic follows the acute disease. In trusting exclusively to this diagnostic point, however, there would be a liability to error arising from the fact that the acute disease may occur in a patient already affected with either the small or the waxy kidney. Much or considerable general dropsy, assuming that cardiac lesions are not involved in its causation, denotes the large kidney. A scanty secretion of urine, with a large proportion of albumen, and the specific gravity not low, has the same significance. Hypertrophy of the left ventricle of the heart, without valvular lesions, may occur in this form of Bright's disease, when the affection is of

sufficient duration. The amount of urine is then increased. Uræmic phenomena, namely, coma and convulsions, cephalalgia, impaired vision, vomiting, diarrhœa, and inflammation of serous membranes, are of less frequent occurrence than in cases of the small kidney; and when they occur they are preceded by the symptoms which are diagnostic of the large kidney. Anæmia is constant and often exists to a marked degree. The youth of the patient is a point in favor of the large, as contrasted with the small, kidney. The absence of phthisis and gout are points of some weight.

2. *The Small Granular Kidney.*—In this form the disease not infrequently is latent as regards any obvious symptoms prior to uræmic manifestations. The minor manifestations, namely, headache, vomiting, impaired vision, etc., may be the first to occur; or those of a graver character, namely, coma and convulsions, pulmonary œdema, pericarditis, may occur without any antecedent events pointing to renal disease. Uræmic phenomena are much more frequent in this form than in the other forms. Dropsy is often wanting, and rarely exists to much extent. The urine is usually increased considerably in quantity (polyuria); its specific gravity is low; albuminuria is often slight, and at times may be wanting. The characters of the pulse which denote arterial tension and hypertrophy of the left ventricle, are so common in this form, and comparatively so infrequent in the other forms, that they have much weight in the differential diagnosis. The age of the patient has diagnostic weight; in the great majority of cases the age is between 40 and 60. The co-existence of gout or of lead-poisoning has a bearing upon the differential diagnosis.

3. *Waxy Kidney.*—Important diagnostic points relate to causative and co-existing diseases. Antecedent to the renal affection are phthisis, disease of bone, suppurations, ulcers, or syphilis. Enlargement of the liver and spleen from waxy disease is often associated. The urine exceeds the normal quantity. It is pale, clear, and of low specific gravity. Albuminuria is rarely absent, but it is variable as regards its degree, the quantity of albumen being usually less than in cases of the large kidney, and more than in cases of the small granular kidney. Anasarca is more frequent and marked than in the small granular kidney, but less so than in the large kidney. Hydroperitoneum may be out of proportion to the general dropsy owing to co-existing disease of the liver. Diarrhœa is a frequent symptom pointing to waxy disease of the intestine. Hypertrophy of the left ventricle does not occur as secondary to the renal affection. Both the minor and the grave manifestations of uræmia are less frequent than in cases of large kidney without waxy degeneration, and much less frequent than in cases of the small granular kidney. This form of disease may occur at any age, but it is rare in very early and in advanced life. The diagnostic points which have been mentioned apply to the typical waxy kidney. In cases in which parenchymatous changes predominate over the waxy, the urine may be scanty, very albuminous, and may contain a large number of casts. Dropsy is then usually very marked. In other words, some of the large kidneys with waxy degeneration give the clinical history usually ascribed to large white kidneys.

Uræmic coma, with or without convulsions, sometimes occurs suddenly in persons not known to be affected with renal disease. To determine that the attack is due to uræmia in these cases, the urine is to be examined with reference to albumen, the presence of casts, the specific gravity, and the quantity, as soon as practicable; and the catheter should be resorted to, if necessary, in order to obtain a specimen with as little delay as possible. Apoplexy, congestive or from extravasation of blood, meningitis, epilepsy, and alcoholism are the affections to be excluded in cases of uræmic coma occurring suddenly, or when the previous history cannot be ascertained.

Prognosis.—In a large proportion of cases, the different forms of chronic Bright's disease destroy life sooner or later, if the patient be not cut off by some intercurrent affection. The duration in fatal cases varies greatly in different cases. It is difficult, in many instances, to determine the actual duration, because the disease is usually developed imperceptibly, and has existed for a greater or less period before its manifestations are observed. Dating from the time when its existence is declared, the fatal termination may take place in a few hours on the one hand, and, on the other hand, the disease may continue many years. Although recovery does not take place, not infrequently the progress of the disease is stayed, or it progresses imperceptibly; the prominent symptoms may disappear, and the patient may have comfortable health for an indefinite period, albumen and casts sometimes disappearing from the urine. The kidneys, like other important organs, such as the heart, liver, lungs, etc., may be damaged to a certain extent, and still be competent to fulfil their functions sufficiently for the continuance of life and health.

A fatal termination is frequently due to accidents or secondary affections, such as pneumonia, pericarditis, œdema of the glottis, cerebral hemorrhage, etc. Co-existing disease of the heart, of the liver, or of other important organs, often hastens the fatal termination. The prospects of improvement will also depend much on the general condition of the system. As regards the mode of dying, it is by apnœa in some cases, and in some cases purely by asthenia. In the former cases, uræmic coma, hydrothorax, pulmonary œdema, or œdema of the glottis, are the immediate causes of death. In the latter cases, long-continued and excessive general dropsy, persistent vomiting, or complete loss of appetite and digestion, precede death, symptoms of uræmic poisoning being absent. Of 45 fatal cases among those which I have analyzed, in 18 the death was attributable to uræmic coma or convulsions; in 6 cases the death was due to exhaustion irrespective of complications, and in 21 cases the causes of death related, measurably or entirely, to complications or intercurrent affections.

Examinations of the urine furnish important prognostics. If the urine continue to be loaded with albumen, this, in conjunction with persisting dropsy and marked anæmia, denotes that the disease will probably not be of very long duration. Danger from uræmia is to be apprehended in proportion to the deficiency of urea in the urine. A scanty secretion of urine and a low specific gravity point to imminent danger in that direction.

The prognosis is not the same in the different forms of chronic Bright's disease. It is most unfavorable in cases of the small granular kidney; yet, it is certain that, with the kidneys considerably damaged from this form, life may continue with comfortable health for an indefinite period. The form of disease represented by the large kidney without waxy degeneration, may exist to a greater or less extent and recovery take place. Bartels cites cases in which there was complete recovery from the waxy kidney. The changes in the small granular kidney do not admit of restoration. Whatever may be the form of disease, it is to be borne in mind that the kidneys may be damaged to an extent equivalent to the loss of the whole of one of the organs, and the remaining portion be quite sufficient for life and health.

Of my 102 recorded cases, in 77 the histories extended to either death or a condition which was considered as denoting recovery, and of these 77 cases, in 22 the latter termination was noted. In a few of these cases, the affection was acute, and in some, instead of a permanent recovery, there may have been only a temporary suspension of the symptomatic phenomena. Making due allowance for these cases, the result of the analysis affords encouragement to hope for recovery in not an insignificant proportion of cases of chronic Bright's disease; and in many cases may be entertained the hope of an arrest of further progress of the disease.

Treatment.—In certain cases of chronic, as well as of acute, Bright's disease, therapeutical indications relate to general dropsy and uræmia. General dropsy, when great or considerable, calls for the same measures as in cases of the acute disease. In general, hydragogue cathartics constitute the most efficient and reliable means of affording relief. If the dropsy be slight or moderate, the saline cathartics may suffice, namely. the sulphate of magnesia or soda, or the citrate of magnesia; but if the dropsical effusion be large, more active hydragogues are required, namely, elaterium, gamboge, or the bitartrate of potassa with jalap. The acrid or drastic cathartics are to be avoided. The hydragogue may be given in doses sufficient to produce free purging, and repeated after intervals of two or three days, or it may be continued in small doses daily, so as to keep up a moderate draining away of liquid. Elaterium is sometimes well borne in doses sufficient to produce a few watery evacuations daily for a considerable period. When it is important to obtain an efficient hydragogue effect as promptly as possible, the elaterium is invaluable. It may be prescribed in doses of from one-sixteenth to one-fourth of a grain hourly until the cathartic operation begins. It should then be at once suspended, in order to avoid vomiting. There is an unnecessary apprehension, in the minds of many physicians, of dangerous prostration from the use of this drug. I have been led by a pretty large experience to consider it safe, employed in the manner just stated. I have repeatedly seen a very marked result from croton oil when a prompt and efficient effect is important. This drug acts as a hydragogue, but it is also drastic in its operation, and the cathartics which are more purely hydragogues are to be preferred.

Diuretics are much less reliable than hydragogue cathartics. Frequently the kidneys will not respond to them, but in some cases they act efficiently. Experience shows that they may be tried without risk of doing harm. The bitartrate of potassa in doses not large enough to purge, or the acetate of potassa, may be given in conjunction with infusion of digitalis, the infusion of broom, or other vegetable diuretics. I have known the infusion of parsley root (Petroselinum) to be remarkably effective as a diuretic remedy. If the state of the stomach and bowels preclude the internal use of diuretics, their external application may be tried after the plan proposed by Christison, namely, an infusion of digitalis ℥j in water ℥xx, applied to the abdomen by cloths soaked in it, or by the *spongio-piline*. I have known this application to be followed by copious diuresis and disappearance of the general dropsy. A liniment of digitalis, iodine, and squill rubbed over the abdomen and limbs will, in some instances, increase notably the quantity of urine. If continued, however, it is apt soon to excite soreness of the skin. As regards digitalis, it may be useful, in certain cases, not only as a diuretic, but by limiting the production of urea. Experimental observations by Mégevaud and Rabuteau, under the direction of Robin, of Paris, showed a marked diminution of urea in the urine as an effect of this drug, this effect being greater in proportion to the retardation of the circulation which the drug occasions. The inhalation of the vapor of juniper has proved useful as a diuretic, in some cases under my observation, when remedies were not tolerated by the stomach. The vapor may be produced by dropping 30 minims of the oil on a sponge dipped in hot water and squeezed. The inhalation may be repeated several times daily.

Sudorifics must be relied upon if hydragogue cathartics be not borne, and if the kidneys do not respond to diuretics. The hot-air bath—that is, heated air introduced under the bedclothes—is the most efficient mode of producing diaphoresis. This may be produced in alternation with cathartics or diuretics. Patients often express a sense of marked relief after perspiring freely under the use of the hot-air bath, but in some cases it occasions a dis-

agreeable heating of the surface without free perspiration, and, if carried too far or repeated too often, it produces prostration. Experience in individual cases must be the guide as to its utility and the extent to which it should be carried. The warm bath, perspiration being kept up for some time afterward by covering the patient with an abundance of clothing, may be employed as a substitute for the hot-air bath when the latter cannot be conveniently employed, or when its operation is unsatisfactory. Jaborandi or its alkaloid, pilocarpin, sometimes acts efficiently as a diaphoretic remedy, but is less reliable than the sudorific measures which act directly upon the skin.

In cases of excessive distension of the integument of the lower limbs and genitals, temporary relief may be obtained by making numerous minute punctures of the skin with a pin, the punctures being so superficial as not to draw blood. The amount of water which drains away through these imperceptible punctures is surprising. This method is to be preferred to deep punctures or incisions, which are apt to lead to erysipelas and gangrene.

Hydragogue cathartics, diuretics, and sudorifics are the means, also, for the elimination of urea in the cases in which symptoms denoting uræmia are present. If uræmic poisoning be manifested by coma or convulsions, diuretics are too uncertain to be depended upon. Active hydragogues and the hot-air bath are indicated. Impending death is to be warded off only by the prompt and efficient action of these measures. We have no knowledge of remedies which will neutralize the toxical properties of urea accumulating in the blood. Elimination, so as to reduce the quantity below the amount requisite to produce poisoning effects, is the only resource. It is a therapeutical object to forestall the development of uræmia sufficient to give rise to poisoning effects in the cases in which an examination of the urine shows a notable deficiency of urea, or an examination of the blood-serum shows an excess of this excrementitious principle. A moderate hydragogue action may be maintained for this object, or the hot-air bath may be employed once or twice daily. Under these circumstances diuretics may be adequate if the kidneys respond to them. It might be supposed that diuretics are objectionable on the score of their increasing the excretion of albumen in the urine. Experience shows that they do not produce this effect; although the quantity of urine is augmented, the amount of albumen is generally not greater than before, and it may even be diminished.

So far the treatment relates, not to the disease itself, but to its effects. There are no special remedies to be employed for the removal of the morbid conditions of the kidneys. Certain remedies have been supposed to have a curative effect, namely, the tincture of cantharides, nitric acid, and preparations of mercury. Experience has failed to establish the efficacy of these or other remedies addressed directly to the kidneys. The iodide of potassium (from 20 to 30 grains daily) was recommended by Bartels in cases of the small and waxy kidney, but with a confession of inability to bring forward evidence of its usefulness except in a single instance. His recommendation is based on the supposed value of this drug in restraining hyperplastic connective-tissue growth in other parts. Remedies, however, indicated by morbid conditions associated with the renal disease, are often of much utility. Anæmia, which is especially associated in cases of the large kidney, calls for chalybeates and tonics having reference to improvement of appetite and digestion. Dyspeptic disorders claim appropriate remedies. Antecedent and co-existing affections which may have caused the renal disease or which may contribute to its progress, furnish therapeutical indications. This statement applies particularly to the waxy kidney, but measurably to the other forms. The maxim that, to improve to the utmost possible extent the general health of the patient is to promote the restoration from, and the tolerance

of, a local lesion which may be irremediable, is an important maxim in its application to chronic Bright's disease.

Hygienic measures are of the first importance. Alimentation as abundant and nutritious as the powers of digestion will admit of, clothing to secure uniform warmth and activity of the functions of the skin, and such an amount of out-door life as the strength of the patient will bear, constitute the hygienic management. In all cases, taking into view the correlation of the cutaneous and renal functions, attention to the skin is of special importance. Travelling and especially long sea-voyages have been found highly useful. The fact that renal disease is infrequent in tropical, and also in cold, climates, renders it desirable, in certain cases, for patients to exchange for these climates one which is unfavorable from its variability and humidity. Experience has shown the utility of this measure.[1] It is hardly necessary to add that all causes of debility or disorder are, as far as possible, to be removed. Overtasking of body or mind, exposure to vicissitudes of weather, the use of alcoholic stimulants (save as a means of aiding appetite and digestion, and taken for these objects, if at all, very sparingly), venereal indulgences, and dietetic imprudences, are to be interdicted.

Symptoms, other than those already referred to, in certain cases call for treatment. Cephalalgia and neuralgic pains in different situations call for palliative measures. With regard to the use of opium to relieve pain, or procure rest, some writers have inculcated the importance of great circumspection, under the belief that, even in moderate doses, this drug is liable to produce undue, and even fatal, narcotism, if the blood be surcharged with urea. Apprehensions on this score have been greatly exaggerated, if, indeed, there be any foundation for them. I have known opium to be taken, habitually, in large doses, for several months, for vomiting and diarrhœa, the urine being loaded with albumen, and the dropsy very great, and, so far from its being injurious, life was apparently prolonged by its use. There is reason to believe that opium renders the nervous system more tolerant of the uræmic poison.

Vomiting and purging, if excessive, claim interference, but it is to be recollected that generally these symptoms denote the vicarious elimination of urea through the alimentary canal. It would be injudicious to attempt to arrest the eliminatory process in this direction, but, as excessive vomiting and purging preclude adequate alimentation, palliative measures are to be employed. Relief may be procured indirectly by favoring elimination through the cutaneous surface by means of the hot-air bath. Direct palliation may be obtained by pieces of ice taken into the stomach, by rubefacients or dry cups applied to the abdomen, and by the internal use of hydrocyanic acid, creasote, the oxalate of cerium, and the preparations of bismuth. The latter are often highly useful. The dilute sulphuric or the hydrochloric acid, given with a view to neutralize the ammonia, is recommended by Johnson.

Astringent remedies have been much used with a view to restrain the excretion of albumen in cases in which the urine is highly albuminous. Gallic acid, the acetate of lead, and the astringent preparations of iron, have been used for this purpose. I have repeatedly made trial of gallic acid for the end just stated, but with little or no effect.

It has been claimed by Donkin that the skim-milk treatment effects a cure in cases of the large kidney, and that marked benefit is derived from it in the other forms. These claims in behalf of this treatment have not been substantiated, but there is evidence of its utility in certain cases. It may be tried, but if the symptoms do not, within a short period, show its utility, it

[1] *Vide* Dickinson, *op. cit.*

should not be persisted in. Buttermilk is sometimes preferred by patients. Owing to the loss of the albumen in the blood, from its elimination by the kidney, it is important, if the degree of albuminuria be great or considerable, to make up this loss by a highly albuminous diet.

The treatment of complications, such as serous inflammations, or of affections which may be accidentally associated with chronic Bright's disease, is to be modified by the co-existence of the latter. Active measures, which, under other circumstances, might be admissible, are contra-indicated. General or local bloodletting, mercury, and other depressing measures, as a rule, are injudicious. If there be exceptions to this rule, they are of rare occurrence.

In conclusion, the management, as has been seen, does not embrace special medication, but, in addition to remedies for particular symptoms or effects, and the treatment of concomitant affections, it consists, in a great measure, in the removal of morbific causes and in hygienic regulations. The object is not to effect recovery from damage that has been done, but to prevent further injury of the diseased organs, recollecting that the existence of a certain amount of disease is not incompatible with the continuance of life and comfortable health for an indefinite period. The advantage of an early diagnosis is very great in this disease. The same consideration is applicable here as in cases of pulmonary tuberculosis, namely, inasmuch as the object to be hoped for is an arrest of the progress of the disease, the earlier its existence is ascertained, the less will be the amount of damage before the disease is stayed.

CHAPTER II.

ACUTE INTERSTITIAL OR SUPPURATIVE NEPHRITIS. DISEASES OF THE URINARY PASSAGES. PERINEPHRITIC ABSCESS.

Suppurative Nephritis and Pyelitis—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Hydronephrosis. Renal Colic and Nephro-Lithiasis. Perinephritic Abscess.

Acute Interstitial or Suppurative Nephritis and Pyelo-Nephritis. Pyelitis.

INFLAMMATION of the mucous membranes of the renal pelvis is called pyelitis. The most common form of suppurative nephritis is that in which a number of small abscesses are present in one or both kidneys. This disease is also called acute interstitial nephritis, and, when there is coincident inflammation of the renal pelvis, pyelo-nephritis. It is sometimes called the surgical kidney, because pyæmia, and operations or diseases involving the genito-urinary organs are its most important causes. Large collections of pus in the substance of the kidney, constituting a single abscess or several abscesses, are rare, and generally are due to traumatism, or to extension of suppurative inflammation from adjoining parts. Acute interstitial nephritis with the formation of many small purulent foci, is due to the presence in the kidney of an infectious agent capable of exciting suppuration. In many

cases of this disease, colonies of sphæro-bacteria or micrococci have been found in the kidney. The microscopical study of the tissues around these bacteria is strongly confirmatory of the doctrine that the organisms are themselves the pyogenic agents. This is one of the affections in which the demonstration of these parasites and of their destructive influence is readily made. The bacteria gain access to the kidney either by the bloodvessels or by the urinary passages. When the inflammatory irritant is brought by the blood to the kidney, the abscesses are called pyæmic or metastatic. These are usually embolic in origin. In this form of interstitial nephritis there are usually abscesses also in other organs. Multiple abscesses may appear in the kidney as a sequence of disease of the urinary passages either with or without pyelitis. In this form of suppurative nephritis, abscesses are often absent in other parts. The causes of pyelo-nephritis belong to the latter group. Diffuse suppurative inflammation of the kidneys has been described, but its existence is doubtful.

Anatomical Characters.—In acute interstitial nephritis both kidneys are usually involved. The organ is swollen. Small yellowish-white elevated spots, often surrounded by a hemorrhagic zone, are generally seen upon the surface after removing the capsule. These purulent foci are present, as a rule, in both cortex and pyramids. In pyæmia they are in largest number in the cortex. Their size varies from that of a pin's head to that of a pea; and even larger collections may be formed by the coalescence of the small foci. The abscesses may appear as minute points of pus, or as yellowish streaks and irregular patches. The arrangement in streaks or lines running parallel to the tubes, is the usual one in the pyramids. The first appearance of the foci is that of whitish or reddish-gray spots of softened but not diffluent consistence. Subsequently fluid pus is formed. In pyæmia the abscesses frequently present a wedge-shaped appearance with the base of the wedge toward the capsule. Miliary abscesses are sometimes grouped together in patches. In pyelo-nephritis the mucous membrane of the renal pelvis is inflamed. It is important to note, however, that acute interstitial nephritis may follow inflammation of the urethra or of the bladder without the ureters and pelvis being affected.

Microscopical examination shows that in the early stages, the discolored foci may consist chiefly of necrotic tissue surrounding one or more colonies of micrococci. Usually, however, pus-cells are found mixed with the necrotic tissue. The fully-formed abscesses with fluid pus present no anatomical peculiarities of especial interest. The death of the tissue for a certain distance around the colonies of bacteria before suppuration begins, can hardly be attributed to anything else than to the action of these organisms. In an early stage of the foci it is not infrequent to find in the centre colonies of micrococci, surrounding these a zone of necrosed tissue, and in the periphery a zone of pus-cells. The micrococci are present in capillaries and small arteries in pyæmic abscesses; they are in the uriniferous tubes when the inflammation has been propagated from the urinary passages. The pus-cells appear first in the interstitial tissue, and are regarded as emigrated white blood-corpuscles. They may be found also in the tubes. In pyæmia, emboli and thrombi may be discovered in the small arteries and capillaries near the suppurating centres. The veins in the neighborhood of the necrotic or of the purulent foci are often thrombosed, but this is probably a secondary process.

Large renal abscesses are not common in the form of disease which has just been described. Many cases which were formerly described as renal abscess are in reality examples of pyonephrosis. In the latter disease a large

amount of pus accumulates in the renal pelvis, which is dilated in consequence of some obstacle to the passage of urine, as a calculus in the pelvis or ureter. In pyonephrosis the kidney may take part in the suppurative process, or it may simply undergo atrophy from pressure. In extreme cases a large sac containing pus is found, the walls of the sac consisting of the atrophied renal tissue and the coats of the renal pelvis. In another class of cases, the origin of the abscess is in the tissue surrounding the kidney (perinephritic abscess), and the latter organ is secondarily involved. Large collections of pus may, however, be formed primarily in the kidney itself. These large renal abscesses (in which the renal pelvis and the perinephritic tissue may be involved) sometimes form tumors of large size, which may discharge their contents externally, into the peritoneal cavity, into adjoining hollow viscera, and even into parts remote from the kidney.

The slighter grades of simple pyelitis (often called catarrhal pyelitis) are sufficiently common, but are of no practical importance. The mucous membrane is hyperæmic and coated with a little mucus and pus. In more severe cases the formation of pus is greater and may produce a considerable sediment in the urine. In many of these cases with profuse production of pus, there is an obstacle to the passage of urine, and the pus is retained in the pelvis, causing the condition just described as pyonephrosis. As has been mentioned, the combination of suppurative pyelitis with suppurative nephritis is common, and constitutes the condition called pyelo-nephritis. In chronic pyelitis the mucous membrane is often thickened in some places, thinned in others, and pigmented. Pyelitis with pseudo-membranous exudation is a rare disease. This is called croupous or diphtheritic pyelitis. It occurs occasionally in severe constitutional disease. Discolored sloughs and ulcers are often present in the mucous membrane, in connection with a fibrinous exudation. The name calculous pyelitis is given to the form caused by the presence and irritation of calculi in the pelvis. Calculous pyelitis is chronic and accompanied almost invariably by secondary changes in the kidney, which consist in chronic interstitial inflammation and atrophy of the organ. Acute interstitial nephritis may likewise be consecutive to calculous pyelitis. This form of pyelitis frequently leads to pyonephrosis.

Clinical History.—The miliary abscesses in the kidneys, which occur in pyæmia, give rise to no marked local symptoms. The urine undergoes no constant distinctive modifications. It may, however, contain pus-corpuscles. Pyæmic renal abscesses are less common than those in the lungs, liver, and spleen, if the pyæmia caused by acute ulcerative endocarditis be excluded.

Acute interstitial nephritis supervening upon disease of the urinary passages, is often of grave import. The symptoms are those of severe constitutional disturbance, namely, repeated chills, irregular fever, delirium, somnolence, coma, etc. These symptoms denote the presence in the blood of some toxic agent. They are attributed by some to uræmia, by some to ammoniæmia, and by some to septicæmia or pyæmia (*vide* page 78). The urine, usually diminished in quantity, is often ammoniacal. It may be albuminous, and may contain casts. The alterations in the urine, however, are not diagnostic of this disease. The symptoms distinctly point to a blood-disease. The nephritic disease is to be suspected when these symptoms follow the causes which give rise to interstitial nephritis. This disease is developed in many of the cases in which death takes place within a few days after an operation for stone in the bladder or for stricture of the urethra. The diagnosis cannot be made with certainty, as similar symptoms and a fatal issue may follow without the kidneys becoming involved. The prognosis is grave, as much so as in cases of pyæmia, with which the condition seems to

be identical. Abscesses may be present in other parts of the body, but they are usually confined to the kidneys.

The consideration of the large renal abscesses, usually of traumatic origin, belongs to surgery. These cases are clearly distinct from those of acute interstitial nephritis, as just described. These renal abscesses are sometimes due to suppuration in adjacent parts, and they sometimes occur without any apparent causation, that is, idiopathically. They are to be distinguished from pyonephrosis and perinephritic abscesses, and, clinically, this is not always easy. In renal abscess the constitutional symptoms may be either slight or marked. An essential diagnostic point is a recognizable tumor, sometimes fluctuating, referable to the kidney.

In pyelitis there is more or less pain in the lumbar region, but the pain is not usually severe, and may be but slight. The pain produced by the presence of calculi, and especially by their passage along the ureter, is to be distinguished from the pain incident to inflammation. Distension of the pelvis and calices, if the ureter be obstructed, occasions an obscure, dull pain in addition to the pain due to the inflammation. The urine is sometimes greatly increased in quantity, and it contains muco-pus or pus in more or less abundance, provided there be not complete occlusion of the ureter. In determining that the muco-purulent or purulent matter comes from the kidney, inflammation of the bladder, or cystitis, is to be excluded. With the local symptoms are associated more or less febrile movement and other symptoms denoting constitutional disturbance. The pyelitis may succeed an attack of pain caused by the passage of a calculus along the ureter, called renal colic, or the latter may occur during the continuance of the pyelitis.

Pyelitis may be acute, and, running its course, end in recovery, or the inflammation may continue and become chronic. In chronic pyelitis, the local symptoms persist, leading to progressive emaciation and debility with hectic fever.

Causation.—In a large proportion of cases, suppurative nephritis is secondary to, and accompanied by, pyelitis. The affection, therefore, is produced by the causes which give rise to pyelitis. As a primary affection, it may be caused by wounds and contusions. Multiple pyæmic abscesses are most frequently caused by infected emboli derived from the pulmonary veins, or from the left side of the heart in cases of ulcerative endocarditis. The bacteria which have been found in the renal vessels and within the abscesses, are considered as constituting an efficient cause of the inflammation. Some, however, regard them as secondary to the inflammatory products.

Pyelitis may be produced by wounds penetrating the pelvis of the kidney, but rarely, if ever, by contusions. The most frequent cause of this affection is the local action of calculi. It may arise from the presence of the entozoön of the kidneys, called the *strongylus gigas*, and from a hydatid production. Next to renal calculi, the most frequent cause is obstruction leading to an accumulation in the pelvis and calices of urine which decomposes and acts as a local irritant. The obstruction may be due to the impaction of a calculus in the ureter, a morbid growth within the canal, a tumor pressing upon it; or to retention of urine within the bladder from stricture of the urethra, enlarged prostate, phimosis, and paralysis of the bladder in cases of paraplegia. In some cases of cystitis the inflammation extends along the ureters to the pelvis of the kidneys. It is contended by Traube, Klebs, and others, that bacteria, gaining access to the bladder by the use of uncleaned catheters, or in other ways, travel thence to the pelvis of the kidneys, occasioning pyelitis,

and, penetrating the uriniferous tubes, give rise to pyelo-nephritis. Pyelitis is sometimes an intercurrent affection in various infectious diseases, and the inflammation may be accompanied by fibrinous exudation.

Diagnosis.—Miliary abscesses due to pyæmia give rise to no diagnostic symptoms. The suppurative inflammation which is of traumatic origin may be diagnosticated by means of unilateral local pain and tenderness, together with more or less fever and other symptoms of constitutional disturbance. When the nephritis follows pyelitis (pyelo-nephritis) caused by calculi, obstruction at some point in the urinary passages, the introduction of bacteria, etc., the diagnosis is to be based on the general symptoms which have been stated in connection with the clinical history, these symptoms denoting an increased gravity of disease. The diagnostic evidence of a large renal abscess is the presence of a fluctuating tumor referable to the kidney. In making this diagnosis, pyonephrosis and perinephritic abscess are to be excluded.

The diagnosis of pyelitis is to be based on characters pertaining to the urine, in conjunction with more or less pain and constitutional disturbance, cystitis being excluded.

Pus-cells and, especially in calculous pyelitis, red blood-corpuscles are found in the urine. To determine that these cells are derived from the renal pelvis, it is necessary to exclude inflammatory affections of the bladder and of the urethra. This can sometimes be done by the symptoms and by physical exploration. It is not, however, in all cases possible to exclude cystitis. In uncomplicated pyelitis the urine is generally acid, whereas in cystitis it is usually alkaline. But this rule has less diagnostic value than is often assigned to it. On the one hand, the urine may undergo ammoniacal decomposition in pyelitis, and, on the other hand, the acid reaction does not of necessity exclude cystitis. Moreover, an uncomplicated pyelitis is rare. In many cases there is coincident inflammation of the bladder. It is a prevalent view that there are characteristic epithelial cells lining the renal pelvis, and that when these cells appear in the urine the diagnosis of pyelitis is established. It is admitted that these cells are not present in all cases, and that they are found more frequently at the onset than in the later stages of the disease. The cells considered characteristic of pyelitis are described as oval, pyriform, fusiform, and caudate cells. The presence of these cells in the urine is not pathognomonic of pyelitis. It is generally admitted by histologists that no essential differences exist between the epithelial cells of the bladder and those of the pelvis of the kidney. Both belong to the so-called transitional type and are characterized by the variety of forms which they present. The same cell-forms which are described as characteristic of pyelitis may also be derived from the bladder.

The occurrence of paroxysms of pain characteristic of the passage of a calculus along the ureter, and the expulsion of calculi or gravel from the bladder, are important diagnostic events. The sudden discharge of pus in more or less abundance with the urine, shows that an accumulation in the pelvis of the kidney has escaped through the ureter into the bladder.

Pyelitis caused by calculi will be likely to be limited to one kidney, but if it follow cystitis, or retention of urine from an obstruction beyond the ureter, both kidneys will be likely to be affected. Complete or very great obstruction, causing an accumulation of urine within the pelves of both kidneys, leads speedily to uræmia. Complete obstruction, however, limited to one kidney, may exist for an indefinite period, without leading to uræmia, the other kidney being sufficient for the excretion of the urine. The accumulation of pus in the pelvis of one kidney may be sufficient to occasion a fluctuating tumor which

may be felt through the abdominal walls. This tumor may attain to a large size, and in women it may simulate an ovarian cyst. It is to be differentiated from perinephritic abscess.

An accumulation of purulent matter within the pelvis and calices, if the ureter remains permanently obstructed, generally eventuates in perforation and the discharge of the pus in some direction, provided the life of the patient be sufficiently prolonged. The source of the pus is to be determined by the antecedent and co-existing symptoms which point to the seat of the affection. The pus may make its way in an outward direction, giving rise to a subcutaneous purulent collection. It may be discharged into the peritoneal cavity, causing a fatal peritonitis. A case in which these two events occurred has fallen under my observation. Not infrequently the pus has escaped by perforation into the intestine. It has been known to pass into the pleural cavity and into the bronchial tubes.

Prognosis.—A purulent collection, if small, may undergo the granulo-fatty degeneration, and be absorbed, recovery in this way taking place. Death sometimes occurs speedily, most speedily when the suppurative inflammation has a traumatic origin. But, in cases of large renal abscess, the pus is discharged in some direction, if life be sufficiently prolonged, and death generally follows a gradual decline with hectic fever and emaciation. If both kidneys be the seat of acute interstitial inflammation, the prognosis is grave. Uræmia may be the immediate cause of death after suppuration, if this involve great damage to both kidneys. The discharge of the pus into the pelvis of the kidney is the most favorable direction, and, next to this, the evacuation of a renal abscess externally. If the pus be discharged into the peritoneal or the pleural cavity, a fatal result is almost inevitable. Recovery has taken place in some of the cases in which the abscess opened externally, and also when the opening was into the intestine.

The gravity of pyelitis depends much on its causes. If produced by an extension of inflammation in cystitis, and there be no permanent obstruction to the flow of urine and pus into the bladder, a favorable termination may be looked for. If due to the presence of calculi, and these make their way into the bladder before destruction of the kidney ensues, recovery will be likely to take place. If from the size of the calculi their escape be impossible, the inflammation will be apt to continue, and the prognosis is unfavorable. Cases have been observed of pyelitis caused by a large calculus, in which, after having led to complete destruction of the kidneys, the inflammation has ceased, and the calculus has remained encysted by the renal capsule, giving rise to little or no inconvenience, the remaining kidney doing all the work of renal elimination. Permanent obstruction to the flow of urine from the pelvis and calices of both kidneys, dependent on cystitis or retention of urine in the bladder from whatever cause, leads to destruction of the renal parenchyma and death from uræmia. An accumulation of urine and pus in the pelvis and calices of one kidney may prove fatal by perforation into the peritoneal cavity. If the discharge take place either into the intestinal canal or externally, the patient is likely to be worn out by the prolonged drain and constitutional disturbance.

Treatment.—The treatment in cases of pyæmic abscesses of the kidneys would not be materially affected by the ability to diagnosticate their presence. The therapeutical indications relate to the endocardial ulcerations or other affections which furnish the infectious emboli, and to the general symptoms. In pyelo-nephritis, the objects of treatment have reference to the pyelitis, to

the affections which may exist in other parts of the urinary passages, and to other causes which may be present. In these cases, the indications derived from the general symptoms are of more importance than those which pertain directly to the nephritic inflammation. The development of uræmia may afford important indications. A large renal abscess calls for surgical interference in the way of aspiration or of nephrotomy, or of both. Suppurative inflammation of the kidney produced traumatically, or occurring as a primary affection, claims the measures of treatment which are appropriate in other inflammatory diseases, namely, local depletion in some cases, counter-irritation, cold applications, rest, etc.

The treatment in cases of pyelitis must have reference to the causation. If dependent on retention of urine from stricture of the urethra, enlarged prostate, or paralysis, measures to relieve the bladder are of prime importance. If consecutive to cystitis, the latter claims appropriate treatment. Quietude is to be enjoined especially in cases in which the affection depends on calculi. Soothing applications to the loins, and anodyne remedies are indicated in proportion to the amount of pain. If the affection become chronic, the balsam of copaiba and other balsamic remedies are sometimes useful. Liquids should be taken freely in order to dilute the urine. If the accumulation of pus (pyo-nephrosis) and urine form a tumor which presents itself in an accessible situation, it should be opened after an exploratory puncture. Tonic and supporting measures are required after the opening of the abscess either externally or into the alimentary canal.

Hydronephrosis.

Hydronephrosis is the name given to dilatation of the pelvis and calices of the kidney by an accumulation of urine in consequence of some obstruction in the urinary passages. This dilatation leads to atrophy of the renal tissue. The obstruction may be seated in the pelvis, ureter, bladder, or urethra, and, consequently, the dilatation may involve, not only the pelvis, but also other parts of the urinary passages. Thus, if the impediment be in the urethra, this canal behind the obstruction, together with the bladder and ureters, will be distended if hydronephrosis be produced.

Anatomical Characters.—Hydronephrosis, especially if the distension be extreme, in the majority of cases is unilateral. It may, however, be bilateral, and then constitutes a graver affection. The degree of distension varies extremely. It may be insignificant, or the dilatation may lead to the formation of an enormous sac filling most of the abdominal cavity, and containing several gallons of fluid. From the pressure of the liquid in the dilated pelvis and calices, the kidney-substance wastes and gradually disappears. At first the papillæ are flattened; then the pyramids are further encroached upon and finally disappear. The cortical substance also undergoes atrophy. This wasting of the kidney is accompanied usually by increase of its interstitial tissue. It is very rare to find the hydronephrosis and the atrophy of the kidney so extreme that no remnant of the renal parenchyma can be found. Even in large hydronephrotic cysts, it is the rule to find a thin border, or, at least, islands of renal tissue upon the cyst-wall. A very large hydronephrotic sac sometimes consists of a single cavity. Usually, however, a number of membranous septa project from the wall into the cavity of the sac, and give to its external surface a lobulated appearance. These septa partially inclose smaller cavities or sacculi which represent the dilated calices, and which, therefore, communicate by wide mouths with the

main cavity or dilated pelvis. These septa may be prominent, or may be reduced to narrow ridges on the inner wall of the sac. The walls of a hydronephrotic sac consist, in addition to atrophic kidney-substance, of dense vascular fibrous tissue. The outer surface may be roughened by adhesions to adjoining parts. According to the seat of obstruction, one or both ureters may be dilated. A dilated ureter may reach the size and present the appearance of a coil of small intestine. With unilateral hydronephrosis and considerable atrophy of the kidney, the other kidney is often hypertrophied.

The liquid contained within a hydronephrotic cyst varies in its composition. It usually has the appearance of watery urine. It is clear in most cases, but may be discolored and rendered somewhat turbid by admixture with blood, pus, or epithelium. The specific gravity is low; the reaction often slightly alkaline. The urinary constituents are usually present, but urea and uric acid may be in small amount or even entirely absent. A small quantity of albumen is almost invariably found. In a few cases the contents have consisted of a gelatinous, colloid substance. Paralbumen, the modified form of albumen present in ovarian cysts, has also been discovered in fluid from hydronephrosis.

Causation.—The causes of hydronephrosis are conveniently divided into *congenital* and *acquired* causes. Of 52 cases of hydronephrosis collected by William Roberts, 20 were congenital. *Congenital* causes are the following: 1. A supernumerary renal artery crossing and compressing the ureter near its origin. 2. Narrowing or obliteration of the orifices or of the lumen of the ureter. 3. A valve-like impediment produced by an oblique insertion of the ureter into the pelvis. 4. The insertion of the ureter into the upper instead of the lower part of the pelvis. 5. Certain abnormalities of the bladder or of the urethra, as vesical diverticula, atresia of the urethra, etc. Congenital hydronephrosis is often associated with malformations of other organs, as imperforate anus, hare-lip, etc.

The causes of *acquired* hydronephrosis may be classified as follows: 1. The impaction of substances in the renal pelvis or in the ureter. Calculi impacted in these parts are among the most frequent causes of this affection. Much less frequently is the lumen of the ureter obstructed by coagula of blood or by parasites (echinococcus). 2. Disease of the walls of the ureter causing partial or complete obliteration of its lumen. To this group of causes belong inflammatory thickening, cicatricial stenosis from ulcers, and tumors, especially cancer. 3. Pressure upon the ureter from without. The causes of pressure include pelvic tumors, inflammation of the pelvic connective tissue or of the pelvic peritoneum, prolapse of the uterus, retroflexion of the pregnant or of the non-pregnant uterus, distension of the rectum. Cancer of the cervix uteri is very frequently complicated by hydronephrosis. It is exceptional for hydronephrosis to be caused by the pressure of an ovarian cyst. The newly-formed fibrous tissue resulting from parametritis and from pelvic peritonitis may compress the ureter. Some of the causes named produce hydronephrosis, not by pressure, but by exerting traction upon the ureter and so causing bends and distortions in its course. 4. Diseases of the bladder which involve one or both of the orifices of the ureters. This class of causes comprises hypertrophy of the coats of the bladder, abscess in the vesical wall, neoplasms, particularly cancer, and large calculi. 5. Affections narrowing the calibre of the urethra. These causes are stricture and the so-called hypertrophy of the prostate. In a few cases hydronephrosis has been attributed to phimosis. Hydronephrosis does not follow these causes until after the bladder has become insufficient to overcome the urethral obstacle. In cases of urethral obstruction, therefore, hydronephrosis is due to

a secondary affection of the bladder. 6. In not a few cases no cause of the hydronephrosis has been found. With some of the largest hydronephrotic sacs the autopsy failed to reveal any impediment to the flow of urine. In some of these cases it is believed that a calculus, once impacted in the ureter, has been dissolved or dislodged. In other cases it is probable that some not very obvious cause escaped detection. The largest hydronephrotic cysts are found more frequently with partial than with complete obstruction in the ureter.

Clinical History.—With double congenital hydronephrosis, the fœtus is generally not viable. There are cases, however, in which life has been continued in apparent health for many years. A moderate degree of hydronephrosis, whether unilateral or bilateral, is unattended by recognizable symptoms. One kidney may be destroyed by the development of a hydronephrotic sac without any symptoms referable to this condition. In this case, the other kidney, which is usually hypertrophied, excretes the normal quantity of urine. If, however, the ureter of the remaining kidney become permanently obstructed, death ensues within a few days with symptoms of uræmia. With double hydronephrosis the condition is manifestly grave if the renal tissue be sufficiently impaired to interfere with its functions. Under these circumstances the urinary constituents are imperfectly eliminated from the body, and death ultimately ensues, usually with the manifestations of uræmia. An important diagnostic sign of hydronephrosis is the discovery of a tumor in the lumbar region. It is only when the hydronephrotic sac is of considerable size that a tumor can be detected. The tumor is fluctuating and presents in some cases a lobulated surface. It has the characteristics of a tumor taking its origin from the kidney, among the most important of which is the recognition of the tympanitic resonance of the colon over its anterior surface. This sign, however, may be wanting, the colon being pushed by the tumor to one side. A symptom of almost pathognomonic value is the disappearance of the tumor coincidently with the discharge of a large quantity of pale liquid into the bladder, and thence externally. This symptom is not common. It is, of course, only present when the obstacle to the flow of urine is removed, or when there is only incomplete obstruction which is more frequent. A hydronephrotic tumor is not painful. It may give rise to symptoms by compression of other parts. Thus obstinate constipation may be due to compression of the colon. The urine presents no abnormal characteristics in most cases of hydronephrosis. As already mentioned, it may be suddenly increased in amount by discharge of the contents of the cyst. If both kidneys be so much involved that their function is interfered with, the urine is usually diminished in quantity. Important symptoms may be referable to the conditions causing hydronephrosis, such as those of renal colic, uterine cancer, etc.

Diagnosis.—If the accumulation of liquid in the renal pelvis be small, the condition is not susceptible of diagnosis. The recognition of one or more of the various causes of hydronephrosis which have been mentioned, is of great importance in the diagnosis. The presence of a tumor and its subsidence with the discharge of a large quantity of urine, are symptoms which are sometimes available in making the diagnosis. Large hydronephrotic sacs filling the greater part of the abdominal cavity may be mistaken for ascites or for ovarian cysts. Such sacs have repeatedly been mistaken for ovarian cysts, and have been punctured on this supposition. The attempt has even been made to remove hydronephrotic cysts by laparotomy under the belief that an ovarian cyst was present. Some of the characteristic signs of an ovarian cyst have been mentioned on page 599. It must be admitted that

in some cases the diagnosis is very difficult. The presence or absence of urea can not serve as a diagnostic point. Urea may be present in fluid from an ovarian cyst. It is frequently small in amount, and may be absent in hydronephrosis. The colon is often present over a hydronephrotic cyst, and is found only very exceptionally in front of an ovarian cyst. The reader is referred to the article on ascites for the symptoms and physical signs of this condition (page 596 *et seq.*). Hydronephrosis may be confounded with pyonephrosis. With the latter condition there is generally more constitutional disturbance with rigors and hectic fever. The presence of pus in the fluid removed by exploratory puncture renders the diagnosis of pyonephrosis certain if other sources of pus can be excluded. The diagnosis also involves the exclusion of hydatid cysts of the kidney, perinephritic abscess and large renal cysts.

Prognosis.—The prognosis of hydronephrosis depends upon the extent to which the functions of the kidneys are interfered with, and the consequent danger of uræmia. Unilateral hydronephrosis is unattended with danger so long as the remaining kidney does its work properly. But if this kidney become diseased, or if its ureter become obstructed, life is endangered. Double hydronephrosis is grave in proportion as the liability to uræmia is developed. The liability to rupture of a hydronephrotic sac is so slight that it hardly enters into the prognosis.

Treatment.—An important object in the treatment is the removal of the cause of obstruction. This cannot often be accomplished. The measures to be pursued for that object in individual cases are to be determined by the nature and seat of the obstructing cause. In some instances, by means of rubbing and kneading over the sac or along the course of the ureter, an obstruction has been overcome, or the urine has been made to pass beyond the obstructed part. These manipulations should not, of course, be so forcible as to cause pain or to incur any risk of rupture. Removal of the liquid by aspiration has proved successful. Using a small aspirating needle or trocar, this measure is attended with little, if any, danger of the escape of the liquid into the peritoneal cavity. For this reason, it is to be preferred to tapping without aspirating. The treatment in other respects is to be governed by the local and general symptoms in each case.

Renal Colic and Nephro-lithiasis.

Urinary concretions, or calculi, are generally formed within the renal cavities. Calculi of small size may pass from the kidneys to the bladder, giving rise to little or no inconvenience, and, having reached the bladder, they are either discharged with the urine, or, remaining in the bladder, they increase in size and may require for their removal surgical interference. In some cases, calculi within the renal cavities, increasing in size, become too large to pass along the ureter, and are consequently retained. As has been seen, retention of urine within the pelvis and calices of the kidney, pyelitis, renal abscess, and destruction of the renal parenchyma, are sometimes attributable to the presence of calculi or a calculus. A calculus retained in the pelvis of the kidney may continue to increase in size, and leading to atrophy of the parenchyma, it may acquire a bulk nearly as great as, or perhaps even greater than, that of the healthy organ. Calculi not too large to pass through the ureter, and not small enough to pass with facility, occasion during their passage more or less pain and constitutional disturbance. The amount and duration of the pain caused by the passage of a calculus is in proportion to its

size and the roughness of its surfaces. The pain begins when the calculus enters the duct, and ends when it reaches the bladder. The paroxysm is analogous to that occasioned by the passage of a gall-stone from the gall-bladder to the duodenum. The latter is commonly known as hepatic colic, and the paroxysm of pain occasioned by the passage of a renal calculus is called *renal colic*. In rare instances attacks of renal colic are produced by the passage of coagulated fibrin and of a hydatid vesicle through the ureter.

A paroxysm of renal colic is usually developed suddenly. The attack, however, may be preceded by more or less pain or a sense of uneasiness, due to irritation or perhaps inflammation caused by the presence of calculi in the pelvis of the kidney. The paroxysm quickly attains to its maximum of intensity. The pain in some cases becomes exceedingly intense. It is referred to the situation of the kidney, on one side, that is, by the side of the last dorsal and the first lumbar vertebra. The pain radiates from this point in different directions, but especially along the course of the ureter, extending frequently to the groin and thigh. In the male, pain is generally felt in the testicle, which is often, but not always, drawn upward by the contraction of the cremaster muscle. Frequently the pain is described as lancinating or tearing. It is sometimes so excessive as to force the patient to groan and cry aloud; he tries a variety of positions to obtain relief, walks about the chamber, and compresses the abdomen with his hands as in intestinal colic. The pain continues without intermission, but there occur exacerbations and remissions. The urine in most cases is notably diminished. The patient experiences a frequent or constant desire to micturate, passing only a few drops at a time. The sensation is well expressed by the term *tenesmus of the bladder*. Not infrequently the urine is bloody. If it contain pus or muco-pus, either pyelitis or cystitis co-exists.

With these local symptoms are associated those denoting more or less constitutional disturbance, namely, anorexia, thirst, nausea, and vomiting, coldness of the surface with sweating, and feebleness of the circulation. The countenance is pallid and expressive of anguish. Suddenly, after a duration varying considerably in different cases, the paroxysm ends. The pain abruptly ceases. An abundant discharge of urine takes place. The calculus has reached the bladder, and, if care be taken, for some time afterward, to examine the urine, it may be found at the bottom of the vessel. The general symptoms rapidly disappear, and in one or two days the recovery may be complete. In some cases, however, one or more additional paroxysms follow, other calculi contained within the pelvis of the kidneys getting into the ureter in consequence of the dilatation caused by the calculus which has just passed. A person who has experienced one paroxysm is liable to recurrences at periods more or less remote.

The duration of an attack of renal colic varies in different cases, but it is usually short. In the majority of cases it lasts but a few hours, but in some cases it continues for one, two, or three days. Although the suffering is often extreme, it very rarely proves fatal. A persistent impaction of a calculus in the ureter, causing obstruction, is followed by hydronephrosis, and, following this, pyelitis and pyelo-nephritis may become developed. Ulceration may take place at the point of the obstruction, and fatal peritonitis be produced by the escape of urine into the peritoneal cavity. These are sources of danger happily of rare occurrence. Simultaneous obstruction of both ureters by calculi has been known to occur, causing anuria and uræmic poisoning.

The diagnostic characters of renal colic are, the suddenness of the attack and termination, the situation of the pain and its extension to the groin, thigh, and testicle, the retraction of the testicle, the diminution of urine, the

tenesmus of the bladder, hæmaturia in some cases, and the discovery of the calculus. The fact of antecedent attacks having occurred will assist in the diagnosis. The affections to be excluded are, the form of muscular rheumatism called lumbago, lumbo-abdominal neuralgia, enteralgia, and hepatic colic. In lumbago the pain is less severe, is provoked especially by movements of the body, and is felt on both sides. Lumbo-abdominal neuralgia is characterized by tenderness at certain points (*vide* page 800). In enteralgia the seat of the pain is within the abdomen. This statement also applies to hepatic colic. In all these affections the characteristic features of nephritic colic are wanting.

The treatment of an attack of renal colic consists of palliative measures. Complete relief depends on the escape of the calculus into the bladder, and there are no means of aiding directly in effecting its passage. The propelling force is derived from the accumulation of urine behind the calculus, and from the peristalsis of the muscular coat of the ureter. The copious ingestion of liquids may, by increasing the urinary secretion, hasten its progress. Fomentations to the loins, the warm bath, morphia given hypodermically, and, if the suffering be excessive, the inhalation of chloroform, constitute the measures for palliation.

The discharge from the body of urinary concretions, either with or without the symptoms of nephritic colic, constitutes *lithiasis* or *gravel*. The term gravel is properly applied only to concretions formed within the body, not to those which form in the urine after its emission. Not infrequently concretions, varying in size from that of a pin's head to a small pea, pass through the ureter without giving rise to sufficient pain to constitute an attack of renal colic. The composition of the concretions varies in different cases. In a large majority of cases (five-sixths), they consist of uric acid. The urine in these cases is always acid. The concretions may consist of the earthy salts, namely, the phosphate of ammonia and magnesia, the phosphate of lime, and the carbonate of lime. Concretions of carbonate of lime are extremely rare in human urine. Ammonio-magnesian calculi are liable to form in cases of cystitis. These concretions are generally not renal but vesical. The urine in these cases is usually alkaline. In another variety the concretions consist of the oxalate of lime. In frequency these come next to the uric acid calculi. They are known as mulberry calculi. In cases of renal colic, the composition of the calculi which occasion the paroxysms may be inferred from the knowledge of concretions which have been already passed, and from an examination of the sediment which the urine deposits. If the urine contain uric acid crystals or abound in the urates, or have an acid reaction, the calculus is probably composed of uric acid. So, the urine will be likely to contain the phosphates in more or less abundance when the calculi consist of the earthy salts. Oxalate of lime or mulberry calculi will be likely to be preceded or accompanied by oxaluria. Oxaluria is not, as was formerly supposed, attended by any characteristic symptoms. It may happen, however, that the calculi giving rise to renal colic are not of recent formation, and the condition of the urine giving rise to their formation may not exist at the time when the attack of colic occurs. A variety of calculus, so rare as to be a curiosity, consists of xanthine. Another rare variety is the cystine calculus. The condition of the urine in which the latter occurs is called cystinuria. In this condition the urine contains hexagonal tablets of cystine. This, more than any other form of lithiasis, has been shown to be hereditary. Cystinuria may exist without the formation of calculi. It lasts for a long time, and sometimes indefinitely.

The treatment of nephro-lithiasis, irrespective of attacks of renal colic,

will depend on the nature of the concretions or the character of the urine. In cases of uric acid gravel, alkaline remedies are indicated. The liquor potassæ, in half drachm doses thrice daily, may be given, but either the bicarbonate or the citrate of potassa, a drachm twice daily, is preferable. The Vichy water and the water of other alkaline springs are well suited to this variety of gravel. The phosphate of soda and ammonia, introduced by Dr. Buckler, of Baltimore, is considered as having the power of keeping uric acid in solution in the urine, given in doses of ten grains thrice daily. The phosphate of soda in doses of from a drachm to six drachms, is recommended by Heller. The benzoic acid is another remedy, given in doses of eight or ten grains thrice daily. The carbonate of lithia was introduced by Garrod as a remedy which promised to be especially valuable from its forming with uric acid a highly soluble compound. It may be given in doses of five grains three times daily. All these remedies act as solvents, and as preventing uric acid concretions. In addition to these remedies, attention to the digestive organs, the skin, and the functions generally, constitutes an important part of the treatment. Liquids should be taken freely between meal-times, in order to dilute the urine. The diet should consist mainly of the white meats, milk, eggs, and farinaceous articles.

In cases in which the concretions are composed of the earthy salts, the mineral acids are indicated, either the sulphuric or hydrochloric. The nitro-hydrochloric acid is especially indicated in cases of oxalate of lime gravel. Diuretic remedies and the ingestion of pure spring, river, or rain water abundantly, form a highly important part of the treatment in all cases of gravel. The phosphatic and oxalate of lime concretions are apt to occur in persons suffering from *nervous asthenia*, and the latter condition claims appropriate management. Abstinence from articles of diet containing oxalic acid is to be enjoined if the concretions consist of the oxalate of lime.

As already stated, the sedimentary deposits which occur in urine after its emission are not properly called gravel. It is important, however, to take cognizance of these as constituting evidence of disorder, and as involving a liability to the formation of concretions within the kidney or bladder. The conditions of the urine known as *lithiuria*, *oxaluria*, and *phosphuria*, standing respectively in relation to the different varieties of gravel just noticed, claim appropriate treatment, although concretions within the body have not taken place. For further details respecting these and other disordered conditions of the urine, the reader is referred to works devoted to urinary affections.[1]

Perinephritic Abscess.

Inflammation of the connective tissue surrounding the kidney is called perinephritis. The tissue involved is the lax adipose tissue in which the kidney is imbedded (the so-called adipose capsule of the kidney) and the neighboring retro-peritoneal tissue. It is possible to distinguish an adhesive and a suppurative variety of perinephritis. The former is characterized by the development of new connective tissue. It accompanies tumors and some other diseases of the kidney. Adhesive perinephritis has no clinical importance, and will receive no further consideration in this article. Suppurative perinephritis or perinephritic abscess is not a frequent disease, but it is attended by characteristic symptoms and merits separate consideration. At the autopsy a collection of pus is found occupying the situation of the adipose

[1] Thudicum on the Urine, and Roberts on Renal and Urinary Diseases, may be especially mentioned.

and connective tissue around the kidney. There may be a number of circumscribed abscesses, but, as a rule, there is a single abscess-cavity. The walls of the abscess may consist of shreddy necrotic tissue, or, in old cases, of tough fibrous tissue. The abscess varies in size and as to the direction in which it extends. It may be confined to the tissue immediately surrounding the kidney, but not infrequently the pus burrows in various directions. In the majority of cases it extends backward and opens externally in the lumbar region. The pus may make its way into the sheath of the psoas muscle, and extend along the course of this muscle to Poupart's ligament, below which it may be discharged. The abscess may extend in the retro-peritoneal tissue toward the diaphragm, and may open by perforation into the pleural cavity or into the lung. The abscess may make its way behind the peritoneum into the pelvis. The peritoneum over the abscess is usually thickened. It is rare for the abscess to open into the peritoneal cavity. More frequently the colon in some part of its course is perforated and the pus is discharged into this viscus. Perinephritic abscess has been known to open also into other parts of the intestine, into the bladder, and into the pelvis of the kidney; also to discharge its contents externally in other directions than those named, as in the gluteal region and in various parts of the abdominal parietes. When allowed to discharge its contents spontaneously, the abscess opens most frequently externally in the lumbar region. The pus in perinephritic abscess often contains shreds of necrotic tissue. It may be good and laudable, or it may be thin and ichorous. The latter is particularly apt to be the case when the abscess is accompanied by infiltration of urine. In very rare instances the abscess has a gangrenous character. When the abscess is secondary to calculous pyelitis, calculi may be found in the abscess-cavity if ulceration of the pelvic walls or of the kidney have occurred.

Of 166 cases of perinephritis collected by Nieden,[1] 70 per cent. were in males and 30 per cent. in females. Twenty-six cases were in children. From an etiological point of view, it is important to distinguish between primary and secondary perinephritic abscess. Secondary perinephritis is much more common than the primary form. The causes of primary perinephritis are traumatism (especially contusions and wounds in or about the kidney), muscular strain, exposure to cold, and severe acute general diseases. Wounds of the kidney are by no means necessarily followed by suppurative inflammation. Perinephritis has been known to develop in the course of pyæmia, of smallpox, of typhus and of typhoid fever, but this complication is extremely rare. Secondary perinephritis is due to disease of neighboring organs. The most important of this second group of causes are affections of the kidney, above all, suppurative pyelitis and pyelonephritis in consequence of the irritation of calculi. Tuberculous inflammation of the kidney has also been complicated in a few cases by perinephritic abscess. Tumors of the kidney, the rupture of renal cysts, and the presence of parasites in the renal pelvis, are among the rare causes of this disease. Perinephritis has been attributed to the extension of inflammation from an inflamed bladder. It has been observed more frequently to follow pelvic cellulitis, especially inflammation of the connective tissue about the uterus. Psoas abscess, which so frequently accompanies caries of the vertebræ, may give rise to perinephritis, but in most cases the thickened sheath of the psoas is an effectual barrier to this extension of the inflammation. Perinephritis may follow typhlitis and perityphlitis, in fact, any suppurative process involving the retroperitoneal tissue. Finally, there are cases of perinephritis for which no cause is discoverable.

[1] Nieden, Ueber Perinephritis, Deutsches Archiv für klin. Med., Bd. 22, p. 451, 1878.

Pain, increased by motion, is a prominent symptom. It is referred to the seat of the inflammation, and shoots downward to the lower limb. It may extend to the testicle, but there is no retraction of the testicle if the kidney be not affected. There is tenderness on deep pressure. The patient is confined to the bed, and lies with the limbs flexed. There is more or less increase of body-heat, with the usual concomitants of fever. Rigors and perspirations are likely to occur. After a variable period, a tumor is felt in, or a little below, the lumbar region. Fluctuation over the site of the tumor may be felt, but this, for some time, is not readily appreciable. There is subcutaneous œdema over the tumor. The urine is unaffected, unless the kidney be involved. With reference to the local symptoms and the diagnosis, the liability of the purulent collection to descend below Poupart's ligament, to open into the intestine, the bladder, or the vagina, and, in some instances, into the pleural cavity and the bronchial tubes, is to be borne in mind.

The diagnosis is to be based on the presence and situation of the tumor, in conjunction with the local and general symptoms denoting inflammation. The symptoms resemble those of suppurative nephritis and pyelitis. These affections are to be excluded by examinations of the urine. In suppurative nephritis, the quantity of urine is notably diminished, whereas in perinephritic abscess there is no interference with the renal secretion. The urine in the latter affection contains neither blood nor casts, and but little, if any, albumen. In pyelitis, with which suppurative nephritis is often associated, the urine contains pus and, it may be, blood.

As soon as the nature of the affection is ascertained, or rendered probable, the tumor should be explored, and, in this way, the presence of pus demonstrated. There should then be no delay in opening the abscess, in order to forestall a spontaneous opening in an unfavorable direction. Bowditch has reported three cases in which an external opening was made, all ending in recovery. A considerable hemorrhage followed the opening in one of the cases. In two of the cases the kidney was felt by the finger at the bottom of the abscess.[1] Gibney has reported twenty-eight cases of perinephritis in children; suppuration, more or less extensive, occurring in sixteen. In fourteen of these cases the abscess was opened by incision, and in two cases the opening was spontaneous. With a single exception, in all of the sixteen cases recovery was complete. A little lameness remained in the excepted case. Gibney is of the opinion that, in a certain proportion of the cases of reputed recovery from hip-joint-disease without lameness or deformity, the affection is in reality a perinephritis.[2]

[2] *Vide* articles by Dr. V. P. Gibney in the American Journal of Obstetrics, April, 1876; in the American Journal of the Medical Sciences, April, 1877, and Oct. 1878; and in the Chicago Medical Journal, June, 1880. To the last of these articles is added a full bibliography of this disease.

CHAPTER III.

STRUCTURAL DISEASES OF THE KIDNEY. HÆMATURIA. HÆMOGLOBINURIA. DIABETES INSIPIDUS AND MELLITUS. SEXUAL DISORDERS.

Renal Cysts. Cystic Degeneration of the Kidneys. Hydatids of the Kidney. Renal Tuberculosis. Carcinoma of the Kidneys. Movable Kidney. Renal Hæmaturia. Endemic Hæmaturia. Hæmoglobinuria. Diabetes Insipidus. Diabetes Mellitus—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Involuntary Seminal Emissions. Spermatorrhœa. Impotence.

THE kidneys are sometimes the seat of affections involving structural changes other than those already considered. Carcinoma and the tuberculous affection occasionally occur in these organs. Hydatids and cysts are additional affections in this category. Some of the structural affections of the kidney are of greater pathological than clinical interest. These will receive only brief consideration.

Renal Cysts. Cystic Degeneration of the Kidneys.

The occurrence of cysts in chronic Bright's disease, especially in the small granular kidneys, has already been mentioned. These cysts are rarely larger than a pea. They frequently contain a colloid substance. They are developed chiefly in the cortical substance. They are attributable to dilatation of Bowman's capsules and of portions of the uriniferous tubes. Similar cysts are often found in senile atrophy of the kidney. Cysts may be formed in otherwise healthy kidneys. These are of pathological rather than of clinical interest.

Sometimes the kidney is converted into a mass of cysts between which little or no renal parenchyma can be discovered. This is the *cystic kidney* or *cystic degeneration of the kidney.* Sometimes only one, but usually both kidneys are affected, although not necessarily in the same degree. Cystic degeneration of the kidney may be a congenital or an acquired condition. Cystic kidneys developed during intra-uterine life may attain to an enormous size, so as to prove a serious mechanical obstacle to the birth of the fœtus. The severe grades of this degeneration render the fœtus non-viable; the lighter grades can be tolerated after birth. In many cases there is some other malformation in the body. Cystic degeneration of the kidney is less frequent in adults than in the fœtus. The causes and the symptoms of this condition are not well understood. An advanced degree of cystic degeneration is sometimes found at autopsies of persons who had presented no symptoms referable to the kidneys during life. There is no doubt, however, that the functions of the kidneys may be so impaired by the cystic formations that death may result therefrom, usually with uræmic symptoms. Sometimes uræmia develops rapidly. In the recorded cases the urine has been rather increased than diminished in quantity. The specific gravity is low. Albuminuria is a frequent but not constant symptom. The development of a tumor is an important symptom in some cases. Without this symptom the

diagnosis is impossible, and with it the existence of cystic degeneration is not easily determined. Hypertrophy of the heart has been known to result from cystic metamorphosis of the kidneys. In most cases in which renal symptoms developed, the affection had been considered as Bright's disease prior to the autopsy. No other mode of formation of renal cysts than by dilatation of the tubes and of Bowman's capsules has been proven.

Echinococcus or Hydatids of the Kidney.

Hydatids in the kidney are, in all respects, similar to those in other organs, for example the liver (*vide* page 626 *et seq.*), and a description of them need not be here repeated. They occur in the kidney more frequently than in any other organ except the liver and the lungs; but, according to Davaine, they are twelve times less frequent in the kidney than in the liver. Men are oftener affected than women. One kidney only is affected, as a rule to which there are very few exceptions. They do not, therefore, diminish the excretion of urine sufficiently to occasion uræmia. If they interfere with the excretory functions of the affected kidney, the augmented functional activity of its fellow makes up for the deficiency. So long as a hydatid cyst remains intact within the renal parenchyma, it gives rise to no well-marked symptoms, and it may remain for an indefinite period completely latent. It has been found after death when no renal trouble had been manifested during life. It may attain to a sufficient size to form a tumor perceptible by palpation. The symptoms to which it gives rise depend on inflammation, ulceration, and the discharge of echinococci in different directions.

If hydatid cysts open into the pelvis of the kidney, the echinococci pass through the ureter into the bladder, and are discharged with the urine. In their passage along the ureter they may give rise to the same train of symptoms as the passage of a renal calculus, in other words, to renal colic. They may also give rise to more or less trouble in their passage through the urethra. Owing to their elasticity, echinococci of considerable size may pass into the bladder and through the urethra without great difficulty, and without much pain. Cases have been reported in which they were discharged in great numbers. Their passage may be accompanied by hæmaturia and pyuria. The latter is due to suppuration of the hydatid cyst or to pyelitis. The opening of the cyst is most frequently into the pelvis of the kidney. Echinococci may form the nuclei of calculi in the pelvis of the kidney or in the bladder.

The hydatid cyst sometimes develops in a direction toward the surface of the kidneys, and opens into the circum-renal areolar tissue. Suppuration takes place and an abscess forms in the lumbar region, which, when opened or allowed to open spontaneously, gives exit to echinococci together with pus in greater or less quantity. Hydatid cysts in the kidneys have been known to open into the stomach, intestinal canal, and even into the lungs, the echinococci, in the latter case, being expectorated. It is possible that here, as in other situations, the parasites sometimes die, the cyst contracts and becomes obliterated, or contains a certain amount of calcareous matter, a spontaneous cure in this way taking place. Instances, however, are extremely rare, and their occurrence has been denied.

The diagnosis, prior to the discharge of the contents of the hydatid cyst in some one of the situations named, can be made positive only by a microscopical examination of the liquid contained in the cyst, obtained by means of an exploratory puncture and aspiration. The diagnostic characters pertaining to the liquid are the same as in hydatids of the liver (*vide* page 629). Hydatids in the kidney are sometimes not readily differentiated from hydatids in the liver or the spleen. Simon recommends an exploration by means of the

hand introduced within the large intestine, in order to determine whether the hydatid tumor be renal or not.[1]

The treatment is chiefly surgical. An attempt should first be nade to destroy the parasite. For this, simple aspiration sometimes suffices. Electrolysis is sometimes effectual. The more effective measure is opening the cyst. Simon's operation is as follows: He thrusts in two canulæ and allows them to remain until adhesions have formed, and then he connects by incision the two openings made by the canulæ. When the tumor is large enough to cause projection of the abdominal parietes, it is time to resort to surgical interference. Simon advises first to make trial of aspiration and electrolysis. These are harmless measures. If at the end of six months they are found not to have succeeded, the cyst should be opened in the manner just described.

Renal Tuberculosis. Renal Phthisis.

Tubercles appear in the kidneys in the following conditions: 1, in acute miliary tuberculosis; 2, as a secondary event in pulmonary phthisis; 3, in primary tuberculosis of the genito-urinary organs. Small, gray, miliary granulations are usually present in the kidneys in acute miliary tuberculosis. They give rise to no symptoms, and, therefore, do not claim clinical consideration. Miliary tubercles may also be found in the kidneys in cases of pulmonary phthisis. More frequently in the latter disease there are present in the kidneys small caseous masses which appear in the pyramids as yellowish-white streaks, and in the cortex, also as striæ, or as irregular nodules. In some cases the affection of the kidney resembles acute interstitial nephritis, but it differs from the latter in the presence of caseous degeneration, and in the absence, at least in most cases, of fluid pus.

There may be formed in the kidney large and small cheesy masses, accompanied often by ulcerative destruction of the affected tissues, and by similar caseous deposits in the renal pelvis, the ureter, and other parts of the genito-urinary apparatus. This condition has been called by various names, such as renal phthisis, nephro-phthisis, genito-urinary tuberculosis, and tuberculous, scrofulous, or strumous inflammation. With this disease the lungs are usually tuberculous, and in many cases the renal affection is secondary to the chronic pulmonary tuberculosis. Extensive caseous infiltration of the kidneys and other parts of the genito-urinary system may, however, occur as a primary disease, and in these cases pulmonary tuberculosis may develop as a secondary event. Writers disagree as to the nature of the process in renal phthisis, some regarding it as renal tuberculosis, others as a peculiar form of inflammation. There is the same disagreement as to similar processes in the lungs. According to the views advocated in this work as to the character of tuberculous changes, these caseous deposits are to be regarded as tuberculous. In most cases, in or about these deposits, the structure of typical tuberculous granula can be demonstrated, and, even where this is not the case, the caseous material is to be regarded as tuberculous in origin for reasons which have been given in a previous part of the work.

In renal phthisis the pelvis and ureters are almost always involved, and not infrequently other parts of the genito-urinary system, namely, the bladder, prostate, urethra, vesiculæ seminales, vasa deferentia, and testicles. The disease is more common in the male than in the female. In the female there is not the same tendency of tuberculosis of the genital organs (especially Fallopian tubes and uterus) to invade the kidneys and urinary passages. In

[1] Die Echinococcuscysten der Nieren, Stuttgart, 1877.

primary genito-urinary tuberculosis, the affection usually begins either in the testicles or in the urinary passages, and involves secondarily the kidneys. The cheesy masses are present both in the pyramids and in the cortex of the kidneys, but, when the disease is primary, they involve by preference the former. These cheesy masses may soften and form cavities which usually, but not necessarily, communicate with the renal pelvis. The whole organ may be destroyed by this process of softening and of excavation. Sometimes only one, but usually both of the kidneys are affected, although often in unequal degree. The diseased kidney may be shrunken, or of normal size, or enlarged. It is usually enlarged. Caseous nodules commonly project from its surface. The mucous membrane of the pelvis and of the ureters is usually thickened from infiltration with fresh and caseous tuberculous material, and presents in some places ulcerations. As in other situations, inflammatory processes are combined with the tuberculous. From the surface of the mucous membrane can be scraped débris consisting of cheesy material, blood, pus, and shreds of tissue. The lumen of the ureter, as a rule, in certain places is diminished, and, as a consequence of this obstruction, the pelvis of the kidney is dilated, so that often pyonephrosis complicates the disease. Tuberculous ulcers may be present in the bladder. There may be caseous nodules in the prostate and in the testicles. The cheesy masses of renal phthisis may result from an agglomeration of miliary tubercles or from diffuse tuberculous infiltration. The tubercles are at first gray and subsequently yellow and cheesy.

Miliary tubercles and small caseous deposits in the kidneys are not revealed by any symptoms. Marked symptoms usually attend that rare form of tuberculous inflammation called renal phthisis, whether the condition be developed primarily or secondarily. The symptoms in this disease are referable, not only to the renal affection, but also to the tuberculous inflammation of the urinary passages, especially to the tuberculous pyelitis. Although the desire to micturate is often increased in frequency, the quantity of urine is generally lessened. Urination may be painful, especially when the bladder is involved. The urine contains pus and at times blood. The hæmaturia is generally moderate in degree. The urine remains acid, unless ammoniacal decomposition takes place, as is apt to be the case if cystitis be developed. Great importance is attached by most writers to the detection in the urine of small particles of caseous material insoluble in acetic acid. These are not to be found in all cases. The presence of fibres of elastic or of connective tissue in the urine indicates ulcerative destruction, but is not distinctive of renal phthisis. More or less granular material and modified pus and epithelial cells may also be discovered by the microscope. In most cases there is pain in the region of the kidneys. The pain is usually dull; but there may be paroxysms of severe pain. Tenderness on pressure is present in most cases, even when there is no spontaneous pain. In some cases a swelling may be discovered in the lumbar region. This is due to enlargement of the kidney or to pyonephrosis, or to both conditions combined. Constitutional symptoms develop sooner or later. These are, hectic fever, chills, night-sweats, progressive emaciation, and loss of strength. There may be diarrhœa with or without tuberculous ulceration of the intestine. In a certain proportion of cases the symptoms of chronic pulmonary tuberculosis are present, and these may either antedate or follow the genito-urinary tuberculosis. Acute miliary tuberculosis may be a sequence of renal phthisis. The recognition of tuberculous nodules in the testicles, or in the prostate, in some cases aids in the diagnosis. Uræmic symptoms do not usually develop in the course of renal phthisis. Bright's disease may, however, occur as an intercurrent affection.

Renal phthisis terminates fatally in the great majority of cases. The

duration generally is not longer than a year. If the affection be localized in one kidney, recovery may take place.

A diagnosis cannot be made prior to the presence of morbid products in the urine. The diagnostic problem, then, is to differentiate the disease from pyelo-nephritis. In rare instances the presence in the urine of cheesy masses, granular detritus, and shreds of tissue point to a tuberculous disease. In general, however, a diagnosis must rest on the co-existence of tuberculous disease in other parts of the genito-urinary system, in vertebræ, and in the lungs, together with hectic fever and progressive emaciation. Waxy degeneration sometimes supervenes upon renal phthisis.

Aside from measures for the palliation of local symptoms, the indications for treatment are those in cases of pulmonary phthisis, with which, in the majority of cases, the disease is associated.

Carcinoma of the Kidney.

A great variety of tumors form in the kidney, but only cancer is of much clinical importance. Cancer may occur in the kidney as a primary or as a secondary growth. It develops secondarily, either in the form of metastases or as a continuous growth from adjoining parts. Secondary renal cancer, although more frequent than the primary form, rarely attains to a large size or gives rise to symptoms drawing attention to the kidneys. It has much less clinical importance than primary cancer, and the latter is the form to be considered in this article. Primary cancer of the kidneys is a rare disease, although less infrequent than was formerly believed. It occurs oftener in the first decade of life than in any succeeding decade, and in this it differs from cancer in other situations. Rohrer has collected 115 cases of primary renal cancer, which is the largest number as yet brought together. Over one-third of the cases occurred within the first ten years of life. The next largest number of cases were those between fifty and sixty years. Notwithstanding its infrequency, cancer of the kidney is the cancer oftenest met with in childhood. Of the cases of renal cancer in children, by far the largest number fall within the first five years of life.[1] In very rare instances it has been observed as a congenital affection.[2] In the majority of cases cancer of the kidney is unilateral. It may, however, develop as a primary affection in both kidneys.[3] Males are somewhat more frequently affected than females.

Renal cancer, in the great majority of cases, belongs to the soft or medullary variety. Cancer in this situation may, however, present all grades of transition between the medullary and the scirrhous forms. Colloid renal

[1] Rohrer, Das primäre Nierencarcinom, Inaug. Diss., Zurich, 1874. Of 107 cases in which the age of the patient was stated, 37 were under 10 years, 4 were between 10 and 20, 5 between 20 and 30, 10 between 30 and 40, 10 between 40 and 50, 17 between 50 and 60, 10 between 60 and 70, 3 between 70 and 80, and 11 were described simply as adults. Of 29 cases of cancer in children collected by Hirschsprung (1868), 15 were of the kidney. 82 per cent. of all renal cancers in childhood fall within the first four years (Rohrer).

[2] Ebstein is mistaken in asserting that cancer of the kidney is never congenital. Weigert observed a renal cancer in a new-born baby (Virchow's Archiv, Bd. 67, p. 492). Hasse saw a renal cancer the size of a child's head in a new-born baby (reported by Kühn (Deutsches Archiv f. klin. Med., Bd. xvi. p. 325). Bednar observed a case in a child one month old. Moreau two cases in children three months old, and Braidwood a case in one four months old. There are other cases in the first months of life.

[3] Of 114 cases the cancer was 52 times on the right side, 50 times on the left, 12 times bilateral. In children the left kidney was oftener affected than the right ($2\frac{1}{2} : 2$), in adults the right oftener than the left ($5 : 4$). Bilateral cancer was of equal frequency in children and in adults (Rohrer).

cancer has also been described. The new growth may appear either as a diffuse infiltration of the kidney or in a nodular form. There may be remnants of intact renal tissue, or the entire parenchyma may be destroyed. The size of the tumor is in many cases enormous, and it is a remarkable fact that relatively, and almost absolutely, the largest tumors are met with in children. According to William Roberts, the average weight in children is $8\frac{1}{2}$ pounds, and in adults $9\frac{1}{2}$ pounds. The maximum weight was 31 pounds, and this was observed in a child. In the most frequent form of renal cancer the consistence is soft. Not infrequently cavities form, containing soft, pulpy, degenerated cancerous material. From the fluctuating feel afforded by these softened masses, renal cancer has often been punctured during life under the supposition that a cyst or an abscess was present. The color is not uniform. In most cases a section of the tumor presents a whitish or yellowish appearance mottled with red and brown portions. The red portions are due to dilated bloodvessels and to hemorrhages. When their number is large, the red patches give a hemorrhagic aspect to the tumor, whence it derives the name fungus hæmatodes. The brown portions result from pigmentary changes in blood-extravasations. Sometimes the tumor is confined within the capsule, at other times it invades surrounding parts. In some cases the appearance is as if the tumor took its origin in the connective tissue or the glands about the kidney, and secondarily invaded this organ. They who maintain the epithelial origin of cancer are unwilling to admit that it ever develops primarily in the perinephritic tissue. The tumor usually contracts adhesions to surrounding parts, but sometimes a cancerous kidney is movable. In nearly all cases the colon lies in front of the tumor. Secondary cancerous growths are found in other organs in rather less than half the cases of cancer of the kidney. It is a peculiarity of primary renal cancer, especially in children, that it does not readily give rise to metastases.[1] The secondary deposits are met with most frequently in the retro-peritoneal glands, the lungs and the liver. The frequency with which the renal vein is involved in the new growth, explains the common occurrence of secondary cancerous deposits in the lungs, as by this implication of the veins cancerous material may gain access to the blood current. Metastases are rare in the lower urinary passages, but cancer of the kidney frequently grows continuously into the renal pelvis, and may invade the ureter. It is not rare to meet with calculi in the pelvis of a cancerous kidney. It is exceptional for renal carcinoma to cause ulceration of the superjacent integument. The intestine, especially the overlying colon, may be perforated by the cancerous growth. Intestinal fistulæ opening externally have been caused by this disease. The vertebræ in some cases are involved in the malignant growth. Pressure upon the inferior vena cava may cause œdema of the lower extremities. Ascites is rare. Displacements and distortions of the abdominal organs are often the result of pressure from cancerous tumors of the kidney. The diaphragm may be pushed upward and the lungs compressed. If the disease be unilateral, the kidney unaffected by cancer is generally hyperæmic. In one case the ureter of this kidney was found to contain blood, as well as the ureter of the cancerous kidney. As pointed out by Kühn, this demonstrates that bloody urine may come from the non-cancerous as well as from the cancerous kidney. Amyloid degeneration of the kidney, as well as of other parts, may be caused by renal cancer.

Upon microscopical examination, the tumor presents the arrangement of cells in alveoli with intervening stroma, which was described as characteristic

[1] According to Kühn, secondary growths are found in 28 per cent. of the cases in children, and in 44 per cent. in adults (*loc. cit.*).

of cancer in Part First, page 45 *et seq.* The microscopical appearances as regards the size of the alveoli, the shape of the cancer cells, the amount and character of the stroma, the degree of vascularity, vary in different cases. The designation of the tumor as medullary or as scirrhus depends upon these variations, as has also been explained in the article on carcinoma in Part First. In the soft renal cancers, the most frequent form, the alveoli are separated by a small amount of stroma and are usually large. It is a peculiarity of soft cancer of the kidney that the alveoli may be separated from each other in some places by nothing but bloodvessels, the appearance being that bloodvessels actually penetrate the alveoli. The stroma of these cancers, in its scanty amount of fibrillated connective tissue, resembles the normal interstitial tissue of the kidney. The stroma is not in all places as thin as has been described, and it may be abundant. In some cases the cancer cells resemble the epithelium of the convoluted tubes, being very granular and indistinctly separated from each other. They are, however, always irregular in shape. Cylindrical celled epithelioma of the kidney has been described by Wagner. Waldeyer, Klebs, Pereverseff, and others have described with much detail the development of cancerous alveoli from the uriniferous tubes, and of cancer-cells from the epithelium of these tubes; the tubes becoming dilated, irregular in shape, giving off processes, and within these dilated branching tubes the epithelial cells proliferate. In the immediate neighborhood of the cancerous growth, the interstitial tissue of the kidney is often increased in amount, and the tubes are in some places compressed and in others dilated. Cancer seems to take its origin more frequently from the cortical than from the medullary tubes.

In a clinical point of view, as already stated, secondary cancer of the kidneys has little interest. It is generally latent as regards diagnostic symptoms. Both kidneys are affected, as the rule; the disease does not advance sufficiently to form appreciable tumors, and there may be no symptoms denoting renal disturbance. Primary cancer, on the other hand, is generally unilateral, and, in a large proportion of cases, gives rise to symptoms which direct attention to the kidney. Lumbar pain on the affected side, extending down the ureter to the thigh, may be a more or less prominent symptom, but it is not so except in a certain proportion of cases, and this symptom for a long time may be wanting. There are loss of appetite, progressive emaciation, and other symptoms which belong to the cancerous cachexia, and denote an inroad upon the constitution, but they may be long deferred. The diagnosis hinges upon the discovery of a renal tumor.

The tumor is felt between the ribs and the pelvis latero-anteriorly. It varies greatly in size and form in different cases. It may be as large as the closed hand or a child's head, and in young subjects it sometimes attains to enormous dimensions, as in the case cited by Roberts in which the weight of the tumor was 31 pounds. In the pictorial representation of that case, the enormously enlarged abdomen contrasts strikingly with the attenuated chest and limbs. The tumor may be smooth or lobulated. The aortic impulses may cause it to pulsate, resembling in this respect an aneurismal tumor. It may be hard and resisting to the touch, or it may give a sense of fluctuation. It is sometimes hard to the touch in some, and soft in other, parts. The tumor sometimes retains the shape of the kidney, although much enlarged, but oftener there is so much distortion that the shape is of no value in the diagnosis. The cancerous disease may extend to the neighboring lymphatic glands, and these may form a mass which may exceed in size the enlarged kidney.

The first point with reference to the diagnosis is to determine that the

tumor is renal. It is to be discriminated from enlargement of the liver and spleen, from an ovarian and from a fecal tumor. It is shown not to be connected with the liver or the spleen if the fingers can be pressed between the lower margin of these organs and the tumor. The evidence afforded by percussion must not be too confidently relied upon. The renal tumor is usually behind the intestine, and, therefore, a tympanitic resonance is often obtained by percussing over it; but it is common to find over the liver and the spleen this resonance, owing to its being conducted from the colon and stomach upward to a greater or less height. Hence the resonance over the liver and over the spleen may be tympanitic, although no part of the intestine is situated over these organs. On the other hand, the portion of intestine situated over a renal tumor may not at all times contain gas, and there may then be flatness on percussion. Too much reliance on a tympanitic resonance over an abdominal tumor, as a differential point, is likely to lead to error in the diagnosis. A cancerous kidney usually becomes closely adherent to adjacent parts, and is not, like the liver and spleen, lowered by the descent of the diaphragm in inspiration. An ovarian tumor differs in being found at first in the iliac fossa, and, as it increases in size, it extends upward, whereas an enlarged kidney is at first felt in the hypochondrium, and, as it enlarges, it descends. For further diagnostic evidence of ovarian tumors the reader is referred to works on gynæcology. Fecal tumors have their characteristics which have been considered (page 495).

A renal cancer is to be discriminated from other affections of the kidney, namely, hydronephrosis, pyonephrosis, renal abscess, hydatid disease, and cystic degeneration. From the palpable characters of the tumor, this is by no means easy. With reference to this differentiation, the antecedent and concomitant symptoms are to be considered, and, as bearing on both the seat and the character of the tumor, hæmaturia is pre-eminently a diagnostic symptom.

Hæmaturia and the existence of a tumor referable to the kidney render the diagnosis of renal cancer almost positive. The analysis, however, of 59 cases by William Roberts gave 28 in which hæmaturia did not occur; and of the larger collection of cases by Rohrer, this symptom was present in only 34 per cent. The absence of hæmaturia, therefore, by no means excludes cancer. Hæmaturia, too, without tumor, is not evidence of renal cancer. It is the conjunction of the hæmaturia and the tumor which establishes the diagnosis; and a positive diagnosis is not possible unless these two events be conjoined.[1]

The hæmaturia may occur for the first time early or late in the progress of the disease. It often recurs more or less frequently after irregular intervals. The hemorrhage is sometimes profuse, and sometimes it is small. Clots formed in the calices or the pelvis of the kidney, in passing through the ureter may give rise to all the symptoms which attend renal colic. The coagula in some instances become moulded in the ureter, and appear in the urine in the form of casts resembling lumbricoid worms. Many of these were passed in a case which came under my observation. The coagula may obstruct the ureter and give rise to hydronephrosis. The blood sometimes coagulates in the bladder, and the coagula are with more or less difficulty expelled through the urethra.

[1] With reference to these two diagnostic events, namely, tumor and hæmaturia, Rohrer divides his 115 cases into four classes as follows: 1. In 36 cases there was neither tumor nor hæmaturia, and the disease was therefore unsuspected. 2. In 12 cases there was hæmaturia without tumor. 3. In 25 cases there were both tumor and hæmaturia. 4. In 42 cases there was tumor without hæmaturia.

The mistake is often made of supposing that the urine may contain cells distinctive of cancer. It is perhaps true that cells from the tumor may be contained in the urine, but these cells have no characters by which they can be distinguished as cancer-cells. The normal epithelial cells lining the urinary bladder present such a great variety of forms that they are often taken as the physiological type or paradigm of cancerous cells. There is no instance of the diagnosis having been based upon the recognition in the urine of masses of cancerous tissue of sufficient size to detect an alveolar structure. If blood or pus be contained in the urine, there is, of course, a certain amount of albuminuria; but, if these elements be absent, renal cancer may exist without any trace of albumen in the urine. The disease may, however, be attended by changes in the kidney which give rise to considerable albuminuria.

The termination in cases of renal cancer is inevitably in death sooner or later. The duration of the disease in children is shorter than in adults. William Roberts found the average duration in children about seven months, the extremes being ten weeks and over a year. In adults the average duration was two and a half years, and the extremes five months and seven years. Rohrer, from his statistics, reaches similar results. It is to be observed that in the cases embraced in these statistical analyses, the latent period of the disease, when there were no symptoms present, cannot be taken into account, and there is reason to believe that this latent period may be of long duration. Wharry mentions a case which proved to be one of renal cancer, in which a tumor, gradually increasing in size, had been ascertained fourteen years before death.[1] Dunlop has reported two cases, the duration having been ascertained to have been in one from ten to twelve years and in the other sixteen years.[2] Rohrer cites a case which lasted seventeen years. These are, of course, exceptional cases; but it is a noteworthy fact that cancer in this situation is tolerated in some instances for a very long period, and a great length of time may elapse without much constitutional disturbance. On the other hand, in some cases, especially in children, the tumor grows with astonishing rapidity.

It is a peculiar feature of primary cancer seated in the kidney, that the tendency is much less than in other situations to extend to neighboring parts, or to give rise to metastatic cancerous disease in situations more or less remote. Heredity seems not to be involved in the causation of the disease in this situation. Respecting the causation, nothing is known.

The indications for treatment have reference in some cases to lumbar pain; to the occurrence of renal colic; to urethral obstruction from clots; to the removal of coagula from the bladder; to hæmaturia when the hemorrhage is profuse, and to other effects, symptoms, or complications which are liable to occur during the progress of the disease. Aside from meeting these indications, the object of treatment is to render the system tolerant of the disease as completely and as long as possible. The measures for this object are the same as in other diseases, in the management of which all that is to be hoped for is retardation of their progress and of their inroads upon the constitution. These measures embrace tonic remedies, palliatives, nutritious diet, and favorable hygienic influences, moral and physical, in the place of those which tend to impair the ability to endure an incurable disease.

[1] The Lancet, Feb. 10, 1877. [2] Ibid., April 21, 1877.

Movable Kidney.

One of the kidneys is sometimes loosened so as to form a movable tumor which may be felt through the abdominal walls. This condition is called movable kidney, floating kidney, wandering kidney, ectopia renis. The degree of mobility varies much in different cases. The kidney is normally held in position by the layer of peritoneum which is attached to the anterior surface of its adipose capsule. In movable kidney the adipose tissue in which the normal kidney is imbedded partly or wholly disappears. The overlying peritoneum becomes lax, and may form a partial or even complete investment of the kidney. In extreme cases the mobility of the organ is restrained only by its vessels and the ureter. Unusual length of the renal vessels is thought to be a predisposing cause of displacement of the kidney. In nearly all cases the intestine is interposed between a movable kidney and the abdominal walls. In very exceptional cases the organ has been found in front of the intestine. A displaced kidney may become fixed in its abnormal position by the formation of adhesions.

It is difficult to form an estimate of the frequency of this abnormality of the kidneys, as the condition doubtless often exists without being recognized. It is probable that abnormal mobility of these organs is not very uncommon. It is far more frequent in women than in men. Of 96 cases collected by Ebstein, 82 were in women and 14 in men.[1] The right kidney, oftener than the left, is movable. Both organs may be affected. Of 91 cases brought together by Ebstein, the right kidney was affected 65 times, the left 14 times, and both kidneys 12 times.[2] The affection may be congenital or acquired. It is usually acquired. In most of the cases the abnormality developed between the twentieth and the forty-fifth year; or, in other words, during the child-bearing period in women. The affection may, however, appear at any age. Mobility of the kidney is attributable to relaxation of the abdominal walls from pregnancies, to the use of corsets, to violence, to increased weight of the organ from disease, to the pressure of tumors growing in the neighborhood of the kidney, and to the traction of hernias. The disappearance of the fat from the adipose capsule of the kidney, as happens in wasting diseases, has also been assigned as a cause, but its efficacy is doubtful. Unusual laxity of the abdominal walls from other causes than pregnancy may be an element in the causation. In congenital floating kidney there is usually some abnormality in the development of the peritoneum covering this organ, or in the length, origin, or distribution of the renal vessels.

Movable kidney may exist without causing any noticeable symptoms. In several cases it has been discovered accidentally by the physician while making a physical examination of the abdomen. Usually, however, the condition gives rise to more or less uneasiness. The patient experiences often a sense of weight and a dragging pain, especially upon walking or standing. There may be severe neuralgic pain radiating from the affected side. If the tumor be first discovered by the patient, it becomes often a source of great mental anxiety. In some cases the movable kidney gives rise to the paroxysmal development of symptoms of considerable severity, to which the name "symptoms of incarceration" was applied by Dietl. These symptoms are chilliness, nausea, vomiting, prostration, intense pain and anxiety. The affected kidney and surrounding tissues are swollen and sensitive to pressure. These symptoms usually subside within a few days under the influence of

[1] Ebstein, Ziemssen's Cyclopædia of the Practice of Medicine, Am. ed., vol. xv. p. 765.

[2] Of 65 cases collected by Roberts, in 42 the right alone was movable, in 9 the left alone, and in 14 both kidneys.

rest and of opiates. They are relieved if the kidney be replaced. The explanation of the cause of the symptoms of incarceration is not satisfactorily established. The symptoms have been ascribed to twisting of the ureter and to retention of the urine in the pelvis of the organ from the temporary obstruction thereby occasioned. In this way it is claimed that an acute hydronephrosis and a pyelitis may develop. Hydronephrosis may co-exist with movable kidney, but this explanation does not seem to be applicable to all cases. The symptoms have more usually been attributed to inflammation of the peritoneum and connective tissue surrounding the kidney. Another possible explanation is, that the symptoms are due to partial strangulation of the kidney from compression or from twisting of its bloodvessels. A movable right kidney pressing on the duodenum may be a cause of dilatation of the stomach, as has already been pointed out in the article on the latter subject (page 474). Constipation may be a result of compression of some part of the intestine, most frequently of the colon, by a movable kidney. Œdema of the lower extremities has been described as a result of compression of the inferior vena cava by a displaced kidney. According to Roberts, epigastric pulsation is in some cases a prominent phenomenon in connection with movable kidney.

The occurrence of movable kidney is to be recollected in determining the nature of obscure tumors within the abdomen. The recognition of this variety of tumor is to be based on the following diagnostic points: It is situated in the hypochondriac region. It has the size and the shape of the normal kidney, and this may be determinable by palpation. It is generally movable, and in some cases it can be restored to its proper situation. Over the normal site of the organ on the affected side, a depression is sometimes observed, and there is a tympanitic resonance on percussion derived from the portion of the intestine which occupies the place which the kidney should have occupied. These two latter diagnostic points are available in only a certain proportion of cases. Other tumors are to be excluded by the absence of their diagnostic characters.

The inconvenience and sometimes suffering attending this anomaly, may be obviated, in a measure at least, by mechanical compression of the abdomen by means of a bandage or belt or abdominal supporter. In attacks of pain, the organ should if possible be replaced; rest and recumbency are to be enjoined; emollient applications made over the abdomen, and, if these measures do not afford relief, opiates are indicated.

Renal Hæmaturia.

Hæmaturia, or bloody urine, occurs in various diseases, as well as after wounds and other injuries of different parts of the urinary apparatus. The hemorrhage may be renal; that is, the blood may come from either the pelvis or the calyces or the uriniferous tubes of the kidney, or it may come from the ureter, the bladder, or the urethra. When it takes place from the bladder or the urethra, whether it be traumatic or symptomatic of disease, it comes within the province of surgery; but the means of determining that the hemorrhage is either cystic or urethral are of importance to the physician, as aiding him to decide by exclusion either that the hæmaturia is renal, or that the blood comes from the ureter. Urethral hemorrhage is easily discriminated. The blood escapes without any effort of micturition, and hæmaturia exists only in so far as blood remaining in the urethra is washed away with the flow of urine. Moreover, the seat of the disease or injury may be ascertained by surgical exploration. Cystic hemorrhage is discriminated by attention to the following points: The passage of pure blood with acts of micturition, after the discharge of urine; obstruction to the free escape of urine from

the presence of coagula within the bladder; the existence of a calculus or of a vesical tumor as determined by surgical exploration; the symptoms of either cystitis, ulceration, or malignant disease of the bladder, and finally, the fact of the bladder having been the seat of a wound or injury.

Excluding the urethra and the bladder as the source of the hemorrhage in cases of hæmaturia, it remains to be determined whether the blood comes from the ureter or from the kidney. Hemorrhage from the ureter generally involves the presence of a calculus in this situation. If, therefore, symptoms denoting this causation be wanting, and the hemorrhage be neither cystic nor urethral, in all probability the source of the hemorrhage is renal. In most of the cases of hæmaturia in which the bloody urine denotes a medical, as distinguished from a surgical, affection, the source of the hemorrhage is the kidney. In certain cases, however, the hemorrhage is both renal and cystic. In tracing blood in the urine to the kidney, aside from the exclusion of the urethra, bladder, and ureter as sources of the hemorrhage, changes in the urine, in addition to those dependent on the presence of blood, and also other symptoms of renal disease, are, of course, to be taken into account. The microscope is sometimes essential in determining the presence of blood in the urine. Purpurine may give to the urine a color resembling that caused by blood. Various articles ingested give rise to an appearance of bloody urine, namely, the prickly pear, beet-root, madder, logwood, etc. On the other hand, blood may be present in so small an amount as not to produce a bloody appearance to the naked eye, when the microscope shows blood-corpuscles in the sediment. The presence of blood-casts in the sediment of the urine is proof that the hemorrhage is renal; so, also, the presence of fibrinous casts of the ureter, the latter being large enough to be seen with the naked eye. A smoky or sooty appearance of the urine denotes the presence of blood, and is somewhat characteristic of renal hemorrhage. It is to be borne in mind that blood-corpuscles may not be discoverable in urine which has become ammoniacal, as under these circumstances they may be speedily destroyed. In urine of low specific gravity the blood-corpuscles appear very pale. If, owing to the absence of the blood-corpuscles, there be doubt as to the appearance of the urine denoting the presence of hæmatin, chemical tests may be employed, or the spectroscope. Bloody urine is always more or less albuminous.

Renal hemorrhage is to be regarded in the light of a symptom. As such, it enters into the clinical history of acute Bright's disease, and, in some rare instances, also of the chronic forms of the disease. It is caused by injury of the kidney. It may occur in pyelitis. It is an important symptom in cases of cancer of the kidney. It may be incident to simple renal congestion, either active or passive. It is also caused by tuberculous inflammation of the kidney, and in very rare instances by hemorrhagic infarctions of this organ.

Hæmaturia from either renal or cystic hemorrhage, or both, is a symptom of certain diseases characterized by the development of a hemorrhagic diathesis. Thus it may be symptomatic of scorbutus, purpura hæmorrhagica, yellow fever, relapsing fever, pernicious malarial fever, etc. In many, if not most, of these instances, however, there is not true hemorrhage, that is, the blood-corpuscles do not pass into the urine, but only their coloring matter, the hæmoglobin which is set free in the blood in consequence of the destruction of the corpuscles. The condition of the blood, under these circumstances, is expressed by the terms hæmatinuria or hæmoglobinuria, instead of hæmaturia.

In cases of renal hæmaturia, if the hemorrhage be considerable, the application of cold over the kidneys, by means of compresses wet in cold water, or the ice-bag, is indicated. Internal hæmostatics which may be employed are tannic or gallic acid, ergot, the muriate and other astringent preparations of

iron, alum, and the acetate of lead. Aside from the treatment having direct reference to the hemorrhage, indications are to be derived from the diseases or morbid conditions with which it is connected as a symptom.

Endemic Hæmaturia.

This name is applied to hæmaturia occurring in Brazil, Egypt, the Cape of Good Hope, and some other tropical countries. In 1851 Bilharz discovered the parasite which he called distoma hæmatobium, for which Cobbold substituted the name *Bilharzia hæmatobia* in honor of the discoverer. The connection of this parasite with hæmaturia was ascertained by Harley in 1864. That it is causative of a disease prevalent in the countries above mentioned, has been established by the added researches of Griesinger, Sonsino, and others. This worm, half an inch or more in length, is found especially within the vessels of the bladder, of the mesentery, and throughout the portal system. The ova and embryos may be discovered in the urine. In a case observed by Roberts, the urine contained living embryos moving about with rapidity by means of the long vibrating cilia with which they were covered. Harley, however, failed to find living embryos in the urine.

The local effects are manifested in the mucous membranes of the urinary cavities, and also in the intestinal canal. After death are found in the bladder, in the pelvis of the kidneys, and in the intestine, blood-extravasations, fungus-like thickening of the membrane, and ulcerations. The hæmaturia is often associated with diarrhœa. The phenomena of the so-called Egyptian chlorosis are explained in some cases by the discovery of this parasite. This helminthic disease is of frequent occurrence in Egypt. Griesinger found the parasite in 117 of 363, and Sonsino in 13 of 34, autopsies.

It is supposed that the larvæ of the parasite are contained in impure drinking water, and that in this way they gain entrance into the system. Cobbold thinks that the infection occurs from swallowing "fresh-water mollusks which contain the higher larval forms in their encysted or pupa condition."[1]

The diagnosis is to be based on the discovery of the ova, and sometimes of the embryos, in the urine and in the dejections.

The local effects of the parasite occasion pain referred to the bladder and kidneys, together with colic pains, and there may be pyrexia and general symptoms which may suggest typhoid fever, or septicæmia. An accumulation of ova may form the nucleus of a renal or a cystic calculus.

The rational object of treatment is the destruction of the parasite in the blood. The remedies by which this object can be effected, have not been ascertained. The local effects of the parasite, and the general condition, are to be treated according to symptomatic indications. Harley recommends the administration of the oil of turpentine and of the male fern (āā ♏xv), and ♏v of chloroform daily, in order to expel the ova from the urinary passages, and a solution of the bicarbonate of potassa to relieve renal pain and irritation. He also recommends injections into the bladder of liquids containing wormwood, oil of male fern, and the iodide of potassium, in order to destroy the parasite or its ova in this viscus.

The disease is rarely fatal; but it may continue for a long period. It may give rise to calculi, pyelitis, and, by obstructing the ureter, to hydronephrosis. In situations other than the urinary passages, it may occasion local effects which have not as yet been studied.

[1] For a full account of this parasite, *vide* Cobbold's Treatise on the entozoa of man and animals, p. 38 *et seq.*, London, 1879.

Hæmoglobinuria. Hæmatinuria.

In 1865 Harley reported cases of supposed hæmaturia occurring in paroxysms. Other cases, under the name *intermittent* or *paroxysmal hæmaturia*, were subsequently reported by Dickinson, Greenhow, Roberts, and others. More recently (1878) Lichtheim has reported cases, and shown that the urine does not contain blood, that is, the red corpuscles, but only the coloring matter or hæmoglobin, and that this constituent of the corpuscles is separated therefrom, not in the urinary organs, but within the bloodvessels.[1] The affection, therefore, does not properly belong to the urinary system; it is a hæmic affection. Lichtheim calls it *periodic hæmoglobinuria*. It is also distinguished as *hæmatinuria*. It has been called *false hæmaturia*. The absence of the blood-corpuscles in the apparent hæmaturic urine in this affection, was ascertained by Pavy in 1865, who, however, adhered to the name paroxysmal hæmaturia.

The paroxysms may be either severe or slight. If more or less severe, the patient is attacked with a well-pronounced chill, accompanied perhaps by rigors, lasting half an hour to an hour, or longer. In some cases pyrexia and sweating follow, and the paroxysm then resembles closely that of intermittent fever, but it is certain that it occurs irrespective of a malarial causation. In the so-called hæmaturic intermittent fever or miasmatic hæmaturia, however, it is probable that the urine in most cases contains hæmoglobin without blood-corpuscles. In many and perhaps in most instances the chill is not followed by pyrexia.

During or following the chill, the urine passed has a dark red color, and appears to the eye to be bloody. The microscope, however, employed at once, shows the absence of red corpuscles. There is a chocolate-colored sediment consisting chiefly of granular matter; the urine is albuminous, and sometimes contains dark granular and hyaline casts. Peculiar reddish-yellow masses, sometimes in the form of drops, and sometimes resembling casts, have been found in the urine. They are probably derived from the hæmoglobin. The same material has been observed in the renal tubes in cases of hæmoglobinuria. After the paroxysm, with each passage of urine it is found to be clearer, and within twenty-four hours it becomes normal. Meanwhile, the other symptoms diminish and disappear, and on the day following that of the paroxysm, except the weakness due to the latter, the usual health of the patient is restored. With a light paroxysm, there is only a severe attack of chilliness followed by little or no fever, and the symptoms may not be sufficient to interrupt the usual occupation of the patient. The paroxysms recur irregularly, at variable periods. Two or more daily sometimes occur, or the intervals may be days, weeks, or months. A paroxysm never occurs at night. In proportion as the paroxysms are frequent and severe, patients present a pale, cachectic aspect, and the affection is, in some cases, associated with jaundice.

A pathological condition of the blood stands in an immediate causative relation to the hæmoglobinuria in this affection. Either the hæmoglobin escapes from the blood-corpuscles, or these undergo dissolution within the bloodvessels. The hæmoglobin suddenly set free in the circulating fluid in considerable quantity, is eliminated by the kidneys. Hence, the seat of the affection is not in the urinary system. The setting free of the hæmoglobin in the blood, involves some ulterior causative agencies. Of the latter we have, at present, no knowledge. A similar blood-change occurs in scorbutus, in purpura hæmorrhagica, in the so-called hemorrhagic smallpox, in some

[1] *Vide* Sammlung Klinischer Vorträge, von Volkmann, No. 134, 1878.

cases of typhoid fever, measles, scarlet fever, etc. In these diseases there is said to be "dissolution of the blood." It has been observed as an effect of inhaling arseniuretted hydrogen and carbonic acid; also of phosphorus-poisoning, and after the transfusion of lamb's blood. The presence of the blood-pigment in the serum of the blood during a paroxysm of hæmoglobinuria, and its absence between the paroxysms, have been demonstrated.[1]

The diagnosis in well-marked cases is easy. The absence of blood-corpuscles in fresh specimens of urine, is the point on which hinges the differentiation from true hæmaturia. The differentiation from other affections in which the urine may have analogous appearances, is made by determining the presence of hæmoglobin in the urine. This may be determined by chemical tests. The presence of hæmoglobin may be demonstrated by means of the spectroscope.

The causation of paroxysmal hæmoglobinuria generally involves the agency of cold. Paroxysms are generally attributable to some exposure. By avoiding this cause, patients apparently escape recurrence of attacks. Of the *modus operandi* of this cause, and of other causes, we possess, as yet, no definite knowledge. The affection occurs almost exclusively in the winter season. Rosenbach produced an attack in summer by causing the patient to bathe his feet in cold water. In nearly all the reported cases the patients have been men.

The affection does not tend to destroy life. Paroxysms may recur for an indefinite period, but recovery may be expected to take place sooner or later. No fatal case has, as yet, been reported.

The treatment during the paroxysm consists in placing the patient in bed, applying heat to the surface, and giving internally hot drinks with the addition of some form of alcoholic stimulant. After a paroxysm, measures to maintain warmth of the surface are of primary importance. Exposures to cold should, as far as practicable, be avoided. A rough, changeable climate may be exchanged with advantage for one which is mild and uniform. There are no known remedies of special efficacy. Chalybeate and other tonics, with good alimentation, and the moderate use of wine, are to be prescribed according to the indications in individual cases.

Chyluria.

This disease is characterized by the passage of urine which resembles milk. It has sometimes a rose or pink tinge due to the presence of a little blood, and it is sometimes associated distinctly with hæmaturia, but in other instances it has the opaque white appearance of milk. After its passage it forms spontaneously a solid coagulum. It sometimes coagulates within the bladder. It is coagulated by heat and nitric acid. The microscope shows the presence of fatty matter in the form of minute granules, and usually blood-globules. The fatty matter is dissolved by ether, and the urine which remains assumes a normal appearance.

The disease prevails in certain tropical countries. In the cases which have fallen under observation in other countries, the disease, as a rule, has been contracted in a hot climate. There are, however, exceptions to this rule. A few cases have been reported by English observers. Abbe has reported two cases occurring in this country, the patients having never visited tropical regions.[2] There is reason to think that cases in a temperate latitude are not as rare as might be inferred from the small number which have been reported.

[1] Kuessner, Deutsche med. Wochenschrift, 1879, No. 37.

[2] *Vide* article by Robert Abbe, M.D., in the New York Med. Journal, Feb. 1880.

The milky urine, in most cases, occurs without any premonition, and generally without any appreciable exciting cause. All the urine passed per diem may be chylous, or it may in part be normal. The chyluria occurs intermittingly, the intervals in different cases varying from days to months and years. There is no regularity as regards either the duration of attacks, or their recurrence, or the period during which they continue to recur. They cease to recur, and recovery takes place in a minority of cases. In the intervals between the attacks there is no evidence of renal disease.

In severe cases there are lumbar pains and symptoms denoting exhaustion. Milder cases are not only exempt from grave symptoms, but there may be nothing which points to any disease aside from the passage, after irregular intervals, of milky urine. The disease is very rarely the cause of death.

We possess no satisfactory explanation of the production of chyluria. In 1872, Lewis, of Calcutta, discovered the existence of an entozoön in great number in the blood and urine of patients affected with this disease. This parasite is a worm resembling the trichina spiralis, but much smaller, its length being $\frac{1}{75}$ of an inch. Lewis gave to it the name *filaria sanguinis hominis*. He found vast numbers in the cortical and pyramidal portions of the kidneys after death.[1] One theory is that they injure, within the kidneys, the walls of the lymphatics, occasioning thus the escape of their contents into the urinary canals. It is possible that the molecular chylous material pre-exists in the blood in this affection.

Manson, of China, advocates a curious theory, namely, that the filariæ are sucked up in great numbers with the blood from patients affected with this disease by mosquitos; that the parasite undergoes further development in the stomach of the latter animal, and, being discharged into water, is prepared to enter again the human body.[2]

This parasite has not been found in all cases, and, assuming a causative relation to the disease in some cases, that it is always referable to this cause is not certain.

Gallic acid, from one to two drachms given daily, is the remedy which thus far has been found most useful. Turpentine is recommended. A decoction of mangrove bark (rhizophora racemosa), an ounce given four times daily, is a popular remedy in British Guiana.[3]

Diabetes Insipidus.

The term diabetes signifies simply increased flow of urine, or diuresis. The term is applied to two affections which differ essentially each from the other. In one of these affections notable diuresis exists, a given quantity of the urine containing a small proportion of solid constituents; that is, the specific gravity is low, being sometimes but little above that of spring water. The morbid abundance of urine in this affection is due to an excessive elimination of water by the kidneys. Considered as a urinary affection, it is called diabetes insipidus. The other affection to which the term diabetes is applied, is characterized by the presence of sugar in the urine. This affection will be presently considered.

A morbid excess of water in the urine, expressed by the terms hydruria and polyuria, is a symptom occurring in various pathological connections. It is a frequent symptom in cases of the small granular kidney, and is not

[1] On a Hæmatozoön in Human Blood; its relations to Chyluria and other diseases, etc. Calcutta, 1874.

[2] *Vide* article by Abbe, op. cit.

[3] *Vide* Roberts on Urinary and Renal Diseases, etc., third Amer. edition, 1879.

infrequent in cases of the waxy kidney. In a case of wasting of the kidneys from hydronephrosis, the organs having the appearance of empty sacs, polyuria had existed for two years, and the case had been diagnosticated diabetes insipidus. Similar cases are given by Roberts and Dickinson. In such cases the polyuria is to be regarded as a symptom of the renal atrophy with which, as a rule, cardiac hypertrophy is combined. Polyuria occurs also, in some cases, as a symptom of cerebral diseases, and of lesions caused by injuries of the skull. It is a symptom in cases of hysteria, asthma, and other nervous affections. In all these instances, the polyuria is not properly to be considered as constituting an individual disease. Polyuria and hydruria, therefore, are terms not synonymous with diabetes insipidus. The latter term, if properly applied, denotes a disease characterized by an excess of water in the urine when not symptomatic of the foregoing diseases.

In well-marked cases of diabetes insipidus, the quantity of urine greatly exceeds that of health. It may amount to fifteen and even twenty quarts per diem. The specific gravity varies between 1003 and 1007. There is no essential change in the composition of the urine, except the excess of water. There is thirst which leads the patient to ingest fluids in an amount proportionate to their loss by the kidneys. When deprived of other liquids, patients have been known to drink their own urine. The need of drinking often, and the frequent acts of micturition, occasion much annoyance and interfere with sleep. The disease may not otherwise interfere with health. Patients of either sex, affected with the disease, have been able to perform active labor, have had children, and their lives have apparently not been shortened by it. It is not incompatible with good appetite, digestion, and nutrition. It has been tolerated for fifty years. The prognosis is favorable as regards the duration of life and the preservation of general health, if the disease be uncomplicated; but it is unfavorable as regards recovery from the disease. As remarked by Senator: "Recovery is rare, but death is still more rare."

The etiology is obscure. The disease has followed injuries of the head, and an hereditary influence is involved in some cases. In the majority of instances the disease cannot be traced to any adequate causes. It occurs not infrequently in infancy. In a proportion of about one-half, when the disease is developed, patients are under 20 years of age, and in about the same proportion the age is between 30 and 50. It is extremely rare after the age of 50. The number of males affected with the disease is considerably larger than that of females.

The pathology is unsettled. The discovery by Bernard that a puncture a little above the fourth ventricle of the brain will produce polyuria without sugar in the urine, naturally directed attention to this situation as the seat of the disease. Cases have been observed in which, after death, lesions were found to involve this part. There is not, however, sufficient ground for assuming that diabetes insipidus depends on anatomical changes here or elsewhere in the brain. The absence of all symptoms of cerebral disease, exclusive of the polyuria, in cases, the duration of which extends over many years, militates against this assumption. That the disease is neuropathic is rendered probable by the occurrence of polyuria as a symptom in various nervous affections. The production of polyuria in animals by division of the splanchnic nerve favors this view. A reasonable hypothesis attributes the polyuria to the dilatation of the renal capillaries from influences exerted through the vaso-motor system. This effect may be produced either by a paralytic effect through the splanchnic nerve, or by an active dilatation of the capillaries by an excitation of vaso-dilator nerves (*vide* page 857). The presence of inosite in the urine has been shown to be an effect, not a cause, of the polyuria. This principle appears in the urine if a large quantity of fluids be ingested by healthy persons.

The polyuria in cases of diabetes insipidus may be suspended during the continuance of an inflammatory or febrile disease. Excluding cases of polyuria as symptomatic of cerebral or of renal lesions, diabetes insipidus is an extremely rare disease. The basis of the diagnosis is a persistent polyuria which is independent of these lesions. The disease is to be distinguished from polydipsia. In the latter disease the excess of water in the urine is an effect of the excess of liquid ingested. If the quantity of urine exceed the quantity of drink, and if polyuria continue notwithstanding a restriction of the latter, the differential diagnosis is established. From diabetes mellitus the discrimination is easy. The low specific gravity of the urine is distinctive, but the exclusion of that disease is rendered positive by the negative result of testing the urine for the presence of sugar.

It is injudicious to attempt to limit the excess of the water in the urine by diminishing the amount of ingested liquid. The disease is not thereby cured, and not only is there suffering from thirst, but, inasmuch as the polyuria continues, serious evils may arise from a morbid reduction of water in the blood. Theoretically it is an object of treatment to diminish the size of the renal capillaries. In a case reported by Da Costa, recovery within a short period was apparently effected by the fluid extract of ergot—drachm doses increased to two drachms and given three times daily. This remedy was recommended, on the basis of experience, many years ago by Prof. Gross. Ergot or ergotin has been found useful by others. Other remedies which are recommended are gallic acid and valerian.

The patient's strength is to be maintained, as far as possible, by tonic remedies, good alimentation, and favorable hygienic influences.

The disease is not in itself fatal; but it may occasion more or less exhaustion and thus increase the liability to death from associated or intercurrent affections.

Diabetes Mellitus.

An increased flow of urine or diuresis, is generally a notable feature of the affection now to be considered. The distinctive feature, however, is the presence of grape sugar or glucose in the urine; hence the significance of the term mellitus. *Glycosuria* and *melituria* are other names applied to the affection characterized by saccharine urine. The affection is far from being of frequent occurrence, yet it is not so rare but that cases come under the observation of every physician. From the number of cases which have come under my observation within the last few years, I have been led to think that the disease is less rare than formerly in this part of the world. One reason of its apparent infrequency is that it is liable to be overlooked in cases which end fatally with some intercurrent disease.

Sugar in the urine, like albuminuria, may occur as a symptom in various pathological connections. It follows anæsthesia produced by the inhalation of chloroform or ether, an epileptic or an hysteric paroxysm, some violent emotion, etc. The sugar under these circumstances is usually not abundant, and the urine contains it for a brief period only. As the distinctive feature of an individual affection, the sugar which the urine contains is in greater or less abundance, and it continues more or less persistently. Even when the affection exists, the saccharine urine is, in fact, merely a symptom. It does not constitute the affection. It is incidental to, or an effect of, the real disease. The sugar exists in the urine because it pre-exists in the blood and is excreted by the kidneys. But, with our present knowledge, the true seat and nature of the disease are not established, and, therefore, provisionally, it is named as if it were a disease of the urinary system, and is included, for the sake of convenience, among the diseases affecting this system.

An abnormal accumulation of sugar in the blood constitutes the morbid condition called glycohæmia. Glycohæmia stands in an immediate causative relation to the presence of glucose in the urine; glycosuria is an effect of the glycohæmia. The latter stands in a nearer relation than the former to the pathology of diabetes mellitus. The pathology of glycohæmia is the pathology of the diabetic disease. Glycohæmia has been considered in Part I. among the morbid conditions of the blood (*vide* page 73), and hence, in now treating of diabetes mellitus as an individual disease, it will be considered exclusively in its practical aspects.

Clinical History.—Notable increase of the urine, or polyuria, is usually the symptom which first awakens suspicion of the existence of the disease. Not only are the acts of micturition more frequent, but the quantity of urine passed in a given time is much greater than in health. The urine is deficient in color in proportion to the amount of sugar which it contains. The appearance is generally clear, as well as pale. It has frequently a sweetish odor like that of whey. The presence of sugar is perceptible to the taste. Flies and bees are attracted to it, if emitted on the ground. The density exceeds that of healthy urine, in proportion to the amount of sugar. The specific gravity varies between 1030 and 1074, the latter being an extreme of increased density. The reaction is in most cases feebly acid; it is sometimes neutral, and in rare cases alkaline. The water of the urine is more or less increased; hence, the increased quantity of urine. The increase in the quantity of urine is generally very great, and sometimes enormous. It may amount to thirty pints, or even more, in the 24 hours. The frequent calls to micturate are a source of great discomfort, and especially during night they constitute a serious evil by interfering with sleep. The action of the sugar on the urethra is apt to occasion a sense of heat and stinging pains; excoriation of the prepuce and glans is sometimes produced, and may lead to phimosis. I was led to the discovery of diabetes by an examination of the urine in a case in which the patient complained only of an itching sensation in the middle of the penis, there being no increase of urine, no thirst, and no symptom of any disease except that just mentioned. The urine was found to be loaded with sugar. In women, eczema of the vulva is a frequent effect, giving rise to distressing pruritus. It has been stated that more liquid is contained in the urine, in some cases, than is ingested. This may be true for a limited period, but examinations extending over several days show that, large as is the quantity of urine, it falls short of the amount of the fluid contained in food and drink. As regards the normal solid constituents of the urine, they are not, as a rule, diminished. The sugar in the urine does not displace these constituents, namely, urea, uric acid, etc.; the urea, in fact, has been found considerably more abundant than in health. If albuminuria exist, it shows either the existence of coincident renal disease, or those conditions which, under other circumstances, give rise to the presence of albumen in the urine.

Cases differ in respect of the quantity of urine and the amount of sugar. Generally, at the commencement of the disease, the quantity of urine and the amount of sugar are not large, but the increase of both is progressive as the disease advances. Exceptionally the quantity of the urine is not increased, although abounding in sugar. This has been true of several cases which have come under my observation, the patients not being under treatment, and for this reason the disease is liable to be overlooked. The quantity of both urine and sugar also varies at different periods of the day, being generally largest within a certain period after meals. According to Bouchardat, the average proportion of sugar to the quantity of urine is 32 to 35

to 1000. The quantity of sugar contained in the urine during twenty-four hours has been known to amount to thirty-two ounces. Inosite has been found in the urine in some cases after the grape sugar had disappeared, the quantity of urine remaining large, and it has been discovered in some specimens associated with grape sugar. Its significance is probably the same as in diabetes insipidus, that is, its presence is due to the polyuria. The urine has also been found in some cases to contain acetone and alcohol.

The urine, when preserved for several days, undergoes the alcoholic fermentation; it remains acid, and is devoid of the ammoniacal odor which is emitted by decomposed healthy urine. It is rendered turbid by the development of the *torula cerevisiæ* or yeast fungus.

Emaciation is usually marked after the disease has existed for some time. Cases differ as regards the rapidity of the emaciation. In general, it is in proportion to the abundance of sugar in the urine, and the duration of the disease; but it is affected in a greater measure by the condition of the digestive organs. It is evident that certain alimentary principles which in health contribute to the growth and repair of the body, are lost to nutrition in this disease. The development of other affections, especially pulmonary tuberculosis, increases the emaciation. The occurrence of diabetes is not infrequently preceded by *embonpoint*, more or less excessive.

Increase of the appetite is usually a prominent symptom. The patient ingests much more food than in health. The abnormal appetite may amount to bulimia or polyphagia. This, coupled with progressive decrease of weight, should excite suspicion of the disease. Exceptionally the appetite is not increased, but, on the contrary, more or less impaired. Not infrequently, in the course of the disease, the appetite fluctuates, being sometimes greater and sometimes less than in health. It fails as the disease approaches a fatal termination.

Thirst is one of the first symptoms, occurring as soon as the quantity of urine is increased. It is urgent in proportion to the degree of diuresis. The quantity of liquid ingested is sometimes enormous. The necessity of drink during the night contributes, with the calls to urinate, to prevent sleep. Dryness of the mouth is a source of considerable inconvenience. The tongue is sometimes moist and coated, and sometimes dry and reddened. The gums are generally affected; they are softened, and either pale or reddened, bleeding readily on pressure. The teeth are apt to become loosened. The saliva is usually acid.

Digestion, until the disease is far advanced, or until serious complications occur, generally appears to be well performed. Dyspeptic ailments, however, are not uncommon. If vomiting occur, the vomited matter is found to contain sugar. Sugar is also contained in the feces. Constipation is the rule, but, in some cases, diarrhœa alternates with constipation. The dejections show a deficiency of bile. Caries of the teeth is apt to occur early in the progress of the disease.

The respiratory function is not disordered, save by the pulmonary affections with which the disease is liable to become complicated, especially pulmonary tuberculosis. The respirations are somewhat under the normal frequency if there be no pulmonary complication. It is stated that the amount of carbonic acid in the expired air is less than that of health. The breath has a mawkish, sweetish odor which is quite characteristic. It has been compared to the odor of hay and of apples. I have recognized a patient whom I had examined at a clinic months before, and whose features I had entirely forgotten, as soon as he came sufficiently near for the odor of his breath to be perceptible. In repeated instances I have been led to suspect the disease by

this peculiar odor. The condition of the gums and teeth renders the breath in some cases fetid.

The circulation offers no symptoms of importance. The pulse, if at all affected, is oftener retarded than accelerated, exclusive, of course, of the effect of complications. I have observed capillary congestion of the surface in a notable degree. The temperature of the body is lowered; the thermometer in the axilla shows a temperature of 96° or 95° F. in some cases in which the disease is uncomplicated. The skin is usually dry and rough. It is rare for perspiration to occur except when pulmonary tuberculosis becomes developed. Furfuraceous desquamation of the epidermis is not uncommon. Itching of the skin is a symptom which sometimes occasions much annoyance. Diabetics are subject to carbuncles, boils and various eruptions, namely, psoriasis, lichen, eczema, and impetigo. Spontaneous gangrene of the lower limbs is an occasional event. I have known of several instances in which this event occurred. The gangrene resembles that of gangrena senilis. Ulcerations of the lower limbs, without gangrene, have been observed. In protracted cases œdema of the legs frequently occurs. Bright's disease is an occasional complication of diabetes.

Muscular feebleness is more or less marked and progressive. Aside from the effect of complications, the patient is enfeebled in proportion to the excessive excretion of the urine, the amount of sugar which it contains, and the duration of the disease. Troubles of vision are not very infrequent. Amblyopia, or feebleness of vision, sometimes occurs early, and may eventuate, as the disease advances, in confirmed amaurosis, either complete or incomplete. The vision was more or less affected in 20 out of 162 cases of diabetes observed by M. Fauconneau Dufresne. In the majority of cases in which the vision is affected, the defect is slight or moderate. Complete amaurosis is extremely rare. In the cases in which amaurosis, complete or incomplete, exists, the ophthalmoscope shows atrophy of the optic disks. Retinitis is a ground for suspecting that albuminuria co-exists. The diabetic condition also favors the development of soft cataract. Dr. S. Weir Mitchell has shown, by injecting syrup beneath the skin of the frog, that sugar has a direct action on the crystalline lens. In some cases recovery from defect of vision occurring in diabetes takes place after the sugar has disappeared from the urine. The mental condition frequently undergoes a marked change; the patient becomes irritable, sad, and hypochondriacal; the intellectual faculties are enfeebled, and sometimes the mental weakness amounts nearly to imbecility. Diminution and, at length, extinction of venereal desire, belong to the clinical history of the disease. This effect frequently occurs early in the history of the disease, before the general powers of the system are much reduced. It may be the first symptom noticed by the patient. It is not, however, a constant symptom. In women, the menstrual discharge gradually diminishes and is at length suppressed.

The march of the disease is generally slow. Its development is imperceptible, and, when discovered, it had probably, in most cases, existed for a considerable period. It is, therefore, difficult to fix the date of its commencement. But, dating from the time when its existence is known, in most cases it continues for many months, and not infrequently for many years before ending fatally. Its duration is indefinite and variable. Exceptionally, it runs rapidly to a fatal issue. Generally in these cases the patient is cut off by some intercurrent affection. Any important disease supervening on this is very apt to destroy life; for example, pneumonitis in a diabetic patient is usually fatal. Griesinger found the mean duration in 225 cases to be from two to three years. Of 700 cases noted by Prout, only 2 were living at the end

of ten years from the time when the disease had been ascertained.[1] During the progress of intercurrent inflammatory and febrile diseases, the sugar is frequently observed to disappear from the urine. Under these circumstances, this is not to be considered as favorable.

Causation.—Our knowledge of the causation of this disease is completely barren of well-ascertained facts beyond the influence of age. In the vast majority of cases the age is between 30 and 50 years. The disease occurs in infancy, youth, and advanced life, but instances are rare. As regards pathogenetic influences pertaining to climate, season, diet, temperament, habits of life, etc., we have only conjectures, without any precise information. Men are oftener affected than women. Of the 225 cases analyzed by Griesinger, in 172 the patients were men, and in 53 women.

In a considerable, not a large, number of instances the disease follows some injury of the head or spine or a concussion of the whole body. In some of these instances the glycosuria may have been only a transient symptom, and in other instances there may be room for doubt as to any causative connection, considering that in a large majority of cases no such causation is evident. There is no constant connection between the disease and cerebral lesions affecting the floor of the fourth ventricle, which the experiments of Bernard on animals showed to stand in a causative relation to glycosuria. Autopsical examinations in cases of diabetes mellitus have failed to discover lesions in this situation, and lesions have been found here when diabetes had not existed. Nor has a pathological connection of the disease with any anatomical changes in the liver been ascertained.[2]

The disease in some cases has been attributed to violent mental emotions.

Diagnosis.—It is to be borne in mind that the fact of sugar existing in the urine is not alone sufficient evidence of the existence of the disease under consideration. Sugar, generally in small quantity, and for a transient period, is not infrequently found in the urine in the course of various maladies. In aged persons the urine sometimes temporarily contains a considerable amount of sugar. A distinguished member of the medical profession in this country, of advanced life, three years ago, was led to observe that the quantity of his urine was notably increased. On examination, it was found to contain a large amount of sugar. Without any medicinal treatment or change of diet, the diuresis ceased, and no evidence of diabetes subsequently occurred. A number of similar instances have fallen under my observation. I have known much needless uneasiness to be occasioned by announcing to a patient the discovery of a trace of sugar after an analysis of the urine.

If diabetes exist, saccharine urine is more or less persistent, the amount of sugar is unusually large, and generally the quantity of urine is notably increased. These points relating to the urine render the diagnosis sufficiently easy and positive. The diagnosis is confirmed by other symptoms belonging to the clinical history of the disease. If the quantity of urine be considerably increased, and, on testing with the urinometer, the specific gravity be found high, sugar is probably present. In cases of polyuria, in which only the water of the urine is increased, as in diabetes insipidus, the specific gravity is extremely low, sometimes but little above that of spring-water. The fragrant odor of diabetic urine is characteristic, and it froths readily on agitation, the air-bubbles remaining for some time. But the practitioner

[1] Archiv für physiologische Heilkunde, 1859–60–62.

[2] *Vide* Roberts, op. cit., and Senator in Ziemssen's Cyc., Am. ed., vol. xvi.

should not be satisfied without demonstrative proof of the presence of sugar. Of the several methods of testing urine for sugar, one readily available is the fermentation test. A common test-tube or phial containing a little ordinary yeast is to be filled with urine, inverted and placed in a saucer containing the urine, care being taken to prevent the entrance of air. Kept at a temperature of 70° Fahr., fermentation ensues, and the gas formed rises in the tube and displaces the urine. The gas is shown to be carbonic acid from its failure to support combustion. Christison states that a cubic inch of the carbonic acid formed in the fermentation test represents a grain of sugar. Of the various other methods of testing for sugar, the employment of Fehling's solution is the most convenient, and it is sufficiently reliable. I have found this solution, as prepared by Squibb, to remain unchanged for a year kept in a glass-stoppered bottle, although used almost daily. Boettger's test with the subnitrate of bismuth is readily applied. The polarization test is probably the most accurate, but it is not necessary to resort to this for clinical purposes. If it be desired to ascertain the actual amount of sugar excreted in a given period, the volumetric method of analysis by Fehling, or Roberts' differential density method may be employed.[1] Examinations of urine are to be repeated, in the first place, to settle the persistence of the saccharine condition, and, in the second place, with reference to improvement or otherwise. In general, it suffices for these objects to ascertain the quantity of urine passed in the twenty-four hours, and its specific gravity, the existence of sugar having been already ascertained.

Prognosis.—Diabetes mellitus is a disease which, in a large majority of cases, offers small encouragement as regards the prospect of permanent recovery. Of course, in this statement reference is had to cases in which the diagnosis is based on persistency of the diabetic condition. Undoubtedly recoveries have taken place. Data are wanting for determining the proportion of radical cures, but they form a small minority. In the great majority of cases, however, the diabetic condition may be notably ameliorated. Not infrequently the quantity of urine may be reduced to within the normal limits, the sugar completely disappearing, and the patient regaining the normal condition of weight and strength. But in a large proportion of these cases relapse occurs sooner or later.

Patients are, however, generally cut off by intercurrent affections. The existence of this disease impairs the ability to cope with affections which, under other circumstances, might not prove serious. If the disease continue for a long time without complications or supervening affections, it induces an extreme degree of debility and marasmus. In a considerable proportion of cases in which the disease is of long duration, pulmonary tuberculosis becomes developed, and this hastens the fatal issue. Phthisis was the immediate cause of death in 43 per cent. of the cases analyzed by Griesinger.

An early diagnosis diminishes the gravity of the prognosis. The chances of arresting the disease are greater if it be recognized before the general condition of the system has undergone much deterioration. This fact enforces the importance of examining the urine for sugar in all cases in which there are any grounds for suspecting its presence; and it is to be recollected that sugar is sometimes persistently present when the quantity of urine is not much, nor even at all, increased. Examination of the urine for sugar should not be omitted whenever failure of strength or emaciation occurs without apparent cause, and especially if the appetite be increased rather than diminished. Unusual thirst, dryness of the mouth or fauces, acidity of the saliva,

[1] *Vide* Roberts on Urinary and Renal Diseases, Am. ed., 1879.

dryness of the skin, impairment of vision, diminution or extinction of venereal desire, in men irritation or inflammation of the prepuce or glans penis, and in women pruritus vulvæ, should suggest the possibility of the existence of this disease. Notable increase in the quantity of urine, of course, should excite strong suspicion, but a certain amount of increase may take place without the attention of the patient being excited, or the patient may not deem it a symptom of importance, and it is therefore necessary for the physician to direct inquiries to this point.

In a considerable number of cases which have come under my observation since the publication of the last edition of this work, the disease has been held in abeyance, the patients having apparently recovered; that is, the urine has been free from sugar, and the general health good. In this statement it is not intended to include only those cases of temporary diabetes already referred to, which after a few days or weeks end in recovery. The occurrence of these cases should be borne in mind with reference to prognosis. In the cases belonging in this category which I have seen, the patients have been middle aged or advanced in years, and they have generally had considerable *embonpoint*.

The age and the weight of the body have a bearing on the prognosis. The prognosis is unfavorable in proportion to the youth of the patient; and as regards this disease corpulency is distinctly an advantage. In respect of prognosis, also, much depends on the ability of the patient to carry out effectually the dietetic treatment. My experience, which has been considerable during the last few years, has led me to modify somewhat the views respecting prognosis which were expressed in the previous editions of this work. The disease seems to me less formidable than heretofore, provided proper treatment be adopted and persisted in. Moreover, I have met with a number of cases which illustrate the tolerance of the disease by those who have not been aware of its existence, and by those who refuse to submit to rigid dietetic restrictions.

On the other hand, I have met with several instances of sudden death with what has been termed diabetic coma. In one of these cases the patient was a merchant who came from a southern State to New York to purchase goods. He contracted a simple pharyngitis which kept him within doors. The urine contained sugar in abundance. With no symptoms which foreshadowed any immediate danger, he suddenly became comatose, with greatly disturbed respiration, for which physical signs gave no explanation, and died within a few hours. Another case, probably of diabetic coma, was still more striking. A woman about 40 years of age had suffered from some dyspeptic ailments, but on the day preceding the night of her death she had felt unusually well, had been out of doors, and had dined heartily. Shortly after dinner she was seized with an attack of coma and convulsions, preceded by long-continued piercing screams. She regained her consciousness after free vomiting, but she soon relapsed into quiet coma, and died comatose within a few hours. Seven pints of urine were withdrawn from the bladder during the coma (the sp. gr. 1.015), and it was found to contain both sugar and albumen. Neither diabetes nor renal disease had been suspected in this case, and within a few weeks of her death the urine had been carefully examined for albumen, casts, and sugar with a negative result. In another case, of a middle-aged woman who had suffered from paroxysms of intense pain, apparently from enteralgia, there occurred a suddenly profuse discharge of urine followed by coma and death. The urine was found to contain sugar which had not been found on previous examinations.

The last two of these cases exemplify a fact ascertained by other observers, namely, the development of diabetes within a few weeks or even a few days

before death. The disease in these cases has been distinguished as *diabetes acutus* and *acutissimus*.[1]

The phenomena of diabetic coma point very distinctly to the sudden development of a toxic agent in the blood. That this agent is acetone, as has been supposed, is not established (*vide* Acetonæmia, p. 75). The attacks have a resemblance to those referable to uræmia, but they occur under circumstances which do not admit of this explanation.

Treatment.—The essential treatment of diabetes mellitus is dietetic. The object is the exclusion, as far as possible, of sugar and starch from the diet. In proportion as this object is effected, the glycohæmia and glycosuria diminish. Not infrequently all evidence of the disease disappears under strict dietetic treatment, and the patient is apparently in perfect health. Difficulties in the way of success from this treatment arise from the inability to carry it out rigidly. Patients sometimes have not sufficient strength of will to adopt and persevere in the dietetic restrictions. In some cases this difficulty does not exist, but the system will not tolerate the restrictions; the vital functions give way under the continuance of the treatment. Complications or associated diseases sometimes render its adoption impracticable.

In not a few instances the physician is responsible for want of success from dietetic treatment, his instructions not being given with sufficient precision. It will not answer to say, in general terms, that saccharine and starchy articles of diet are to be avoided. Most patients have not sufficient knowledge of alimentary principles to discriminate correctly the food which is allowable. I have known instances, for example, of diabetic patients eating freely of rye and corn-meal bread, under the belief that only wheat bread was interdicted. It is essential that a written or printed list be furnished to patients of all the articles which may enter into the diet, and of all those which are to be excluded. Such a list is essential in order to meet another requisite for success. The dietetic treatment must be made to satisfy, not only the needs of nutrition, but the desires of the patient. This can be done only by varying the articles of diet from day by day, by making combinations to suit the appetite, and by the preparation of food in ways to be acceptable to the taste. Hence, the diet-list should be as comprehensive as possible.

Bread occasions more difficulty than any other article of food. The force of the phrase "staff of life," as applied to bread, is appreciated when the attempt is made to exclude it persistently from the diet. Diabetic patients of good resolution are apt to commence the dietetic treatment with the conviction that they can do very well without bread, but, after a time, the desire for it becomes too imperative to be resisted without great discomfort. The fact, then, is to be accepted, that some form of bread must enter into the diet. Different substitutes for bread which have been devised do not satisfy the want of it. Flour consisting only of bran, prepared after Complin's method, is generally tolerated but for a short time. Patients soon have a repugnance for it, and, as it is innutritious, there is then no advantage in persisting in its use. This is measurably true also of flour consisting of pure gluten, and of the almond flour recommended by Pavy. Either a certain quantity of ordinary bread must be allowed, or a flour used containing a diminished proportion of starch without its entire exclusion. A flour prepared by the "New York Health Food Co.," called gluten flour, contains a moderate proportion of starch. An analysis made for me by Prof. Doremus gave twenty per cent. of starch, whereas in ordinary flour the proportion is from sixty to eighty per cent. Bread made from this so-called gluten flour is palatable. In a number of cases

[1] *Vide* Senator, *op. cit.*

in which I have advised its use, patients have found it to be a satisfactory form of bread. It must not, however, be taken *ad libitum*. No more should be eaten than suffices to satisfy the craving for bread. It should be toasted as much as possible without rendering it unsatisfactory.[1] This should be done, of course, if ordinary bread be allowed.

The bill of fare for diabetes is very extensive. All varieties of shell-fish are allowable. Soups of various kinds may be prepared without flour, rice, vermicelli, or any other article which contains starch. Fish of every description may be eaten, either fresh, salted, or preserved in oil. Of meats, poultry, and game, there is but a single exception, namely, the livers may contain enough sugar for their exclusion. Salads may be made of lettuce, celery, cucumber, *romaine*, watercress, Brussels sprouts, chicory, dandelion, young onions, cold slaw, and olives. Of vegetables, other than those just named, the list embraces spinach, cabbage, cauliflower, string beans, pickles, beet-tops, sorrel, radishes, mushrooms, asparagus, truffles, artichokes, oyster plant or salsify, and tomatoes. Of fruits, are embraced sour apples, used moderately, lemons, sour oranges, strawberries, and currants. Eggs, caviar, cheese of all kinds, butter, buttermilk, cream, milk in moderation, unsweetened jellies, filberts, pecan-nuts, almonds, butternuts, and walnuts, Brazil-nuts and cocoanuts are included. Of drinks, coffee, tea, and cocoa, without sugar, whiskey, brandy, gin, claret and Burgundy wine, hock, and dry sherry are permissible. Glycerine may be used in lieu of sugar in coffee and tea. A patient of mine ate with relish custards made with glycerine instead of sugar. It is stated that mannite, inosite, levulose, and inulin are forms of sugar which may be taken without rendering the urine saccharine. This statement needs further confirmation based on experimental observation. The interdicted kinds of food are, sugar, syrups of all kinds and honey, wheat and rye flour and corn meal, arrowroot, sago, tapioca, oatmeal, barley, potatoes, beets, parsnips, carrots, rhubarb, peas and beans, chestnuts, sweet fruits of any kind, chocolate, cider, most malt liquors, champagne and other sparkling wines, all the sweet wines, sweetened spirits, and liqueurs.

The very bitter ales may be taken moderately. Turnips are considered by some as allowable. Celery is by some interdicted, but probably without reason. Much restriction in the use of milk is not necessary. There have been doubts as to tomatoes, but they are probably correctly placed in the list of allowable articles. The patient should not be rendered uncomfortable by restricting the quantity of ingested fluids.

For the sake of emphasis it may be repeated, that success will depend on the pains taken to vary, combine, and prepare the allowable kinds of food, so as to render the diet satisfactory as regards the patient's taste, appetite, and digestion. To do this will require much and constant attention on the part of those who have charge of the dietary of diabetic patients. It is difficult to carry out the dietetic treatment properly in hospitals. Patients can rarely have it properly carried out in hotels and boarding-houses. Poverty is sometimes a serious obstacle in the treatment of this disease.

Under the dietetic treatment, faithfully carried out, the sugar in the urine is speedily diminished. In a considerable proportion of cases it disappears, the quantity of urine decreases and often becomes normal in this regard, the thirst disappears, and there may be no evidence of ill health. Patients have repeatedly declared, even when the urine still contained some sugar, that, were it not for the knowledge of this fact, they would not suspect the existence of any malady. Not infrequently there is a consciousness of better health than for a long time before the diabetic disease was discovered.

[1] Shedden & Co., pharmaceutists, of New York, prepare a flour which claims to have a much less percentage of starch.

The return to the articles which are not in the list of those allowable, is to be made after a time gradually and tentatively, watching the effect upon the urine. Probably in most instances an unrestricted diet will cause a return of the saccharine urine, if the cases of transient diabetes, to which reference has been made, be excepted. Under these circumstances, patients cannot be considered as cured; but, on the other hand, the restricted diet, with proper pains, may be well tolerated indefinitely, the general health remaining excellent. Although, therefore, the disease be not cured (quoting the language of Senator), it may be made entirely harmless.

Reference may be here made to the skimmed-milk treatment proposed by Donkin. His method consists in confining the patient strictly to skimmed milk, from six to eight pints being taken daily, the treatment to be continued for ten or twelve weeks; after this period other articles of diet being gradually added and at length substituted. That this plan of treatment has proved useful in some instances, must be admitted; in other instances, however, it has been not only nugatory, but hurtful and even destructive. It may be tried if the patient be not enfeebled, but it should not be persisted in if it be not well tolerated. There is little ground for the expectation that the method will prove in any instance curative.

As regards the employment of drugs, if there be no special symptomatic indications to be met by remedies, before any medication is employed it should be ascertained how much may be effected by diet alone.

The alkalies, first employed for theoretical reasons, have been found to be useful in some cases. Trousseau's method was to give a drachm daily of the bicarbonate of soda, and to increase the doses gradually to three or even four drachms. In order to avoid the evils incident to super-alkalinity of the blood, he advised that the remedy be given only during ten consecutive days in each month. I have seen the good effect, apparently, of this treatment when there was not much restriction in diet. The benefit which patients derive from treatment at Carlsbad and Vichy cannot depend greatly on the alkaline springs, for the same benefit is not derived from the water when drank at home. The credit belongs, in a great measure, to accessory circumstances in these watering-places, and to the treatment in other respects. A cure is not to be expected from the use of alkalies, and it is seldom advisable when patients can carry out and tolerate strict dietetic treatment.

Opium causes diminution of the sugar in the urine. Pavy, who advocates the opium treatment, advises, in preference to other preparations, codeia, giving it in doses gradually increased from a quarter of a grain to two grains three times daily. The treatment relieves, but it does not effect a cure, and it is open to objection on the score of a liability to the formation of the opium-habit. Opium, however, is indicated in some cases for the relief of muscular pains, from which diabetics not infrequently suffer, and which prevent sleep.

Other remedies among the great number which have been recommended, are, the carbonate of ammonia, lactic acid, cod-liver oil, the iodide of potassium, arsenic, carbolic acid, strychnia, rennet, and yeast. Each of these, in certain cases, is more or less useful, but no one is entitled to be considered as a curative remedy. The late Dr. Frick, of Baltimore, studied the relative effects of different remedies in a case under his observation for nine months, and the diminution of the sugar in the urine was most marked under the use of strychnia. Dickinson remarks that "strychnia is, of all remedies, the most constantly useful."

A remedy has recently been recommended as having a curative agency, by Dr. N. C. Husted. Dr. Husted was himself affected with the disease. Under dietetic treatment, giving up his arduous labors as a practitioner in the city, and going into the country, the improvement was marked, but the sugar did not disappear entirely from the urine. He suffered from boils, and

for this complication he took the sulphide of calcium. Under the use of this remedy not only was he relieved of the boils, but the sugar disappeared from the urine. He continued the use of the remedy for several months, and for the past eight months he has been free from all evidence of the disease, under a diet of late not much restricted. This single instance proves but little, for the case may have been one in which there was no tendency in the disease to persistence. But Dr. Husted states that he has found this remedy to have a marked influence over the disease in other cases which have come under his observation since his restoration to health. At the present time this remedy enters into the treatment of several cases under my observation, which are progressing favorably; but it is difficult to estimate the effect of it, inasmuch as conjoined with its use are dietetic restrictions carried out as rigidly as possible. Whether the remedy has power to control the morbid defects or perversions in which the disease consists, is to be settled by further observations.

There may be indications for remedies without reference to any curative effect. Tonics are indicated if the appetite or the digestion be impaired. Anæmia, as in other pathological connections, calls for iron. The nervous system may be tranquillized and sleep induced by the bromides or other hypnotic remedies. Various symptoms may require palliative treatment.

An important part of the treatment of diabetes pertains to hygienic observances. The body should be protected against atmospherical changes, and the functions of the skin well maintained. The warm bath or sponging the body, if the immediate effect be agreeable, is to be recommended. The hydropathic pack has been found serviceable. A change from a climate which is cold and variable to one uniform and warm, is often highly advantageous. A long sea-voyage in a warm latitude has proved signally beneficial. Exercise in the open air is to be advised, not exceeding so far the limits of comfort as to induce over-fatigue or exhaustion. Gymnastic exercises may sometimes be resorted to with profit. Last, but not least in importance, mental relaxation and recreation are to be enumerated in the list of regimenal measures.

The most efficient treatment in cases of diabetic coma is yet to be ascertained by experience. Meanwhile, symptomatic indications in individual cases are to govern the therapeutical measures employed. The coma now referred to is that which is independent of uræmia.

Involuntary Seminal Emissions. Spermatorrhœa. Impotence.

Involuntary seminal emissions, spermatorrhœa, and impotence frequently depend on abnormal conditions which belong to surgery, but not infrequently they fall properly within the sphere of the practice of medicine. By involuntary seminal emissions is meant the ejaculation of semen and the venereal orgasm, without any voluntary effort, either natural or unnatural. Involuntary emissions occurring during sleep are common, taking place in connection with erotic dreams. Occurring after intervals of several days, in persons of continent habits, they are physiological rather than pathological. They denote simply a certain amount of functional activity of the generative organs. They do not imply a morbid condition, nor do they lead to any morbid effects. They are apt especially to occur when habitual sexual intercourse is, from any cause, interrupted. Under these circumstances, they are manifestations of health rather than disease. The physician is warranted in giving such assurances to patients, who are often rendered needlessly apprehensive and unhappy by popular works or lectures, the object of which is to excite fears for a mercenary purpose.

Occurring more frequently, the emissions denote a morbid erethism and weakness of the organs of generation. They occur sometimes nightly, and sometimes even repeatedly during the same night. They then call for remedial measures, although, even under these circumstances, their morbid effects have been much exaggerated. Occurring in persons debilitated from any cause, they may take place without erection, and with little or no venereal excitement, the patient sometimes becoming aware of their occurrence only by the seminal stains. They occur sometimes during the day when the venereal desire is excited. These are called diurnal, in distinction from nocturnal, emissions. A patient stated to me that they had occurred, in his case, from excitement caused by shampooing the head in a barber's shop. Persons who have been addicted to venereal excesses or to the unnatural abuse of the sexual function, are especially subject to this morbid frequency of involuntary emissions. The mind, in such cases, particularly if the affection be attributable to unnatural abuse, is apt to become greatly depressed; the patient is apprehensive of impotence, or fancies that he is already impotent; his attention is absorbed with the affection; he suffers from a sense of pollution and degradation; he believes that his constitution is ruined, and that there is danger of insanity. Patients in the condition just sketched form an unfortunate class with which every practitioner is more or less familiar. They go from one physician to another, and upon patients of this class quacks prey largely. The affection sometimes exists in a still greater degree. The emissions are diurnal, as well as nocturnal. They are produced by anything which provokes the sexual passion, and may take place with little or no excitement of the external organs.

Spermatorrhœa means, strictly, the discharge of semen without the occurrence of the orgasm. It is an affection superadded to morbid seminal emissions, the seminal secretion passing into the urethra, and sometimes into the bladder, without the consciousness of the patient. In cases of spermatorrhœa, the semen is expelled in the acts of micturition and defecation. Cases of true spermatorrhœa are far less frequent than has been supposed. Persons have been regarded as having this affection whenever a mucilaginous fluid bearing some resemblance to semen is discharged from the urethra. The microscope affords the only trustworthy mode of determining that the liquid is seminal. Were this mode of examination generally employed, cases of spermatorrhœa would be found to be extremely rare. In examining the sediment of the morning urine, it is to be borne in mind that spermatozoa will be likely to be found if sexual intercourse or a seminal emission have taken place during the night. The presence of the spermatozoa, under these circumstances, is not evidence of spermatorrhœa. Veritable spermatorrhœa doubtless occurs, but probably always in persons who are affected with a morbid frequency of seminal emissions. Muco-purulent matter escaping from the urethra, or observed in the urine, in cases of cystitis, may give rise, in the mind of the patient, to the apprehension of spermatorrhœa. A transparent viscid liquid escaping, in a small quantity, from the urethra, especially after prolonged erection, not infrequently occasions much uneasiness in the minds of persons whose attention is directed to the sexual organs with reference to spermatorrhœa, and of those who have had gonorrhœa. This is treated as a gleety discharge by empirics. The discharge is a secretion from the bulbo-urethral glands, or the glands of Cowper, and is of no practical importance. It is sometimes of importance in a medico-legal view to determine whether stains on linen are caused by dried semen. The physical characters of suspected stains are not to be relied upon; nor is chemical analysis reliable. If, however, water be slowly added to the stains, and

portions be examined by the microscope, spermatozoa will be recognizable when the stains are seminal.

Involuntary seminal emissions and spermatorrhœa are frequently associated with symptoms denoting various kinds of functional disorder, and more especially disturbance of the nervous system. These symptoms have been considered as direct morbid effects of seminal losses. More or less general debility is undoubtedly a result of an abnormal discharge of semen, but the latter is often incidental to disorder of the system otherwise produced; and the disturbance of the nervous system so frequently associated with seminal losses, is measurably due to the mental depression and apprehensions which they are apt to occasion.

In the treatment of seminal emissions, the distinction which has been made between their physiological and pathological character is to be kept in view. Occurring infrequently in a person of full health, in addition to assurances of their innocuousness, it will generally suffice to advise moderation in the use of wine or spirits and stimulating articles of food, saline laxatives occasionally, cold ablution of the genital organs at night, avoidance of undue warmth from the bed or bedclothes, and the mind to be diverted as much as possible from provocatives of sexual desire. If these measures do not suffice, certain remedies which appear to exert an anaphrodisiac influence may be prescribed. Remedies which may be given for this purpose are camphor, lupulin or the tincture of hops, conium, belladonna, and the bromide of potassium. The remedy last named has seemed to me to be distinctly efficacious. Marriage is always remedial in these cases.

Cases in which the emissions depend upon a morbid erethism and weakness of the generative organs, and cases of spermatorrhœa, are of more importance, and the treatment is more difficult. The anaphrodisiac remedies are indicated in these cases; but in these cases much benefit is derived from tonic remedies and an invigorating regimen. Quinia, small doses of strychnia or nux vomica, and the preparations of iron are useful; sea-bathing or the sponge-bath and out-of-door life or gymnastic exercises are useful regimenal measures. The diet should be nutritious, but not stimulating, and alcoholic stimulants are to be taken very moderately or interdicted. Everything calculated to provoke sexual desire should, as far as practicable, be avoided. Healthful mental occupation and chaste associations do very much toward effecting a cure. It is obvious that, to carry out the moral part of the treatment, requires on the part of the patient a determination and perseverance which are often wanting. Taking into view all the circumstances in individual cases, it is sometimes judicious to encourage or recommend marriage.

Attention is to be directed to the condition of the urethra in cases of seminal emissions and spermatorrhœa; they are apt to follow gonorrhœa, and are sometimes dependent more or less on urethral stricture. According to Lallemand, seminal losses often depend on an abnormal sensibility at or near the prostatic portion of the urethra, and the treatment in these cases requires the use of the bougie and cauterizing applications. The opinion of Lallemand is held by distinguished surgeons at the present time. For information on this point the reader is referred to surgical works. Trousseau advises in some cases a mechanical method of treatment, consisting in the introduction within the rectum of a kind of pessary of an elongated oval form, varying in size from that of a pigeon's to a hen's egg, connected by a stem with a metal plate applied to the perineum and coccyx, the object being to compress the urethra at the orifices of the ejaculatory ducts.[1]

Impotence means inability to perform the act of coition. The term does

[1] Clinique Médicale, tome ii.

not mean want of the power of procreation; the latter may be wanting when there is no incapacity for sexual intercourse. Exclusive of malformations and other abnormal conditions of a surgical nature, impotence, in the first place, may involve absence of sexual desire. Different persons in health differ widely as regards the venereal propensity; in some persons the sexual desire is intense and importunate, in others it is feeble, and sometimes it is altogether wanting. The propensity may, on the one hand, be increased by indulgence, and by fostering in various ways ideas connected with it; and on the other hand, it may be diminished and extinguished by an opposite course. In the marital relation, frigidity, as regards this propensity, may depend on personal antipathy, and hence a not infrequent source of domestic unhappiness. Absence of sexual desire may arise from general debility, and is incident to various diseases. If the disease with which it is connected be not serious nor permanent, a return of sexual desire may be expected on recovery of the accustomed health. Intense mental preoccupation, the depressing emotions, and exaltation of the higher sentiments, tend to repress sexual desire.

As the loss of virility is generally dreaded, physicians are often consulted when a notable change as regards the venereal propensity is experienced. The circumstances which have led to the change, in individual cases, are to be investigated, and the conclusion with respect to the probability of impotence, together with the treatment, is to be based on these circumstances. In a large proportion of cases, the deficiency or absence of sexual desire is due to temporary causes. Premature decline or extinction may result, on the one hand, from early and excessive indulgence or abuse of the generative function, and, on the other hand, from prolonged continence. Under certain circumstances aphrodisiac remedies are desired. The remedies so called are of doubtful efficacy. Phosphorus, cantharides, and nux vomica have been considered as special stimulants acting on the organs of generation. They should be given circumspectly. It is sometimes useful to secure the moral effect of remedies supposed to have this effect.

Impotence may exist without loss of sexual desire. Temporary incapacity proceeds from timidity or deficient self-confidence. The physician is not infrequently consulted by persons about to enter upon marriage, who are apprehensive of being incompetent to accomplish coition. Assurances of capability, if it be evident that the apprehensions are imaginary, may be all that these cases require. Persons who have practised masturbation in boyhood, and they who are subject to involuntary emissions during sleep, are not infrequently led to believe that they are impotent by pernicious publications or lectures designed to alarm sensitive minds; and apprehension on the score of ability to accomplish the act of coition creates incapacity. A failure to accomplish the act is apt to be followed by the conviction that impotency exists, and, practically, it does exist as long as this conviction continues. In such cases all that is requisite is that the act of coition should be undertaken without any anxiety as to success. It is useful, in such cases, to interdict sexual intercourse for a certain time, in order to prevent tentative efforts which, if unsuccessful, fasten the conviction of impotency more and more upon the mind. If a certain period of abstinence be enforced, it will be likely to happen that the patient is impelled by his desires to demonstrate his capacity before the period expires. It is sometimes the case, however, that coition is permanently prevented by fancied incapacity. I have known an instance in which this was the probable explanation of the absence of sexual intercourse during the whole of a married life lasting over fifteen years; and in another instance five years had elapsed without any accomplishment of the act of coition. In both instances seminal emissions occurred not infrequently. A remedy pre-

scribed with an assurance of a cure, doubtless sometimes proves curative by a moral effect. In certain cases, impotence, with sexual desire, is a result of the erethism and weakness of the generative organs, associated with seminal emissions and spermatorrhœa. The ejaculation and orgasm take place at the beginning of, or prior to, the act of coition. This kind of impotence is sometimes, temporarily, a result of prolonged continence. The measures of treatment in such cases are those indicated by seminal emissions and spermatorrhœa. Persistence in the employment of these measures, together with a proper degree of reserve, as regards the frequency of the attempts to consummate sexual intercourse, will generally prove successful.

Excessive indulgence in venery, when it does not lead to involuntary seminal emissions, spermatorrhœa, or impotence, is a not infrequent cause of ill health. Dyspeptic ailments, attacks of vertigo, functional disorder of the heart, melancholia, and hypochondriasis, are among the morbid effects of this cause. It is the duty of the physician to inquire into the habits of patients in this regard. The evils of excessive indulgence, aside from moral consequences, are greater when it is illicit than when it is marital; moreover, the former is far more apt to be excessive. The limits of healthful indulgence doubtless vary according to constitutional vigor, but it may be considered as excessive if the acts of coition are repeated several times a week.

The unnatural abuse of the sexual function, or masturbation, as a cause of involuntary seminal emissions, spermatorrhœa, and sometimes impotence, has been already referred to. The effects on mind, as well as body, are pernicious. It is plainly the duty of the physician not only to endeavor to discover and arrest this practice in individual cases, but to enjoin upon parents, teachers, and associates the importance of watchfulness, in this respect, over those for whose welfare they are, to a greater or less extent, responsible. There is also another duty of the physician connected with this important topic. Many sensitive persons who have been addicted to self-abuse in early life, suffer greatly from the belief that their mental and physical powers have been irreparably injured. The evils, great as they sometimes are, are greatly exaggerated by popular works and lectures designed to excite fears for a mercenary end. The physician may often do much good by removing undue apprehensions connected with the errors of youth.

SECTION SEVENTH.

FEVERS AND OTHER GENERAL DISEASES.

CHAPTER I.

CLASSIFICATION AND PATHOLOGY OF FEVERS. CONTINUED FEVERS.

Classification of Fevers. The General Pathology of Fever. Febricula. Typhoid Fever—Anatomical Characters and Clinical History.

THIS concluding section will be devoted to fevers and other general diseases. The diseases to be considered in this section differ from those which have been considered in the preceding sections in this: They do not, so far as at present known, proceed from an affection of any particular part, and hence they are distinguished as general diseases. The diseases known as *fevers* are plainly thus distinguished from diseases of which the primary manifestations are always referable to some organ or structure; hence the latter are called local diseases. Diseases other than fevers, which it is convenient to distinguish, nosologically, as general diseases, are those which have no fixed or uniform seat, as regards their local manifestations. Diphtheria, acute and chronic rheumatism, gout, scorbutus, and purpura belong in this category. These diseases will be considered in this section.

Of the general diseases, fever will be first considered. At the present time, it is unnecessary to discuss the grounds for recognizing fevers as idiopathic affections. It is sufficient to state the distinction between an idiopathic fever and the morbid condition, also called fever, which is dependent on a local affection. The latter is distinguished as symptomatic fever. It embraces elevation of temperature and increased frequency of the heart's action, together with other morbid phenomena therewith connected, which enter into the clinical history of acute inflammations wherever seated. The fever, under these circumstances, is secondary to the local affection; it is symptomatic of the latter; whereas fever, when idiopathic, is primary, local affections, if they co-exist, being secondary. The term *essential* distinguishes a fever which is not secondary or symptomatic, but primary or idiopathic.

The number of fevers is sufficient to render a classification of them desirable. The arrangement generally adopted is sufficiently natural and convenient.

First. A form of fever characterized by its short duration and mildness, is called *febricula.*

Second. Certain fevers are distinguished by the unbroken continuity of the febrile phenomena, and, hence, they are called *continued fevers.* This class will embrace the fevers known as *typhus* and *typhoid. Relapsing fever* and *erysipelatous fever* may be included in this class.

Third. In contrast with those of the preceding class, certain fevers are distinguished by the occurrence of distinct paroxysms or notable exacerbations as regards the febrile phenomena, and, hence, they are known as *periodical fevers.* This class embraces *intermittent fever* and *remittent fever.*

Yellow fever is usually included in this class. The fever called *dengue* may be here placed. In this connection will be noticed *typho-malarial fever.*

Fourth. An eruption on the surface of the body is a prominent feature of certain fevers. These are distinguished as *eruptive fevers* or the *exanthematica.* This class embraces *variola* or *smallpox*, *scarlatina* or *scarlet fever*, *rubeola* or *measles*, and *roseola* or *roserash.*

The foregoing list of fevers does not comprehend all that exist. It comprehends, however, those which, from their prevalence and established individuality, it is desirable to consider in this work. Distinct species of fever, not now recognized as such, may be hereafter ascertained.

It is somewhat necessary to refer to certain distinctions and names heretofore in vogue, in order that the meaning of terms still more or less used may be understood. Fevers have been distinguished and named according to the organ or system prominently affected. Hence the terms gastric fever, mucous fever, nervous fever, etc. These names were used when the distinction was not clearly made between essential, or idiopathic, and symptomatic fever. The names gastric fever and mucous fever are still used by some authors to denote cases of either transient gastritis, or of febricula attended with notable disorder of the stomach. The general feature or complexion, so to speak, arising from the predominance of certain symptoms, has served as the basis of certain distinctions and names. Thus, fevers characterized by great prostration have been called *adynamic.* Fevers have been said to be *ataxic*, when symptoms referable to the nervous system, such as delirium, etc., are prominent. These names are still sometimes employed to denote the general character of different fevers. Fevers tending intrinsically to a fatal result have been, and are still, called *malignant.* Fevers supposed to furnish evidence of septic changes in the fluids have been called *putrid.* Fevers of unusually long duration have been called *slow;* if attended with unusual depression, they have been called *low*, this term having the same sense as adynamic; when the febrile phenomena are intense, the fever is said be *high.* The term *congestive fever* has been much used to denote an accumulation of blood within the vessels of internal organs. This term is still often applied, in this country, to certain cases of periodical fever. Again, names have been applied to fevers, expressive of their source, or the places in which they prevail. Thus, typhus has been known as jail, ship, or camp fever; and periodical fevers, in different localities, have been called Bona Vista fever, Walcheren fever, jungle or coast fever, swamp fever, Panama fever, etc.

Before treating of the different species of fever separately, it will be advisable to present some general considerations relating to the general pathology of fevers collectively. The few preliminary considerations to be presented, will render it unnecessary to consider the pathological character of the individual fevers.

The following question at once arises: What morbid phenomena are necessary to the existence of an essential fever? Practically, the problem generally is to determine whether a fever be symptomatic or essential. An enumeration of the obvious phenomena belonging to an essential fever, that is, of features common to all essential fevers, embraces the following points: In most cases the invasion is not abrupt or sudden, but there is a period of access, or a forming stage. Different fevers differ as regards the time occupied in the development of the disease, and certain prodromic symptoms are peculiar to particular fevers. Generally, the affection is attended by a chill or by chilliness, and frequently by rigors. The pulse becomes more or less accelerated, and usually there is a very perceptible increase of the heat of the surface. The thermometer shows, as a rule to which there are no exceptions, more or less increase of temperature; hence, the source and significance of

the name fever. This increase of temperature is chiefly owing to an abnormal production of animal heat. The increased amount of heat which is given off from the body in fever does not compensate for this increased production within the body. Anorexia and thirst are usually present; nausea is rarely wanting, and often vomiting occurs. Other symptoms are, frontal headache, pain in the loins and limbs, lassitude, restlessness, vigilance, or imperfect sleep. The urine and other secretions are diminished. The scantiness of urine, however, is due to deficiency of water, the specific gravity being from 1020 to 1025 or more. The coloring matter of the urine is generally increased. The abnormal amount of excrementitious products which represent the waste of the tissues, corresponds to the increase of animal heat above that of health. The urea and uric acid are, with rare exceptions, increased, the amount of the latter being sometimes double that of health. This shows augmented waste of the tissues. The chlorides are diminished at least one-half. There is more or less rapid and notable loss of weight, the loss being greater than the reduction of alimentation. The amount of carbonic acid eliminated in expiration is notably increased. In most of the fevers the morbid phenomena continue for a limited period and then spontaneously end. The muscular debility is usually sufficient to cause the patient to take to the bed.

The combination of all these phenomena would not denote an essential, as distinguished from a symptomatic, fever, without a negative condition, namely, the absence of any local disease adequate to account for them. We judge, then, that a patient has an essential fever of some kind, when he presents an *ensemble* of certain symptoms with the proviso just stated. But it will be seen hereafter that the different species of fever present, severally, certain symptoms which are characteristic of each species, that is, distinctive, on the one hand, of fever as contrasted with other diseases, and, on the other hand, of a particular species of fever as contrasted with other species.

Fevers are acute infectious diseases, using the term infectious as it is now generally used, and as defined in the first part of this work (*vide* page 89). Different fevers exemplify the different varieties of infection. Of some fevers, the special causes are produced without, and never within, the organism. These are miasmatic infectious fevers. Examples are the periodical fevers, yellow fever, dengue. Other fevers require the introduction into the body of a special infecting agent derived from a body affected with the same disease. This infecting agent is a contagium. A contagium is an infective agent derived from the body of a patient affected with a particular disease, and one which, without undergoing any modification or further development in its transit, is capable of producing that disease when it enters the body of a healthy subject. It is reproduced within the body in an unlimited amount, and is thrown off from the body either in an impalpable form or miasm, or contained in a palpable morbid product. The latter is a virus. The contagious fevers are typhus, relapsing fever, smallpox, scarlet fever, measles. Again, it is supposed that the infection may consist of a special cause derived from the body of a patient, but that this special causative agent is not capable of producing the disease in others until certain modifications or further developments have taken place, under favorable conditions, after it has left the body. Typhoid fever is generally considered as produced by an infecting agent of this description. The term miasmatic-contagious is applied to fevers of this class.

Facts warrant the belief that each of the essential fevers has its own special cause; in other words, that each requires a particular causative agent capable of producing that fever and none other. It is most consistent with our present knowledge, if it be not logically certain, that this causative agent

is a living organism. The reasons for accepting the germ theory have been stated in the first part of this work (*vide* pages 93 and 97). The period of incubation, that is, a period variable in duration as regards different fevers, but definite and uniform as regards individual fevers, after the reception of the special cause, before the first manifestations of disease appear; the prodromic period, or period of access, which belongs to the history of most of the fevers; their self-limited duration, generally, within certain fixed boundaries of time; the unlimited reproduction of the special cause within the organism in the contagious fevers; the local manifestations distinctive of the different fevers, together with the characteristic lesions—these are clinical facts of which the germ theory alone affords a rational explanation. In one of the fevers (relapsing fever) the causative organism has been discovered in the blood. It is fair to assume that the discovery of the particular organisms causative of other fevers, severally, is a question only of time.

The organisms causing different fevers are to be regarded as parasites. Each parasitical organism holds a relation to the phenomena of the particular disease of which it is the causative agent, somewhat analogous to that of the trichina spiralis to trichiniasis. In the existing state of knowledge it is not easy to explain fully the *modus operandi* by which all the varied phenomena of the different fevers are produced. The germ theory, however, renders this a less difficult problem than if regarded from any other point of view. To pursue inquiries in the wide field opened up by these remarks, would be to go beyond the scope of this work.[1]

Febricula. Ephemeral Fever. Simple Fever.

The term *febricula*, a diminutive of *febris*, is perhaps the best name to denote a mild, short fever which is everywhere of not infrequent occurrence. If very short, lasting only a single day, it is appropriately called an *ephemeral fever*. When not ephemeral, the fever may continue for a period varying from three to eight, or even ten, days. It has been known by a variety of names; it is frequently called *simple continued* or *simple fever*.

This fever has no known anatomical characters; the opportunity of post-mortem examination is seldom offered, for the disease rarely, if ever, of itself ends fatally, at least in cold or temperate climates. No lesions belonging to the fever have been found in cases in which, owing to complications, death has taken place.

The invasion in cases of febricula is generally abrupt; but, in a certain proportion of cases, lassitude, loss of appetite, and general malaise exist for two or three days before the fever is developed. Irregular chilly sensations may accompany the attack, but there is seldom a well-pronounced chill. The febrile movement is more or less intense; not infrequently the acceleration of the pulse and heat of the surface are greater than at the commencement of typhus and typhoid fever. Pain in the head is a prominent symptom, the pain being generally frontal; there is more or less pain in the loins and limbs. Anorexia is usually complete. Constipation is the rule, and the abdominal symptoms which belong to typhoid fever are wanting. The urine is scanty and high colored; the intelligence remains unaffected; the hebetude which characterizes typhus and typhoid fever is not observed. There is no characteristic eruption; herpetic vesicles about the mouth sometimes occur, and bluish spots (*tâches bleuatres*), from three to eight lines in diameter, not

[1] With reference to these inquiries, the reader is referred to "The Germ Theory Applied to the Explanation of the Phenomena of the Specific Fevers," by T. Maclagan, M.D., London, 1876.

elevated and not disappearing on pressure, have been observed. These occur occasionally in typhoid fever.

The febrile career ends suddenly after one, two, three, or more days, the limit of the duration being ten days. Frequently with the cessation of fever there is a copious perspiration; epistaxis and occasionally hemorrhage from the uterus and rectum have been observed at the end of the fever. The convalescence is usually rapid, and there are no sequels. The thermometer indicates a sudden rise of temperature of four or five degrees, and as rapid a decline, the heat passing, in one or two days, to the normal standard.

This species of fever is supposed to occur irrespective of any special cause; that is, ordinary causes are supposed to produce it. It is observed to follow over-exertion, dietetic excesses, and exposure to the sun's rays. This view of the causation is, however, conjectural. It is probable that certain cases which, from their short duration, are considered as cases of febricula, are in fact cases of typhoid or typhus fever, the disease ending without going through its usual career; in other words, cases of ephemeral fever may be cases of abortive continued fever.

The diagnosis of febricula is of importance with reference to the success of measures employed to arrest or abridge the duration of typhoid and typhus fever. In cases in which measures employed for these ends appear to prove successful, the question is: was the disease typhoid or typhus fever, or was it a febricula? The following are considered as diagnostic points: 1. The abrupt development of the fever. 2. The attack succeeding obvious and ordinary causes. To these is to be added absence of diagnostic traits belonging to the clinical history of either typhoid or typhus fever. Cases, however, occur in which it is difficult or impossible to decide, during the progress of the fever, whether it be typhoid, or typhus, or a febricula; and, after the fever ends, whether it have been a febricula or an abortive or arrested typhoid or typhus fever.

Febricula in cold and temperate climates is rarely, if ever, fatal, except from an accidental complication of a serious nature. It is said to prove fatal not infrequently in tropical countries.

As regards the treatment of febricula in cold and temperate climates, hygienic and palliative measures only are called for. A saline laxative, refrigerants, and anodynes are the remedies indicated.

Typhoid Fever.

The name *typhoid* signifies *typhus-like*. The pertinency of this name, as applied to the fever to be now considered, consists in the resemblance of the disease to typhus fever. It might, therefore, seem most appropriate to consider, first, typhus fever; but typhoid fever prevails very extensively in this country, and has been known with us as *common continued fever*, whereas typhus is comparatively rare, and the latter is perhaps never an indigenous disease. For this reason, reversing the order which the name suggests, I shall consider, first, typhoid fever, with reference to its anatomical characters, clinical history, causation, diagnosis, and prognosis; afterward typhus, under the several aspects just named, and, lastly, the treatment of typhoid and typhus fever.

The name *typhoid* is open to objection. It is customary to apply this name to a condition or state incidental to many diseases, and hence has arisen confusion. Of other names which have been proposed, no one has been generally adopted, and probably the disease will continue to be called typhoid fever. This name was introduced by Louis, whose clinical researches were of great value, not merely with reference to our knowledge of this disease,

but as inaugurating the true method of the study of the clinical history of all diseases, namely, by means of the analysis of carefully recorded cases. The correspondence of the results of the researches of Louis, as regards typhoid fever, with the results of similar researches by others in different countries, furnishes the best possible proof of the value of the method of study, and, at the same time, shows the remarkable uniformity of the disease at different times and places. By German writers, the disease is called *abdominal typhus* or *ileo-typhus*. Prof. Geo. B. Wood suggested, as an appropriate name, *enteric fever*. Both these names relate to the intestinal lesions which are characteristic of the disease, and they are objectionable because they convey the impression that the fever is the result of these lesions. Murchison proposed as the name, *pythogenic fever*, a name which implies that the disease is produced by putrescent matter. It is an objection to this name that the source of the special cause, implied in the name, has not been established.

Anatomical Characters.—The characteristic lesions of typhoid fever are seated in the lymphatic structures of the intestine, namely, Peyer's patches and the solitary follicles. Corresponding to the intestinal changes are alterations in the mesenteric glands. There are also important changes in other organs of the body, but most of the latter changes are common to many infectious diseases.

Four stages of the morbid process in the *intestine* may be distinguished: 1. The stage of congestion and simple inflammation of the mucous membrane. 2. The stage of medullary infiltration of the lymphatic structures. 3. The stage of retrograde metamorphosis and ulceration. 4. The stage of repair. These stages correspond approximately to certain periods of the clinical history. In the *first* week of the disease are developed congestion and inflammation of the mucous membrane of the small intestine, together with swelling of a certain number of solitary follicles and agminated glands. In the *second* week the general congestion of the mucous membrane diminishes; the swelling and infiltration of the solitary follicles and Peyer's patches increase. During this week necrotic changes in the swollen follicles and patches take place. The casting off of the necrotic tissue results in the formation of the typhoid ulcers. In the *third* week the process of ulceration is completed. After this follows the period of repair of the ulcers, which occupies a variable time. It is to be noted that different stages of the lesions are usually found in the same case. The changes are most advanced in the small intestine near the ileo-cæcal valve.

At the onset of the disease the mucous membrane of the lower part of the small intestine is hyperæmic, swollen, softened, and coated with mucus. At the same time Peyer's patches and the solitary follicles of the lower half of the ileum begin to enlarge. As their enlargement increases, the hyperæmia diminishes except in the immediate neighborhood of the swollen follicles and patches; these remain surrounded by a zone of congestion. The morbid process is most intense in the ileum near the ileo-cæcal valve. In some cases the solitary follicles of the large intestine are swollen and may ulcerate. This involvement of the large intestine is more common in some epidemics than in others. The follicles of the jejunum may likewise become swollen, but ulceration in this situation is rare. According to Hoffmann,[1] the disease rarely extends higher than nine and a half feet above the valve. Usually both Peyer's patches and the solitary follicles are involved. Sometimes the changes are more marked in one of these structures than in the other. In

[1] Hoffmann, Untersuchungen über die path.-anatom. Veränderungen der Organe beim Abdominaltyphus, Leipzig, 1869.

the stage of *medullary infiltration*, the solitary follicles and Peyer's patches are swollen and project one, two, three, or even four lines above the plane of the adjacent mucous membrane. The enlarged solitary follicles preserve their round shape and may attain the size of a pea. The swollen Peyerian plaques are elliptical or long-oval in shape. Swellings many inches in length may be produced, especially near the valve, by the confluence of several enlarged patches. Usually the patches are indurated to the touch. Their surface is sometimes smooth, and sometimes it presents an irregular, granulated aspect. The edges are generally abrupt; sometimes they are constricted near the base, so that the patch has somewhat of a mushroom shape. Upon section the infiltrated follicles and plaques have a grayish-red or a whitish color. The appearance on section frequently resembles that of the white matter of the brain or spinal cord, and hence the name medullary infiltration which is applied to this condition. The peritoneum corresponding to the affected patches is usually congested. The swelling of Peyer's patches and of the solitary follicles is due to an increase in the number of lymphoid cells normally present in these structures. In addition to the ordinary lymphoid cells, there are also found larger cells with a greater amount of granular protoplasm. Some of these large cells contain several nuclei. It is probable that the large cells are developed from the small lymphoid cells. The new cells are generally considered to be the offspring of the pre-existing lymph-cells of the follicles, and the whole process is regarded as a hyperplasia of the lymphatic structures. It is equally probable that the new cells, at least in part, are emigrated white blood-corpuscles. The cellular infiltration is not confined to the limits of the solitary follicles, or of Peyer's patches, but extends for a certain distance into the surrounding mucous membrane. It also extends in depth for a variable distance; sometimes chains of lymphoid cells can be traced from the follicles through the muscular coat to the subserous tissue. According to Klein[1] there is also a new production of lymphoid cells in the adenoid tissue of the mucous membrane independently of any connection with the follicles. This writer thinks that some of the projections which present the appearance of swollen solitary follicles are in reality nodular accumulations of lymphoid cells developed in the mucous membrane independently of the follicles.

The medullary infiltration may terminate in *resolution* or in *ulceration*. In the process of resolution the swelling of the follicles gradually diminishes; many of the new cells undergo fatty degeneration and are absorbed. As a rule, this retrograde metamorphosis by degeneration and absorption occurs in some of the swollen follicles and plaques, while in others ulceration takes place. Sometimes the individual follicles of a Peyerian patch soften and discharge their contents. In these patches the interstitial tissue forms a projecting network around the sunken follicles. This appearance characterizes the so-called reticulated patches. A reticulated aspect of the patches may also be due to simple degeneration and absorption of the infiltrated material in the follicles. The most characteristic termination of the process, however, is in the formation of a slough, and, by the separation of the slough, the production of the typical typhoid ulcer. The slough may occupy a whole Peyer's patch, or only portions of a patch. It has usually a yellowish color from imbibition with bile. It may present a hemorrhagic appearance. The rapidity with which the sloughing process takes place varies in different cases. The process usually reaches its acme in the second week, but cases have been described in which the ulcers were fully formed on the seventh or eighth day

[1] Klein, Report on the intimate anatomical changes in enteric or typhoid fever. Rep. of the med. office of the Privy Council, new ser. 1875, No. 6, p. 80.

of the disease. It must be remembered that it is by no means easy to determine in all cases the day on which the disease begins. It may be stated here that there is no constant relation between the extent of the intestinal lesions and the severity of the disease, as denoted by the abdominal and other symptoms. The sloughing and ulceration take place earliest in the glands nearest the ileo-cæcal valve, and, usually, different degrees of progress are presented in the series above this point. The necrosis or sloughing of the infiltrated glands is usually ascribed to arrest of the circulation from the pressure upon the small bloodvessels exerted by the excessive production of new cells. The necrosis does not usually extend beyond the boundaries of the affected Peyerian patches. Sometimes the slough separates *en masse;* more frequently it is thrown off in fragments, leaving at first small irregular losses of substance. After the sloughing is completed, ulcers take the place of the affected solitary follicles and Peyer's patches. These ulcers have certain distinctive features. Those resulting from necrosis of the solitary follicles are round; those which take their origin from Peyer's patches preserve the oval or elliptical shape of these patches, the long axis of the ulcer being parallel to the direction of the intestine. The bottom of the ulcer is usually smooth, and often presents to view the transverse muscular fibres of the intestine. The edges are undermined and usually thin, but they may be somewhat swollen and congested, especially in the early period of formation of the ulcer. The ulcer may extend in depth and reach the deeper layers of the muscular coat, or its floor may consist only of the serous membrane. *Cicatrization* is the last step in the series of processes. Granulation-tissue springs from the floor of the ulcers. The undermined edges become united with the bottom of the ulcer. The resulting cicatrix is whitish, or more frequently pigmented, slightly depressed and covered by epithelium. The villi and glands of the mucous membrane, according to most writers, are not regenerated. It is a remarkable fact that the cicatrices of typhoid ulcers have very little tendency to cause stenosis of the intestinal lumen. The process of cicatrization usually begins in the third week of the disease, and is going on during convalescence. The time occupied in the completion of this process varies in different cases. It is sometimes unusually slow, a fact which accounts for the persistence of the abdominal symptoms, in certain cases, for some time after the career of the fever is ended.

Perforation of the intestine is liable to occur in one or more of the ulcers. According to Hoffmann, perforation occurs in about one per cent. of the cases of typhoid fever, and in about eight per cent. of the deaths from this disease. It is most frequent from the third to the fifth week of the disease. It is rarely caused by the primary sloughing, but is due to secondary ulceration after the separation of the slough. The perforation may be due to rupture of the thin floor of an ulcer by distension of the intestine with gas, by the contact of feces, or by the presence of round worms. The opening in the peritoneal coat may be of considerable size, or it may be no larger than a pin's point. With intestinal perforation are associated appearances denoting acute diffuse peritonitis, the latter being occasioned by the escape of the gaseous and other contents of the intestine into the peritoneal sac. In rare instances the peritonitis is circumscribed around the seat of perforation by means of adhesions. Death may occur before sufficient time has elapsed for the production of inflammatory exudation. Profuse hemorrhage may occur from the primary sloughing or from the secondary ulceration.

More or less enlargement of the *mesenteric glands* is always associated with the intestinal lesions. The mesenteric glands which are in immediate relation to the affected Peyerian and solitary glands, are especially enlarged. Their volume is often much increased; not infrequently they attain to the

size of a pigeon's egg. The enlargement is due to congestion and to the production of new cells resembling those normally present in the glands. The same large, granular, sometimes multinuclear, cells found in the infiltrated follicles of the intestine are met with in the swollen mesenteric glands. The morbid process, in fact, in these glands is of the same nature as that in the lymphatic structures of the intestine. Only in exceptional cases does the morbid growth which gives rise to the enlargement produce sloughing. This process of necrosis is, however, an occasional source of peritonitis developed in the course of the disease. Usually the glands diminish in size as the process of ulceration is going on in the intestine. The new cells undergo fatty degeneration; the resulting molecular mass in part is absorbed, and in part remains as a dry detritus which may become infiltrated with the salts of lime.

The *spleen* is enlarged, dark red in color, and softened. It is often two or three times the normal size, and may be larger. In very exceptional cases no swelling of the spleen is found. The enlargement is due to congestion and to hyperplasia of the cellular elements. Large cells containing one or more red blood-corpuscles, or fragments of corpuscles, are found in the splenic pulp and veins. Hemorrhagic infarctions are occasionally met with in the spleen. Instances of rupture of the capsule of the spleen with escape of blood into the peritoneal cavity have occurred. The result is a fatal peritonitis or sudden death.

Typhoid fever, like other infectious diseases, is attended by *parenchymatous degenerations*. The parts most affected are the cardiac muscle, the liver, the kidney, and the glands of the stomach. The voluntary muscles also undergo the change. For the description of this metamorphosis the reader is referred to Part First, page 54, and to the accounts of this degeneration in connection with diseases of the organs named. The degeneration may be produced both by high temperature and by infectious blood-changes, and doubtless both of these factors enter into its production in typhoid fever. Zenker has described a pseudo-waxy change in some of the muscles. This change affects only certain muscular fibres, not the whole muscle uniformly. It is observed most frequently in the recti abdominis, in the adductors of the thigh, and in the diaphragm. It may also occur in the cardiac muscle. The affected portions of muscle are pale and have a grayish waxy lustre. The muscular fibres are transformed into a homogeneous, friable mass without trace of the normal transverse striation. This change may lead to rupture of the muscular fibres with hemorrhage. This pseudo-waxy metamorphosis is not confined to typhoid fever, but may occur in other diseases, and may be produced in animals by injuries to the muscles. Regeneration of muscular fibres destroyed by parenchymatous or by pseudo-waxy metamorphosis takes place during convalescence (*vide* page 41).

Changes in the *lungs* are present in nearly all cases of typhoid fever. Congestion and inflammation of the bronchial mucous membrane form an almost constant element in the disease. Hypostatic congestion and the condition called splenization of the lungs are found in a large proportion of cases. Pulmonary œdema is not uncommon. Pneumonia, usually in the lobular, but sometimes in the lobar, form, is a frequent complication. Hemorrhagic infarctions may be caused by emboli derived from thrombi formed in the right cavities in the heart.

Ulcerations in the *larynx* are found in many cases. These occur most frequently on the edges of the epiglottis, and on the posterior wall of the larynx just above the vocal cords. Writers are not agreed as to whether some of these ulcers are specifically typhoid or not. These ulcers may extend in depth and cause perichondritis. Œdema of the glottis is a rare complication of typhoid fever. Aphthous inflammation of the mouth and pharynx is not very infrequent in typhoid fever.

The *liver* is usually somewhat swollen, pale, and softened. The hepatic cells are in a condition of parenchymatous degeneration. Accumulations of lymphoid cells in the interlobular tissue about the branches of the portal vein are described by Wagner under the name of typhoid lymphomata. The bile is usually pale yellow and thin. The *kidneys* may present lymphomata similar to those in the liver. Parenchymatous degeneration of the renal epithelium is the rule. A genuine acute nephritis may occur, but it is rare. Hoffmann describes as a frequent occurrence proliferation and parenchymatous degeneration of the cells in the acini of the *salivary glands* and *pancreas*. Abscess of the parotid gland may occur in typhoid as well as in typhus fever.

No changes have been discovered in the *central nervous system* to explain the mental disturbance which characterizes this disease. There may be some increase of the cerebro-spinal fluid. Lymphoid cells are sometimes found around the ganglion-cells of the brain, but these wandering cells may be present in various other conditions.

The *blood* in typhoid fever, as in other infectious diseases, is poor in fibrin, and contains a relatively or absolutely larger number of white blood-corpuscles than normal.

Many attempts have been made to discover a specific organism or germ as the infectious agent in typhoid fever. The existence of such an organism has not, however, been satisfactorily demonstrated. Klein describes with minuteness the existence of colonies of micrococci in the infiltrated lymphatic organs of the intestine. To the accumulation of these organisms in the bloodvessels of the swollen follicles and patches he ascribes the necrotic changes which lead to ulceration. Recently Klebs[1] and Eberth[2] have described the occurrence of rod-shaped bacteria or bacilli which they regard as the specific organisms of this disease. These bacteria are found in the lymphatic apparatus of the intestine, in the mesenteric glands, and in the spleen; furthermore, according to Klebs, in laryngeal ulcers, in lungs affected with pneumonia, and in œdematous pia mater. Eberth points out certain characteristics of these bacilli which, he considers, distinguish them from the rod-shaped bacteria of decomposition.

No disease is accompanied by so great a number and variety of *complications* as typhoid fever. Some have already been mentioned. Other possible complications or sequelæ are: peritonitis without perforation, pleuritis, pericarditis, endocarditis, meningitis, cerebral hemorrhage, otitis media or externa, cystitis, epididymitis, embolism of arteries of the lower extremities with dry gangrene, embolism of the pulmonary artery, thrombosis of the femoral vein with phlegmasia alba dolens, thrombosis of other veins, thrombosis of the heart, necrosis of bone, noma, gangrene of various parts of the body, bed-sores, septicæmia from bed-sores, pyæmia with abscesses in the lungs, spleen, and other parts, erysipelas faciei, furuncles, dysentery (during convalescence), croupous or diphtheritic inflammation of the larynx and pharynx, hemorrhagic diathesis, icterus gravis, ulcer of the cornea, neuro-retinitis, inflammation of the mucous membrane of the gall-bladder, pyæmic or rheumatic polyarthritis.

CLINICAL HISTORY.—Typhoid fever, as a rule, is developed gradually. After the development of the disease, the most convenient division of stages is into septenary periods. The career of the disease will embrace the first, second, third, and sometimes a fourth, fifth, sixth, or even a seventh week.

In a large proportion of cases, patients are unable to fix the precise date

[1] Klebs, Der Ileo-typhus eine Schistomycose, Arch. f. experimentelle Pathologie, Bd. xii., 1880.

[2] Eberth. Die Organismen in den Organen bei Typhus abdominalis, Virchow's Archiv, Bd. 81, 1880.

of their ailments, so imperceptible is the commencement of the disease. It is, therefore, often not easy to determine accurately the duration of the prodromic period. This period ends when the disease is developed. My rule has been to consider the fever as established when the patient takes to the bed. This is an arbitrary criterion, and not always accurate, but the instances in which patients take to the bed before and after the full development of the disease, will about compensate for each other. The first chill, or chilly sensations, and an increase of the temperature, are more correct criteria; but, in a large majority of cases, patients do not come under observation until the fever is developed, and they often cannot recall the first chill or chilly sensations. Judged by the rule just stated, the prodromic period varies from one to ten days, and the mean duration is about five days. Exceptionally, the attack is abrupt, the patient taking at once to the bed.

The following are the prodromic symptoms: Chills, more or less pronounced, or chilly sensations, recurring irregularly, sometimes followed by perspiration and sometimes not. Cephalalgia, the pain generally referred to the frontal region. Mental irritability, with difficulty of concentrating the attention or exerting the faculties of the mind. Loss of appetite, occasional nausea, and sometimes slight vomiting. Epistaxis, in a pretty large proportion of cases. Pain in the loins and limbs. Looseness of the bowels, or hypercatharsis if a mild purgative be given. Lassitude and progressive debility until, at length, the patient, who, up to this time, has kept up with more or less effort, feels compelled to take to the bed.

Of the symptoms in the foregoing list, those especially of diagnostic importance are looseness of the bowels and epistaxis. The duration of this period is of importance in diagnosis.

The symptoms which after this period make up the clinical history, may be distributed into those referable to the countenance or general aspect, the nervous system, the digestive system, the skin, the respiratory system, the circulation, the temperature, and the urinary system.

Countenance and General Aspect.—There is no marked alteration of the countenance for the first few days. The face in the early period of the disease is usually more or less flushed. Afterward, the countenance presents a dull or listless expression, and in severe cases there is lack of expression, or an appearance of stupidity. The latter corresponds with the gravity of the disease, and is more and more marked as the disease continues. These alterations of the physiognomy are dependent on the mental condition.

The surface presents slight or moderate capillary congestion, like that produced by the action of cold. This is most marked on the face, and especially on the cheeks. Distinctly circumscribed redness of the cheeks is rare save in the cases in which the disease is complicated with pneumonitis. The redness disappears on pressure, and returns more or less quickly. In some cases the hue of the surface is slightly dusky. The capillary congestion observable on the face is diffused over the body, but, next to the face, it is most marked on the hands and arms. It is rational to consider this appearance as denoting paresis of the peripheral arteries. Slight or moderate congestion of the conjunctiva is not infrequently observed.

Nervous System.—Pain in the head is more or less complained of during the first week. It is not always a prominent symptom, and never has the intensity which belongs to the pain in the first stage of acute meningitis. It gradually becomes less and less a subject of complaint, and usually ceases during the second week. The cephalalgia is not accompanied with notable intolerance of light and sounds. Pain in the back is also complained of in the early part of the disease, but is rarely a very prominent symptom.

Delirium is manifested in the majority of cases. As a rule it is not

manifested until the second week, and sometimes not until the third or fourth week. Exceptionally, it is manifested in the first week, and even when the patient first takes to the bed. Cases differ much as regards the degree of delirium; it may be slight, or, on the other hand, a very prominent symptom. Generally, the first evidence of mental aberration is temporary confusion on awakening from sleep, the patient being unable to recall where he is, and asking incoherent questions. Increasing, the patient talks incoherently, and mutters like a person talking in sleep. Efforts to get out of bed are common, and when asked where they would go, patients often say they wish to go home. In most cases they are easily persuaded to lie down, but after a few moments the effort to get up is repeated. If not watched, they sometimes get up and succeed in getting on their clothes. The delirium is always greater, and may be manifested only, during the night. In the great majority of cases, the delirium is of a quiet, passive kind. It apparently proceeds from weakness of mind; there is inability to carry on connected trains of thought. The incoherent talking or muttering usually relates to habitual pursuits. The patient is in a dreamy state, a succession of disjointed ideas passing through the mind.

There are occasional exceptions to the rule regarding the kind of delirium. It is sometimes noisy and active; the patient shouts, and makes strong and persistent efforts to get up. Constant forcible restraint may be necessary. Fixed delusions, either of the senses or ideas, during the progress of the disease, are certainly rare; they may occur at the time of convalescence. In one of my cases the patient fancied that he had become immensely rich, and this delusion continued for several days after convalescence. In another case, the patient being a young woman, the delirium in convalescence had the character of delirium tremens. Hysterical delirium is not uncommon. The delirium, during the course of the fever, is in general marked in proportion to the intensity of the disease. So far as my observations go, persisting, active, or violent delirium, requiring restraint, is an extremely unfavorable symptom.

Patients are sometimes perfectly coherent, but not rational. They reply to questions at hap-hazard, and no reliance is to be placed on their statements with respect to the events of their illness. In some cases there are no manifestations of delirium during the whole course of the disease, but, after recovery, there is very little recollection of anything that occurred. The delirium sometimes has an hysterical character, consisting in emotional manifestations—weeping and sobbing—the emotions being very rarely mirthful.

Delirium, however prominent as a symptom, is no evidence of encephalic inflammation. The appearances of meningitis are not found after death in cases characterized by very active delirium, nor is there an abnormal amount of congestion.

Irrespective of delirium, the mental condition in the second, third, fourth, week, or longer, is characterized by hebetude, indifference, inanimation. Blunted perception is shown by various circumstances; the patient asks for nothing—not for drink, although the mouth may be dry and desiccated, nor for the position of the body to be changed; flies creeping over the face may occasion little or no annoyance, etc. In grave cases the urine and feces may be passed in bed, not from paralysis of the sphincters, but through indifference and a reluctance to make any effort. The special senses are impaired, especially the sense of hearing; deafness in one or both ears is frequently marked. General and special sensibility are diminished, as a rule, in proportion to the intensity of the disease. Frequently there is dilatation of the pupils.

Wakefulness is complained of during the first few days; the patient experi-

ences discomfort from the want of refreshing sleep. Afterward, the want of sleep may not be appreciated, owing to the mental condition. The patient, indeed, may seem to doze most of the time, but without obtaining true sleep, being easily aroused, but directly relapsing into a pseudo-somnolent state. This state, in which the patient may be said to be both sleeping and wakeful, is called *coma-vigil*, the significance of the term depending on the incongruity of the words which it combines. This name is also applied to a state occasionally observed, in which the patient is unconscious with the eyes open. In coma-vigil, or the pseudo-somnolent state, from which the patient is readily aroused, the mind is frequently occupied with a series of disconnected ideas or dreamy delusions which give rise to the muttering delirium. This combination of stupor and delirium is expressed by the term *typho-mania*. The want of true sleep doubtless contributes not only to the exhaustion, but to delirium and other disordered nervous phenomena, as in delirium tremens.

Coma-vigil and typho-mania do not involve a tendency to true coma; but in a certain proportion of cases, coma is gradually developed in the latter part of the career of the fever, and under these circumstances a fatal result is to be expected. In a certain proportion of cases coma is sudden; it occurs unexpectedly, and in mild as well as in severe cases. These cases end fatally, the mode of dying being by apnœa. This apoplectic coma is often preceded by disturbance of the rhythm of respiration, the inspiratory act being shortened and quickened.

Other symptoms referable to the nervous system, or ataxic symptoms, denoting gravity of disease, are, grasping at invisible objects or carphologia, pulling-up of the bedclothes or fumbling with the body linen, visible twitchings of the muscles of the face and of the extremities, and movements of the tendons of the wrist perceptible to the touch, the latter called *subsultus tendinum*, rigidity of the muscles of the neck or extremities, and convulsions. Muscular rigidity and convulsions are very rare, and betoken a fatal termination. There is reason to believe that the pathological condition giving rise to convulsions with coma is frequently, if not always, uræmia. In these cases the urine will be found to be albuminous.

Digestive System.—Anorexia is the rule, but to this rule there are exceptions; the appetite is sometimes preserved throughout the disease. Food is sometimes acceptable when, owing to the mental condition, it is not asked for. Thirst is usually a prominent symptom until perception becomes blunted. Drink, although not asked for, is often taken with avidity when given. The condition of the mouth would involve a desire for drink were the ability to perceive morbid sensations not impaired.

The tongue generally presents morbid appearances. It may be simply furred or frosted, but it is oftener covered with a coating more or less thick, which, in different cases, is whitish, yellowish, brownish, or even black. Not infrequently the coatings are thrown off once or repeatedly, and the surface is then usually reddened. Exfoliation of the coating or its gradual thinning, the surface being moist and of a natural color, betokens convalescence. The varied appearances of the coatings have no special significance. The surface of the tongue is sometimes reddened and smooth or glazed. It sometimes becomes dry and hard. This occurs in coma-vigil; the patient breathing with the mouth open, the surface is desiccated. It sometimes becomes cracked and deeply fissured. Tremulousness of the tongue, as in cases of delirium tremens, is sometimes observed, usually preceding or accompanying grave ataxic symptoms. The tongue, in some cases, at an advanced period, is protruded with apparent hesitation and difficulty, and, when protruded, may not be withdrawn, apparently from forgetfulness. The delay in

protruding and withdrawing the tongue, represents the weakness and slowness of the mental acts.

Dark or black matter, called *sordes*, after the first week, is apt to collect upon the teeth and lips, especially in grave cases. Hemorrhage from the gums is an occasional symptom, occurring in mild, as well as severe, cases. Redness of the gums and bleeding on slight pressure are common.

A rare complication is inflammation of one or both of the parotid glands. It leads to notable enlargement, and the appearance is like that of ordinary *parotiditis* or *mumps*. But, unlike the affection just named, in the great majority of cases suppuration takes place, and not infrequently more or less sloughing of the areolar tissue. This complication adds to the danger and retards convalescence. It may occur at any period of the febrile career or during convalescence. It is not to be regarded as a critical event. The discharge of pus is sometimes into the *meatus auditorius*. This complication occurs in typhus, as well as in typhoid, fever. It occurred in 5 of 30 cases of typhus and typhoid fever which I recorded in the winter of 1849–50. Prior to that year I had never met with an example, and since that year I have met with a very few examples only, in a much larger field of observation.

Vomiting is an occasional symptom. Generally it is a result of over-ingestion. As regards the occurrence of this symptom, typhoid fever is in striking contrast with remitting fever.

Diarrhœa or looseness of the bowels exists in a large majority of cases, and belongs among the diagnostic symptoms of the disease. The dejections often have a yellow, ochre color. They give an alkaline reaction, but this is not distinctive of the disease. Exceptionally, constipation exists, and the dejections may have a natural appearance throughout the disease. The bowels are often evacuated in bed either from indifference or from paralysis of the *sphincter ani*. The involuntary evacuations denote great gravity of disease.

Hemorrhage from the bowels is an important event in the clinical history of this disease. It occurs in a proportion of from 5 to 8 per cent. The hemorrhage may be slight, moderate, or profuse. It may cease after a single occurrence, or there may be a greater or less number of recurrences. The loss of blood is sometimes the immediate cause of death. Statistics, however, show that in the larger number of cases patients recover. Even very profuse hemorrhages do not always prove fatal. I have known the loss of blood to occasion complete collapse for several hours in cases which ended in recovery. The hemorrhage occurs late in the disease, and, in most instances, is from the intestinal ulcers. Its occurrence may be foreshadowed by a sudden and notable decline of the temperature of the body. I have met with a case in which the decline of the axillary temperature to 98° was, for a time, considered as evidence that the fever had ended; but within a few hours profuse hemorrhage from the bowels occurred, and the patient died from the loss of blood.

Other abdominal symptoms are, meteorism or tympanites, tenderness or pain on pressure, and gurgling. The abdomen is always resonant from the presence of intestinal gas; frequently there is more or less distension, and sometimes the tympanitic enlargement is great. Tenderness on pressure in the iliac region, especially on the right side, is very rarely absent. Sudden and forcible pressure may be required for the manifestation of pain, if perception be much blunted. The tenderness is often marked, and sometimes extends over the greater part of the abdomen. Gurgling on pressure in the iliac region, as a sound, and as a tactile sensation, is a frequent symptom. These three symptoms, namely, meteorism or tympanites, iliac tenderness and gurgling, especially the two former, conjoined with diarrhœa or looseness,

and ochre discharges, form a group of abdominal symptoms highly diagnostic of this form of fever. The tympanites, tenderness, and gurgling, as regards their prominence, are not proportionate to the amount of intestinal lesions. By percussion over the region of the spleen, this organ is found to be enlarged.

Perforation of the small, or, in rare instances, the large, intestine takes place in a certain proportion of cases, namely, in from 8 to 10 per cent. of fatal cases, and from 1 to 2 per cent. of both fatal and non-fatal cases. It takes place late in the disease or during convalescence, and sometimes even after apparent recovery from the fever. It occurs as often in mild as in severe cases. It occurs oftener in men than in women, and almost never in children.

Perforation gives rise to peritonitis which is generally developed abruptly. The sudden occurrence of notable tenderness diffused over the abdomen, abdominal pain, increased tympanitic distension, rigidity of the abdominal walls, with marked frequency of pulse, prostration, haggard expression of countenance, etc., point to peritonitis from perforation. In some cases, the perforation being quite small, the development of the peritonitis is gradual; it may be circumscribed under these circumstances. Peritonitis does not invariably denote perforation; it may be caused by the evacuation into the peritoneal sac of liquefied matter within a mesenteric gland. It may occur irrespective of either this cause or perforation. In a hospital case, in which death took place from typhus fever, the disease occurring during convalescence from typhoid fever, the post-mortem examination showed recovery from recent peritonitis, adhesions over the Peyerian patches indicating the point of departure of the peritoneal inflammation to have been the intestinal ulcerations. Probably in most of the reputed cases of recovery after the occurrence of peritonitis, perforation was not involved. Peritonitis from perforation is almost certainly fatal.

Skin.—Of the symptoms referable to the skin, the most important is a characteristic eruption. The eruption consists of isolated papules, generally limited to the trunk, of a rose or pink color, called by Louis lenticular rose-colored spots. They are slightly elevated, and therefore are *papulæ*, not *maculæ*. The elevation is distinctly felt if the finger be carried lightly over them. They are slightly oval in form, and are from one to two lines in diameter. The redness momentarily disappears on light pressure. The number of papules is generally small, in the majority of cases not exceeding fifteen or twenty, and sometimes only four or five can be discovered. Exceptionally they are abundant over the trunk, and the eruption sometimes extends to the extremities. Fresh papules appear from time to time during the course of the fever, taking the place of those of anterior date. They are to be sought for over the chest and abdomen in front, and over the back; they are sometimes found exclusively in the latter situation.

Dating from the time of taking to the bed, the average time of the appearance of the eruption is about the seventh day. Papules continue to disappear and to appear during the career of the disease, and sometimes the eruption persists into the stage of convalescence. The papules are not apparent after death.

The eruption is not invariably present. The proportion of cases in which it occurs varies in different years, as my statistics show. It appears to be less frequent in the country than in the city. It is less frequent in children than in adults. The copiousness of the eruption is no evidence of severity of the fever, and, on the other hand, it is as likely to be absent in mild as in severe cases. A scarlet rash occasionally precedes the characteristic rose eruption.

Miliary vesicles or sudamina are not infrequently observed in the middle

and latter part of the disease, on the neck, chest, and abdomen. This eruption is observed in various affections in which perspiration occurs. Petechiæ or minute ecchymoses are occasionally observed. These do not denote unusual gravity of the disease; they occur in mild as well as in severe cases.

Bluish patches (*taches bleuâtres*) of irregular form, from three to eight lines in diameter, are occasionally observed on the abdomen, back, and thighs. They are not peculiar to this disease, and are more likely to occur in mild than in severe cases.

Perspiration more or less abundant, and recurring more or less frequently, is observed in about one-half of the cases, exclusively of its occurrence at the time of convalescence or just before death. It occurs in about an equal proportion of fatal cases and of those ending in recovery. Observation does not show a connection between this symptom and any particular antecedent events; but taking the frequency of the pulse as a criterion of the gravity of the disease, and comparing the pulse before and after the occurrence of perspiration, in the majority of cases improvement follows. While this symptom, therefore, has no bearing on the prognosis, it often betokens some amelioration. As a rule, during the greater part of the career of the fever, the skin is dry.

Gangrene is apt to occur in situations exposed to pressure. Spontaneous gangrene of the extremities has been observed, the probable explanation being arterial thrombosis. Gangrene and troublesome ulcers are liable to follow vesication. The liability to bed-sores on the nates, hips, and shoulders, is to be borne in mind. These may be prevented by changing from time to time the position of the body, the use of air-pillows, etc. Erysipelas is an occasional complication of typhoid fever.

Respiratory System.—Cough is not a prominent symptom, unless an important pulmonary complication exists; but slight or moderate cough is almost invariably present, proceeding from subacute bronchitis. A sibilant râle is frequently heard over the chest on auscultation.

Pneumonia is a not infrequent complication. It is rendered probable by prominence of cough and accelerated breathing; but the proof of its existence is afforded by the physical signs. It is sometimes latent as regards diagnostic symptoms, and is determinable only by physical exploration. Its occurrence adds to the danger, but by no means precludes recovery. Hypostatic congestion and œdema of the posterior portions of both lungs are incident to the feeble circulation in the latter part of the disease. These physical conditions are represented by dulness on percussion, weak respiratory murmur, and subcrepitant râles. Irrespective of any pulmonary complication, except subacute bronchitis, the frequency of the respirations is increased, the average being about twenty-one per minute.

Frequent sighing in the early part of the disease is a forerunner of ataxic symptoms of grave omen. A spasmodic or jerking inspiration, when pneumonia does not exist, is a precursor of coma. This statement holds good in other forms of fever than typhoid. The importance of this symptom is enhanced by the fact that it may sometimes be observed when no other symptoms denote impending coma. This was true of several cases which I have observed.

Epistaxis has been mentioned as a symptom of diagnostic value early in the disease. It occurs not infrequently afterward. Generally the hemorrhage is small, but occasionally it is profuse, and it may require to be arrested by mechanical means. When slight or moderate, it does not appear to have any influence on the progress of the disease. Uterine hemorrhage is not uncommon. Its occurrence is not limited to the period when menstruation should take place.

Pharyngitis, laryngitis, and œdema of the glottis are occasional complications of typhoid fever.

Circulation.—More or less acceleration of the pulse belongs to the history of the disease. The acceleration varies considerably in different cases and at different periods of the disease in the same case. There is a greater average frequency in fatal cases than in those ending in recovery. The danger is usually considerable if the pulse exceed 120 per minute, and the danger is augmented in a geometrical ratio as the frequency rises higher than this. The mean frequency in cases not proving fatal, of those which I have analyzed, was 93; in the fatal cases 110. In some mild cases the average frequency during the whole of the disease is less than the average frequency of health. In one of my cases the average frequency was 69. But in these cases the pulse at times exceeds the healthy standard; hence, the pulse may at times fall below the standard of health. This is not infrequently observed at or near the time of convalescence. I have noted it as low as 64, 60, and 40. Others have observed it to fall still lower. Oftener the pulse continues more or less accelerated after convalescence is declared. A sudden and considerable increase of the frequency of the pulse denotes the occurrence of some important event, such as pneumonia or peritonitis.

As regards characters of the pulse other than frequency, it is quick and vibratory, not hard or resisting. It denotes increased action, but not increased power, of the ventricular systole. It becomes feeble or compressible in proportion as it is frequent. The force is always notably diminished if the frequency much exceed 120. An unfavorable progress of the disease toward asthenia is shown by progressive increase in frequency and diminution of force. Under these circumstances, the first sound of the heart, on auscultation over the apex, is notably weakened, and may be inappreciable. The form of the pulse, as traced by the sphygmograph, presents the following characters: a short and nearly vertical line of ascent, indicative of weakness and quickness of the ventricular systole; a line of descent denoting the free passage of blood from the arteries in the capillaries, and notable dicrotism. The dicrotism of the radial artery is sometimes appreciable by the touch. These characters belong to the graphic pulse also in cases of typhus, and in all affections with which is associated the typhoid condition.

Temperature.—More or less increase of the heat of the body is invariable. In general, the thermometer in the axilla shows a daily increase of temperature for the first five or six days. This gradual rise of temperature from day to day during the first week is diagnostic of typhoid fever. At the end of this period, the temperature at least rises to 103° Fahr. If, in the progress of the disease, the thermometer show much increase above this, the prognosis is unfavorable, whereas, a decline of the temperature in the morning to near the normal standard is evidence of convalescence. During the progress of the disease there is, as a rule, an oscillation of temperature between morning and evening, the difference varying from half a degree to a degree and a half, up to the time of convalescence, when the oscillations become much greater, the difference being four to five degrees, the temperature in the morning falling to the normal standard 98° or lower. The difference between the morning and evening temperature at the time of convalescence has been observed to be over nine degrees. A high elevation of temperature in the morning, namely, 106° to 108°, indicates the approach of death. The laws of the disease, as regards temperature, are sufficiently characteristic to render the thermometer useful in diagnosis as well as in prognosis. A sudden and considerable rise of temperature, during the progress of the disease, points to the occurrence of an inflammatory complication. A sudden and considerable fall of temperature, other symptoms not denoting convalescence or improvement,

is unfavorable. This may precede hemorrhage from the bowels. It is important, however, to note that, irrespective of complications, the temperature, in some cases, becomes increased, and the rise may continue for several days; and, on the other hand, a decline of from one to two and a half degrees sometimes takes place, lasting for several hours, without any obvious cause and having no special significance.

Urine.—The urine is usually scanty and of high specific gravity until the approach of convalescence, when it becomes abundant and of a low specific gravity. During the progress of the disease, as a rule, the urea and uric acid are absolutely increased. The coloring matter is also more abundant than in health. The presence of albumen during a portion of the febrile career is not uncommon. An abundance of albumen denotes gravity. This symptom occurs in the middle or latter part of the disease, and may continue for a period varying from 24 hours to 12 days. In the fatal cases in which it occurs, it continues up to the time of death. In these cases the kidneys after death may be found to be simply congested, no deposit nor structural change existing.

An abundance of renal casts in the urine denotes disease of the kidneys, either having existed prior to the fever, or developed as a complication. It is probable that coma and convulsions occurring in the progress of typhoid fever are due to uræmic poisoning. I have met with a case in which, following a large hemorrhage from the bowels, profuse hæmaturia took place, the blood passed from the bladder forming clots after its emission. The patient became much blanched from the loss of blood, but he recovered.

The urine is sometimes retained in cases of typhoid fever, and, owing to the blunted perception, the bladder may become greatly distended. The practitioner should not omit to ascertain the condition of the bladder, by examination of the abdomen, during the progress of the disease, and resort seasonably to the use of the catheter when required. On the other hand, the urine is often passed in bed, sometimes from indifference and sometimes from incontinence.

In order so determine the duration of the disease, it is necessary to fix upon certain points which shall mark the beginning and the end of the febrile career. The time of taking to the bed is a convenient, and, in a collection of cases, a tolerably correct, criterion of the development of the fever. It is difficult to find any one circumstance which will answer equally well to denote the date of convalescence. The career of the fever rarely ends abruptly; the termination in convalescence, like the development, is gradual. The decision that a patient is convalescent is a matter of judgment, and is to be based on the *ensemble* of symptoms. Different practitioners would differ in individual cases as to the precise day of convalescence. This fact disposes at once of the doctrine of critical days. A believer in this doctrine would fix upon a critical day as the date on which the fever ends, whereas a non-believer would be as likely to fix upon some other day; hence, it is clear that observations collected by believers in critical days would go to support the doctrine. Of 42 cases, ending in recovery, analyzed with reference to the duration of the fever, dating from the time of taking to the bed to the time when the improvement in all the symptoms was sufficient for the patients to be considered convalescent, the average duration was 16 days. The maximum duration was 28 days; the minimum 5 days. The longest duration in any case under my observation was in a female hospital patient, the disease continuing, in this case, without any important complication, 58 days. It is perhaps of importance to state that these cases were observed long before the recent introduction in medical practice of antipyretic measures of treatment. The mean duration in 75 cases observed by Murchison, was a fraction over

24 days. This greater duration, as compared with my cases, is probably owing to the commencement being fixed at an earlier period than the date of taking to the bed. Of 45 fatal cases in my collection, the mean duration was a fraction over 14 days, the maximum being 26, and the minimum 9 days. The mean duration in 12 fatal cases observed by Murchison was a fraction over 22 days. The average duration of convalescence is from one to two weeks. The return of the axillary temperature to the normal standard, that is, complete defervescence, denotes, of course, that the febrile career is ended. Sometimes the defervescence is rapid, and the temperature quickly falls to that of health. But generally it is gradual, and paroxysms or exacerbations of fever, as indicated by the thermometer, are liable to occur for some days after the appetite, mental condition, and other symptoms denote convalescence. The temperature may be kept up by complications which persist after the career of the fever is ended. A temporary fever is apt to accompany the change of diet from liquid to solid animal food.

Relapses of typhoid fever sometimes occur. Many examples have fallen under my observation. A return of the fever may take place after ten days or a fortnight from the date of convalescence, and the patient pass through a second career, the eruption and other characteristic symptoms being reproduced. The duration of the second career is usually shorter, and the severity greater than the first, but a fatal termination is rare.

Complications which are apt to arise in the course of typhoid fever have been noticed in connection with the symptoms referable to different anatomical systems. To these is to be added the occasional occurrence of thrombosis of the iliac or femoral vein on one side or on both sides. Typhoid fever may be associated with intermittent fever (typho-malarial fever), scarlatina, rubeola, diphtheria, and perhaps with typhus. Occasional sequels are acute miliary tuberculosis, pulmonary phthisis, and subcutaneous abscesses. Progressive emaciation and death from inanition have been known to follow; but in many instances, nutrition becomes extremely active after recovery, and the patient attains to a greater weight than ever before. The mental powers in some cases are enfeebled for a considerable period.

CHAPTER II.

CONTINUED FEVERS—(Continued.)

Typhoid Fever, Continued—Causation—Diagnosis—Prognosis. Typhus Fever—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis.

THE anatomical characters and clinical history of typhoid fever have been considered in the preceding chapter, and it remains to consider the causation, diagnosis, and prognosis of this disease before entering on the consideration of typhus fever.

Causation.—Typhoid fever is not restricted within any geographical limits; it is endemic in every quarter of the globe. It prevails, however, often within circumscribed districts, and not infrequently does not extend beyond a few houses, or even a single house. In certain of the so-called malarial districts it is not observed, as distinct from remittent fever; but there is reason to believe that, in these districts, it is obscured by being

blended with periodical fever. It is certain that in some situations in this country, well-marked cases of typhoid fever were hardly known so long as malarial fevers were rife, but the former became the common form of fever after intermittent and remittent fevers ceased to prevail. As regards the seasons of the year, it shows a decided predilection for the autumn. Of 45 cases analyzed with reference to this point, 16 were in October, 9 in November, and 12 in December. It is stated that a warm dry summer favors the occurrence of the disease in the following autumn. According to Buhl and Pettenkofer, the disease prevails in Munich when the level of the ground water is low, and the prevalence has been observed to end when the level of the water has been raised by abundant rain.

A decided predisposing influence pertains to age. The susceptibility is greatest between the ages of 15 and 25; next between 10 and 15, and next from 25 to 30. It is rare in infancy but not infrequent in childhood. A considerable proportion of the cases of so-called infantile remittent fever are cases of typhoid fever. The susceptibility is small after 50 and still smaller after 60. I have, however, met with a considerable number of cases in persons over 50, and several cases in persons over 60.

Both sexes appear to be about equally liable to the disease. It was observed by Louis to occur especially among persons who had resided for a short period only in Paris. It has been observed to prevail among recent residents in other cities. A rational explanation of this fact is that the older residents have acquired an insusceptibility to the infection, as persons by use are able to tolerate certain drugs in enormous doses. Generally patients are in good health when attacked; other diseases do not seem to predispose to it. No causative influences relating to social position, occupation, or habits of life, have been ascertained. Phthisis, pregnancy, and lactation seem to be protective against the disease.

Typhoid fever is communicable, but rarely, if ever, in the same way as contagious diseases like typhus, smallpox, scarlet fever, measles, and relapsing fever. Emanations from the bodies of those affected with the disease do not, as a rule, infect the surrounding atmosphere; hence, in hospital wards, the disease is not diffused by typhoid cases among patients affected with other diseases. Physicians, nurses, and members of families brought into close proximity to cases, seldom, and perhaps never, contract it in consequence thereof. Nevertheless, the causative germs are produced within the bodies of typhoid patients. It is logically certain that these germs are expelled from the body with the intestinal dejections. It is probable that, when expelled, they are not at once capable of producing the disease. They become infecting agents after certain modifications or developments have taken place under conditions which pertain to decomposing human excrement. Having acquired the capability of infection, they may gain access into the system by being contained in drinking water, or by being present in the atmosphere. Whether or not the disease is ever communicated by means of emanations from the body, that is, whether the breath or exhalations from the skin of typhoid patients contain a contagium, is an open question. It is certain that the disease is rarely communicated thereby.[1]

The communicability of typhoid fever is proven by instances in which persons, having contracted the disease in one locality, go to another in which the disease was not prevailing, and, of the residents in the latter, a greater or less number become affected. Many instances of this kind have been

[1] For evidence in behalf of the affirmative answer to this question, *vide* "Uber Entstehung und Verbreitung des Abdominaltyphus," von A. Biermer, Volkmann's Sammlung klinischer Vörtrage, No. 53; also, Jenner, in Trans. Clin. Society of London, vol. viii.

reported,[1] but the most remarkable instance on record came under my observation in a little settlement called North Boston, consisting of nine families, all being within an area of a hundred rods in diameter. The few houses in which the disease occurred were closely grouped together around a tavern, the house furthest removed from the tavern being only ten rods distant. A stranger from New England, travelling in a stage-coach which passed through this settlement, had been ill for several days, and on arriving at this stopping-place was unable to proceed further. He remained at the tavern, and, after a few days, died. He was seen by several physicians of the vicinity, and there can be no doubt that his disease was the same as that with which others were subsequently affected. Up to this time typhoid fever had never been known in that neighborhood. Members of the family of the tavern-keeper were the first to become affected, the first case occurring twenty-three days after the arrival of the stranger. Other cases speedily occurred in the surrounding families. In a month, more than one-half the population, numbering 43, had been affected, and ten had died. The disease was undoubtedly typhoid fever. Visiting this settlement during the prevalence of the disease, and recording the symptoms of several cases then in progress, the clinical histories furnished abundant evidence of the nature of the disease. Moreover, I made an examination of the body of one of those who had died with the disease, and found the Peyerian patches ulcerated and the mesenteric glands greatly enlarged.[2]

Instances like the foregoing establish the communicability of the disease. Other facts relating to the North Boston epidemic go to establish more than this, namely, the diffusion of the disease by means of drinking water. Of the several families living in close proximity to the tavern, one family escaped. The members of this family (named Stearns) had no intercourse with the family of the tavern-keeper, and very little with the other families, all of whom were tenants of the latter. This was in consequence of a quarrel between Stearns and the tavern-keeper. The tavern-keeper had refused to the family of Stearns the use of a well which was used in common by the other families, so that Stearns was obliged to dig a well for the use of his family. The occurrence of the disease produced much excitement in the neighborhood, and Stearns was accused of having poisoned the well in revenge for having been denied its use. These facts point to the well as the source of the infection, although an examination of the water revealed no impurity. The examination, however, had reference only to the presence of a mineral poison of some kind.

This epidemic came under my observation as long ago as 1843. An account of it was published with reference to the proof of communicability, at that time a mooted point. I supposed the disease to have been communicated by personal intercourse with the patients, and I attributed the exemption of the family of Stearns to non-intercourse with the other families. Had the water of the common well been considered as the vehicle of the infection, either by myself or by any of the readers of the published account of the epidemic, the subsequent important discovery of Budd would have been anticipated. Within a few years I have learned from a physician residing, at the time of the epidemic, in the neighborhood, that a privy used in common was in close proximity to the well.

A few years since, the prevalence of the disease within a certain district in London was traced to the milk supply from a dairy farm on which cases

[1] *Vide* Murchison, on the Continued Fevers of Great Britain.

[2] For fuller details, *vide* Clinical Reports on Continued Fever, etc., 1852, and American Journal of the Medical Sciences, July, 1845.

of typhoid fever had occurred. The vehicle of the infection here was the water used in cleansing the cans, or, perhaps, in diluting the milk. The disease has also been traced to ice added in summer to drinking water.

The infection may be conveyed, not only by water polluted with human excrement, but by emanations from sewers, cesspools, drains, and waste-pipes. These must be the chief sources in New York, the water supply being from a river fifty miles distant. Murchison cites several striking outbreaks of typhoid fever attributable to obstructed drains or cesspools, as well as from drinking water tainted with sewage. Reports of many outbreaks in hotels, colleges, schools, and private houses are to be found in the medical literature of this country. At the time of writing, a college in the neighborhood of New York has temporarily disbanded in consequence of an outbreak distinctly referable to water polluted from an adjacent cesspool, and to emanations from unventilated pipes leading to the dormitories of the students. The following is a striking instance of an outbreak limited to a single household:—

Mr. C. spent the summer at his country-house, leaving his house in the city in charge of two persons. He returned, with his family, to town in the middle of September. After his return, five of his children within a few days fell ill, and the disease proved to be typhoid fever. A nephew who left town shortly after the return of the family was taken ill after leaving, and had typhoid fever. A child was ill for a few days with vomiting and fever, but the disease in this case did not prove to be typhoid fever. With the exception of the person last referred to, every member of the family, except the parents, had typhoid fever. All were attacked within a few days. All recovered except one, who had profuse hemorrhage from the bowels. The ages of the patients were between 7 and 22 years. On examination of the premises, the waste-pipe in the cellar was found to be defective, and at times a bad odor from it had been perceived. The house had been shut up during the summer. The disease was not prevailing in the neighborhood.

The agency of emanations from drains, cesspools, and privies, and of water thereby polluted, enforces the importance of measures of prophylaxis, consisting of effective sewerage, providing against obstructions of house-drains, preventing leakage from these and cesspools, taking care that the trapping of hand-basins, sinks, and water-closets is complete, and the speedy removal of the excreta of patients affected with the disease.

It is assumed in the foregoing remarks that water or air polluted with human excrement contains germs derived from the dejections of patients affected with typhoid fever. The infecting agents are these germs. Without these, no matter how offensive the polluted water or air, typhoid fever is never produced. Now, are the germs which produce the disease always derived from the dejections of typhoid patients? According to Budd and others, the answer is affirmative. In the present state of knowledge, however, the correctness of this answer cannot be considered as established. It is difficult to reconcile therewith instances of outbreaks in situations where, previously, cases of typhoid fever had not been known to have occurred. Such instances are not infrequent. It is to be considered that in mild cases of typhoid fever, and cases without the usual diagnostic symptoms, the disease may not be recognized. Moreover, it is true of diseases which are regarded as always involving a contagium, for example, smallpox, that they occur sometimes in situations in which it is impossible to trace a connection with previous cases. Whether the production of the causative germs is ever independent of the disease, is not settled; in other words, it is an unsettled question whether the disease be ever produced irrespective of communicability.

The length of time that the typhoid germs retain their vitality or infecting power is a point of interest and importance. Facts have shown that they may retain their life and activity for, at least, two years.[1]

The interval from the introduction of the germs and the first manifestation of disease, or the period of incubation, is usually about two weeks. The duration is longer than this in some instances, but, probably, never several months, as has been supposed. On the other hand, the duration sometimes does not exceed one or two days.[2] This disease is one of those which are very rarely experienced twice; a person who has had the disease, as a rule, is thereafter unaffected by the special cause. As already stated, however, a relapse sometimes occurs shortly after the date of convalescence.

Diagnosis.—Typhoid fever is to be discriminated from other essential fevers, more especially typhus, remittent, and typho-malarial fever. The differential diagnosis cannot be fully considered without anticipating the diagnostic events which belong to the clinical history of these fevers. The discrimination is to be made by ascertaining the presence of more or less of the events which are diagnostic of typhoid fever, and the absence of events diagnostic of other fevers. The points in the clinical history which are distinctive of typhoid fever are as follows: the gradual development, the absence of marked remissions, the abdominal symptoms, namely, diarrhœa with ochre-colored dejections, tympanites, tenderness in the iliac regions, and gurgling; the occurrence of epistaxis and the characteristic eruption. As regards the eruption, a fact important to be borne in mind is, that rose-colored papules, like those belonging to the history of typhoid fever, are sometimes found in other affections. Other points to be taken into account are, the autumnal season, and the youth of the patient. The foregoing points, taken in connection with the absence of features distinctive of other fevers, generally render the diagnosis easy, after a certain duration of the disease. In typho-malarial fever, as will be seen, the symptomatic phenomena of typhoid and malarial fever are commingled in variable relative proportions in different cases.

Local affections with which typhoid fever may be confounded are, meningitis, bronchitis, pneumonitis, acute tuberculosis, and enteritis.

Acute meningitis, as distinguished from typhoid fever, is characterized by more intense cephalalgia, by intolerance of light and sounds, early and active delirium, frequently by vomiting as a prominent symptom, and somnolency and coma succeeding the delirium. There is generally constipation; the abdomen is not tympanitic, but frequently depressed, and iliac tenderness is wanting. This differential diagnosis is required chiefly in children.

Subacute bronchitis is an element of typhoid fever. If the bronchitis be unusually prominent and the fever unusually mild, the latter may be overlooked and the disease considered a primary bronchitis. This error can only happen in the early part of the fever; the duration and progressive increase of the disease, together with the characteristic events of the fever, will lead to a correction of the diagnosis. If the bronchitis be capillary, owing to the predominance of the pulmonary symptoms, this may be supposed to be the primary and sole disease. An instance has fallen under my observation; but capillary bronchitis, as a complication, is extremely rare.

Typhoid fever may be confounded with pneumonitis, when the latter exists as a complication. The existence of pneumonitis is shown by its physical signs. The differential diagnosis is to be based on facts which show the existence of fever prior to the occurrence of the pneumonitis, and on the

[1] *Vide* article by Alison, in Archives Générales de Médecine, Jan. 1880.
[2] *Vide* Murchison in St. Thomas's Hospital Reports, vol. ii.

events characteristic of typhoid fever, namely, the abdominal symptoms and eruption. Cases of primary pneumonitis, in which the existence of typhoid fever may be suspected, are cases of so-called typhoid pneumonitis, that is, pneumonitis with phenomena denoting the typhoid state, namely, low delirium, prostration, subsultus tendinum, etc.

Acute miliary tuberculosis has not infrequently been mistaken for typhoid fever. The former is to be discriminated by the notable frequency of respirations, the prominence of the cough, the occurrence of hæmoptysis in some cases, the abundance of subcrepitant râles, by marked lividity in some cases, and by the absence of the abdominal and other characteristic events of typhoid fever.

Typhoid fever may be considered as primary enteritis when the abdominal symptoms are unusually prominent from the beginning. The liability to this error is chiefly in children. Events, other than the abdominal symptoms, belonging to the history of typhoid fever, are to be sought after. Some of these are not as readily appreciated in children as in adults, especially those relating to the mind, and the eruption is oftener wanting. Hence, typhoid fever in children is not infrequently called enteritis. With due care in tracing the development and progress of the disease, this error of diagnosis should generally be avoided.

It is evident that familiarity with the phenomena and laws of typhoid fever and of the diseases with which it is liable to be confounded, namely, other fevers and the local affections just referred to, is an essential qualification for accuracy in diagnosis. This remark is of general application to diagnosis.

The thermometer may be brought to bear upon the diagnosis of this disease at an early period, before the eruption of other distinctive features is fully declared. A moderate increase of temperature daily for several successive days, with an evening exacerbation, points to typhoid fever, as contrasted with typhus, periodical, relapsing, or an eruptive fever, assuming the disease to be an essential fever and not an inflammatory disease. Various circumstances, however, may occasion deviation from this gradual increment of fever in typical, uncomplicated cases.

In some cases the disease may be overlooked in consequence of the phenomena being imperfectly developed. These cases were called by Louis cases of "latent typhoid fever." They are called by German writers cases of "*typhus ambulatorius;*" and the term "walking cases" is in use in this country. The patients do not take to the bed, and perhaps they continue their usual avocations. They complain only of debility, loss of appetite, and mild diarrhœa. Under these circumstances, death sometimes takes place from intestinal perforation, profuse hemorrhage, or some grave complication, and, on post-mortem examination, the characteristic typhoid lesions of the intestine are found. The only explanation of these cases to be given is that the effects of the special cause are concentrated on the glandular elements of the small intestine.

PROGNOSIS.—Of 18,612 cases aggregated by Murchison, occurring at the London Fever Hospital in 14 years, Guy's Hospital, St. Thomas's Hospital, and King's Hospital, of London, at Strasbourg, Paris, and the provinces of France, and the Infirmary at Glasgow, the mortality was 18.62 per cent., or 1 in 5.4. The separate collections of cases which make up the above aggregate show a variation in mortality between 16 and 32 per cent. Excluding 190 cases at Strasbourg, in which the mortality was 23 per cent., and 147 cases at Paris, giving a mortality of 32 per cent., the variation in the remaining collections was between 16 and a fraction over 20 per cent. Of 303 cases received in the Massachusetts General Hospital, and analyzed by James Jackson, 42 were fatal, being 1 in about 7 cases, or a fraction under 13 per

cent. Of the 73 cases which I have analyzed, 18 were fatal, nearly 1 in 4, or about 24 per cent.

These facts show much variation in the death-rate in different collections of cases occurring at different places and periods. That the variation is often considerable at different seasons in the same place, and under similar circumstances as regards surroundings and treatment, is shown by the ratio of deaths in successive years in the Massachusetts General Hospital.[1] In 1828, of 22 cases, 2 died; in 1829, of 25 cases, 1 died; in 1830, of 14 cases, 4 died; in 1831, of 29 cases, 2 died; in 1832, of 23 cases, 4 died; in 1833, of 37 cases, 6 died; in 1834, of 34 cases, 6 died; and in 1835, of 35 cases, 6 died. It is evident that there are wide differences in the intrinsic tendency of the disease to a fatal issue at different periods and places—a fact to be considered in estimating the influence of therapeutical measures.

As regards age, Murchison's statistics show the lowest rate of mortality to be from 10 to 15 years, and the next lowest from 5 to 10 years; the number of cases analyzed under 5 years being insignificant. The highest rate under 55 years is from 30 to 35 years. Jackson's statistics show the death-rate to be greater above than below 30 years of age; and they show a greater mortality in the cold than in the warm months. It is a matter of common observation that vigorous persons are more likely to succumb than those of feeble constitution.

A fatal result in a considerable proportion of cases is attributable to complications or accidents such as pneumonitis, peritonitis, and hemorrhage. Pre-existing disease may lead to a fatal result—for example, chronic disease of the kidneys. Unusual severity of the abdominal lesions is sometimes the cause of death. In the great majority of fatal cases the mode of dying is by asthenia. Apnœa is combined with asthenia in the cases in which sudden coma precedes death.

Coma and convulsions, probably uræmic in most cases, render the prognosis extremely unfavorable. Other marked ataxic symptoms, such as carphologia, subsultus, etc., are ominous. Cases characterized by active persistent delirium usually end fatally. The prognosis is unfavorable whenever the pulse becomes extremely frequent and feeble, and the first sound of the heart is notably weakened. The immediate cause of death in these, as in all cases in which the mode of dying is by slow asthenia, is the giving way of the power of the heart's action. Great prostration is evidence of much danger. In cases of pregnancy, abortion generally takes place, and death follows. The chances of recovery may be good, notwithstanding the occurrence of pneumonitis limited to one lobe. Intestinal hemorrhage is less serious than has been supposed by some; recovery takes place in the majority of the cases in which this event occurs. Death may be caused by gangrene or bed-sores in parts exposed to continued pressure from the weight of the body. An increase of the axillary temperature above 105° denotes great danger; a temperature of 106°, or 107°, or upward, is a fatal prognostic. On the other hand, a considerable decrease of temperature below the minimum of health is ominous. In general, after the few first days of the disease, the temperature having daily increased up to this time, the heat as shown by the thermometer varies in the morning from 102° to 103°, and in the evening from 103° to 105°.

A favorable prognosis may be entertained so long as ataxic symptoms are not marked, the adynamia not great, the pulse not very frequent or feeble, and there are no serious complications; but, under these circumstances, the prognosis should always be guarded, in view of the liability at any period of

[1] Report on Typhoid Fever, by James Jackson, M.D.

the disease to serious complications or accidents. It is to be borne in mind that sudden coma and perforation of intestine are not less liable to occur in mild than in severe cases. The liability to perforation during convalescence is to be recollected. On the other hand, recovery may be hoped for in cases in which the symptoms denote the utmost gravity.

Typhus Fever.

The fever called typhus, known from the earliest antiquity, has received a great variety of names. The name typhus, introduced by Sauvages in 1759, and now generally adopted by writers of all countries, has the negative merit of not involving any hypothesis concerning the nature and seat of the disease. Derived from τυφος, denoting stupor, it relates to a feature which is usually more or less prominent in this disease. In this country, from the fact that the disease is imported in vessels bringing emigrants from Ireland, it has been commonly known as *ship fever*.

This fever has many features in common with typhoid fever. The identity or non-identity of the two affections has been, heretofore, a mooted question. They present points of contrast amply sufficient to show that they are distinct diseases. In considering typhus it will suffice to present the traits by which it is distinguished from typhoid fever.

Anatomical Characters.—In typhus, the abdominal lesions which are characteristic of typhoid fever are wanting. The Peyerian and solitary glands of the small intestine are either unaffected or they are simply more conspicuous than usual, sometimes presenting numerous black points, giving rise to what has been called the *shaven-beard appearance*. The mesenteric glands are not infiltrated as in typhoid fever, and are generally healthy.

The disease has no known special anatomical characters; that is, there are no lesions peculiar to the disease and constantly present. Morbid appearances in different parts are frequently found after death, but they are due to complications, or are such as belong to infectious diseases in general.

The spleen is frequently enlarged and softened; the heart is often flabby and softened. The blood in the heart and large vessels is unnaturally dark and fluid; coagula, if they exist at all, are dark and soft. Hypostatic congestion of the lungs and pulmonary œdema are more frequent than in typhoid fever. Slight extravasation of blood into the arachnoid cavity occurs in a small proportion of cases. Cerebral congestion and effusion of serum into the ventricles of the brain, the subarachnoid space, and the arachnoid cavity, are not uncommon, but they are usually unattended by inflammatory exudation. Meningitis is a rare complication. The same parenchymatous degenerations which are present in typhoid fever may also occur in typhus. The kidneys are apt to be congested; they are sometimes enlarged, and may present the appearances of an acute nephritis. Nephritis is much more common in typhus than in typhoid fever. The granular and waxy changes in fibres of voluntary muscles, noticed as occurring in typhoid fever, have also been observed in typhus.

Clinical History.—The duration of the access is shorter than in typhoid fever, and cases of an abrupt invasion are not as rare. Patients in the great majority of cases take to the bed on the second or third day after the first manifestation of illness. The symptoms during the development of the disease are essentially the same as in typhoid fever, with this important difference, namely, the abdominal symptoms of typhoid fever—diarrhœa, meteorism, iliac tenderness, and gurgling—are wanting.

Countenance, and General Aspect.—Capillary congestion of the face, extremities, and trunk, is more marked in typhus than in typhoid fever. It gives to the surface, especially of the face, a dusky or dingy hue so distinctive of typhus as compared with typhoid fever, that even nurses and attendants, after becoming conversant with the two diseases, learn to discriminate them by the physiognomy. The conjunctiva is more frequently and more deeply congested. A besotted or expressionless countenance is earlier and more strongly marked.

Nervous System.—The symptoms referable to the nervous system which belong to the clinical history of typhoid fever, occur in typhus. Coma-vigil and typho-mania are observed in a larger proportion of cases of typhus, they are oftener present in a marked degree, and they occur earlier in the career of the disease. Other ataxic symptoms, such as subsultus and carphologia, are of more frequent occurrence. Prostration is apt to be more marked and earlier manifested. Persistent active delirium, in my experience, has occurred oftener in typhoid than in typhus fever. Contraction of the pupil often accompanies delirium or stupor, and is sometimes extremely marked, called by Graves the *pin-hole* pupil. I have observed oscillations of the eyeballs, occurring in a marked degree, the movements being lateral and notably rapid. The oscillations occurred whenever the patient was raised. The cases ended fatally. Coma and convulsions occurring in typhus, as in typhoid, fever, are generally attributable to uræmia. Hyperæsthesia of the surface, even when the mental perception is notably blunted, is sometimes manifested.

Digestive System.—The tongue, more frequently than in typhoid fever, becomes covered with a thick, brown, or black coating. It is less frequently reddened, glazed, and fissured. It is oftener with difficulty protruded. Sordes occurs more frequently, earlier, and in greater abundance. As regards the abdominal symptoms which are highly diagnostic of typhoid fever, the two diseases present a striking contrast. Diarrhœa very rarely occurs in typhus, and, if present, it is almost invariably slight. The stools have not the ochre color of those in typhoid fever. Tympanites is much oftener wanting, and generally when present, is slight in typhus. This statement applies also to iliac tenderness. Intestinal perforation does not occur in typhus. Hemorrhage from the bowels is one of the rarest of events, exclusive of cases in which dysentery is a complication.

Parotiditis is liable to occur, and the remarks made with reference to this complication in typhoid fever are equally applicable to its occurrence in typhus.

Skin.—A characteristic eruption occurs in a larger proportion of cases of typhus than of typhoid fever. Murchison states that of 3506 cases received at the London Fever Hospital, it was not observed in 403, or a fraction over 11 per cent. Of 65 cases which I have analyzed, it existed in 57. It is oftener wanting in children than in adults. The eruption appears earlier in typhus. The average period from the time of taking to the bed to the first appearance of the eruption is somewhat under three days. The eruption in typhus is much oftener abundant, frequently being copious over the extremities as well as on the trunk, and sometimes appearing on the face.

Other distinctive points relating to the eruption are as follows: It is a maculated, not a papular, eruption. The spots become of a dull, dingy or dark red color, and, after the first two or three days, the redness cannot readily be made to disappear by pressure. In some cases, in the latter part of the disease, the spots become truly petechial. They are smaller than the papules of typhoid fever. They do not come and go like the rose papules of typhoid; they all appear in the course of three or four days, and remain

during the greater part or whole of the disease, sometimes even continuing into convalescence. They are often apparent after death.

The copiousness of the typhus eruption represents generally a corresponding gravity of disease. This statement does not hold good with respect to the eruption in typhoid fever.

In a certain proportion of cases of typhus, intermingled with the characteristic *maculæ* are more or less of the rose papules which are characteristic of typhoid fever.

Petechiæ are observed in some cases of typhus, as in cases of typhoid fever, as well as in various other diseases. As already stated, the characteristic typhus-spots sometimes become petechial. The eruption of typhus is sometimes called a petechial eruption. This is incorrect. *Petechiæ* are spots caused by minute extravasations of blood, that is, they are ecchymoses, and these are not distinctive of typhus. Vibices are occasionally observed in cases of typhus. Sudamina or miliary vesicles occur in cases of typhus as well as of typhoid fever.

The statements with respect to sweating and moisture of the skin in typhoid, are also applicable to typhus fever.

The odor from typhus patients is stated to be characteristic. I have met with persons who declared that they were able to discriminate cases of typhus from typhoid fever by the sense of smell. I can bear testimony to an offensive odor emanating from patients affected with either disease, but I have not been able to appreciate its value as a diagnostic symptom.

Erysipelas sometimes occurs in typhus as in typhoid fever. Bed-sores are less liable to occur in consequence of the shorter duration of typhus. Spontaneous gangrene, not produced by pressure, is an occasional event. I have seen a case in which gangrene of both feet took place. The nose, penis, and scrotum have been known to slough away. Ulceration or sloughing of the cornea has been observed. The affection known as *noma* is another serious complication occurring sometimes, not only in children, but in adults. These complications occur in hospitals among patients who, prior to the disease, were suffering from innutrition.

Respiratory System.—The account of symptoms referable to the respiratory system in typhoid fever, is mainly applicable to typhus. The significance of a spasmodic inspiration occurring without any pulmonary complication, is the same in the latter as in the former disease. Cough from bronchitis is apt to be more prominent than in typhoid fever. Pseudo-pneumonitis, that is, hypostatic congestion and œdema, are more frequent, whereas true pneumonitis appears to be less frequent than in typhoid fever. Epistaxis occurs less frequently. It appears to be established that the expired breath contains more ammonia than in health.

Circulation and Temperature.—The average frequency of the pulse in cases of typhus is greater than in typhoid fever. The significance of frequency and other characters of the pulse, and of weakness or absence of the first sound of the heart over the apex, as representing the state of the vital forces, is not less in typhus than in typhoid fever.

The temperature of the body, as determined by the thermometer, is more or less increased, varying from 102° to 107° Fahr. The increase of temperature corresponds to the intensity of the disease. A decline of temperature is coincident with the occurrence of convalescence. The defervescence in some cases is notably rapid, but in other cases gradual. At the time of convalescence the temperature frequently falls below the standard of health. As in typhoid fever, and in other essential fevers, a sudden and considerable rise of temperature renders probable some inflammatory complication; and, on the other hand, a sudden fall of temperature below the

average range of health denotes a serious change for the worse. As a rule, the increase of temperature daily is progressive from the commencement of the disease to about the fifth day, and the daily oscillations of the morning and evening temperature are not observed prior to this period. An analysis of 58 cases ending in recovery, by Dr. Maclagan, gave, as the average temperature in the morning, a fraction over 102°, and in the evening a fraction over 103° Fahr. The highest point reached in any of these cases was a fraction over 105°. In typhus, as in other fevers, a fall of temperature not infrequently denotes approaching convalescence, prior to any appreciable improvement in the pulse and other symptoms.

Urine.—The urea and uric acid are generally increased as in cases of typhoid fever. According to Murchison, the chlorides are greatly diminished or disappear entirely.

Albuminuria is of more frequent occurrence in typhus than in typhoid fever. Murchison found it in 20 of 28 cases, or a fraction over 71 per cent. In about one-half of the cases the amount of albumen was considerable. In most of the latter cases there was no evidence of pre-existing renal disease. In typhus, as in typhoid, fever, the early appearance of albumen in the urine, its abundance and duration, denote gravity of disease. Epithelial and blood-casts are sometimes observed.

The duration of typhus is less than that of typhoid fever. Of 53 uncomplicated cases ending in recovery, analyzed by Murchison, the duration varied between 8 and 20 days, the mean duration being a fraction over 14 days. The mean duration in 10 fatal cases was 15 days. Of 45 cases ending in recovery which I have analyzed, the maximum duration was 26 and the minimum 9 days, the mean being 14 days. The mean duration in 9 fatal cases was 10 days. In my cases the commencement of the disease was reckoned from the time of taking to the bed.

Relapses of typhus are extremely rare. Examples of this fever having been experienced more than once are also very infrequent. There are no special sequels, and, in the great majority of cases, the health is excellent after recovery. Temporary loss of the hair is a common consequence of both typhoid and typhus fever. Mental imbecility sometimes remains for a certain period after the general condition of the body denotes recovery.

Typhus fever is sometimes associated with dysentery. Typhus and variola have been known to be combined. Probably typhus and typhoid fever may co-exist.

Causation.—The contagiousness of typhus is shown by the occurrence of successive cases in particular houses and neighborhoods, by the number who are attacked of persons brought into contact with typhus patients, especially in hospitals, either as physicians, attendants, or fellow-patients, and by the importation of the disease in localities where it did not previously exist. Referring the reader to works on fever for the further evidence of the contagiousness of typhus, I shall subjoin some illustrative facts falling within my own knowledge.

In 1850, '51, and '52 I was engaged in the clinical study of typhus and typhoid fever in the Buffalo Hospital of the Sisters of Charity. I recorded during these years sixty-five cases of typhus. Twelve Sisters of Charity were assigned to this hospital during the period just named. Of these twelve Sisters, five contracted typhus fever. These five Sisters alone had charge of the fever patients; the remaining seven Sisters, performing other duties, were not brought into contact with the fever patients. Thus, every Sister who nursed fever cases had an attack of the disease. During the last of these years, eleven patients, admitted for other affections, contracted the disease,

the number of cases of typhus received during this year being considerably larger than during the two preceding years.

Typhus fever began to prevail in certain parts of the city of New York, as an epidemic, in 1861, the disease having been imported from Ireland. From Jan. 1, 1861, to Nov. 1, 1864, 1428 cases were admitted into Bellevue Hospital, over 500 cases having been received during the six months preceding Nov. 1, 1864. Of 22 members of the house staff during the time above stated, 15 contracted the fever. Of persons employed in the hospitals as orderlies, watchers, etc., 16 were attacked with fever. From June, 1863, to June, 1864, 26 patients, admitted into the hospital for various affections, contracted the fever. In May, 1864, the fever patients were transferred to tents, and no new cases were received. There was subsequently no development of the disease in the hospital.

The infectious miasm emanating from typhus patients rarely communicates the disease except to those who are in immediate proximity to patients. Concentration of the miasm is generally necessary. Hence, the disease is apt to be contracted by those who render personal attentions to patients, and especially by those who are exposed to the atmosphere of ill-ventilated feverwards containing a large number of cases. A single patient in a spacious, well-ventilated apartment, seldom communicates the disease. All persons at all times, moreover, are not equally susceptible, and, hence, some contract the disease after comparatively slight exposure, while others who are much exposed escape. There is no proof that the disease is diffused from one house to another, or from hospitals to adjoining houses, except by intercommunication. Facts show that the disease may be communicated by fomites; but a considerable impregnation of articles of clothing, etc., is necessary. Exposure of infected clothing to a dry heat of 200° Fahr., probably destroys the miasm. Some facts appear to show that the disease may be contracted by dissecting bodies dead with typhus; but this is not certain. The period of the disease in which it is most apt to be communicated is after the first week. Facts appear to show that it may be communicated during convalescence.

The fact that in the emanations from the bodies of patients a contagium exists, capable at once, that is, without modifications or further development, of producing the disease, is distinctive of typhus as contrasted with typhoid fever. There is no reason for supposing that the infecting capability of the typhus germs depends on any changes taking place after they are thrown off from the body.

There is considerable variation in the estimation by different observers, of the period of incubation. Probably this period varies considerably in different cases. Murchison has determined the average period to be about twelve days. Exceptionally it is longer than this, but it rarely, if ever, exceeds three weeks. On the other hand, in many cases it is less than twelve days, and occasionally the symptoms commence almost at the instant of exposure.[1] Persons have sometimes had an impression that they received the poison at a particular moment when they were conscious of a peculiar sickening odor inhaled from the body of a typhus patient. Little or no reliance is to be placed on this impression as evidence of the reception of the infection. Probably physicians have very many times experienced this sickening odor without having had typhus. Such has been repeatedly my experience.

As a rule, in this country, typhus fever is an imported disease and diffused exclusively by contagion. It is, however, difficult to trace all outbreaks of the disease to contagion, and, hence, the opinion is held by some that the special cause is sometimes produced outside of the body. The disease some-

[1] *Vide* St. Thomas's Hospital Reports, vol. ii.

times appears to be developed as a consequence of overcrowding and deficient ventilation; in other words, the concentrated emanations from the bodies of healthy persons apparently suffice for the generation of typhus germs.[1] Outbreaks in jails, hospitals, workhouses, ships, and unventilated tenement houses crammed with occupants, are thus accounted for in some instances irrespective of contagion.

In 1841 I reported four cases of typhus developed in the Erie County almshouse. They occurred during the winter months. The wards in this institution were quite small and crowded, and, for the sake of warmth, fireplaces, which had previously been used, had been bricked up and close stoves substituted. There was an abundant eruption in all these cases, and an examination after death, in the only case which proved fatal, showed the absence of the typhoid lesions. These cases seemed fairly attributable to overcrowding and want of ventilation.[2] No cases of typhus occurred out of the almshouse, and the disease was not imported.

Overcrowding, deficient ventilation, especially if conjoined with innutrition, are powerful auxiliary causes acting in conjunction with contagion. The causative influence of destitution and starvation is strikingly shown by the prevalence of typhus in Ireland in periods of famine, and by the large proportion of cases, among those received in hospitals, in which the deprivations and hardships of poverty have been experienced prior to the attack of fever.

Typhus attacks the two sexes in about an equal proportion. Persons are more liable to be attacked after adult age, but children are not exempt, and this fever does not, like typhoid, spare those who are beyond the middle period of life. It is more likely to prevail in the winter and spring months than in autumn, in this respect differing from typhoid fever.

Diagnosis.—The remarks on the discrimination of typhoid fever from remittent fever and several local affections will apply to typhus fever (*vide* page 964). The discrimination of typhoid and typhus fever is to be here noticed. The following are the more important points in this differential diagnosis: The relatively long duration of the forming stage in typhoid, and its short duration in typhus. Absence, in typhus, of the characteristic abdominal symptoms of typhoid, namely, diarrhœa, meteorism, iliac tenderness and gurgling, or their presence in comparatively a slight degree. The dusky or dingy hue of the surface in typhus. The appearance of the eruption earlier in typhus. The different characters of the eruption, namely, in typhoid, papular, rose-colored, the redness disappearing on pressure; in typhus, after two or three days, if not at first, maculated, the color dark red, and the redness not disappearing on pressure. Other distinctive points relate to the eruption, namely, the sparseness in typhoid, and the copiousness in typhus; the frequent extension, in the latter, of the eruption over the extremities; the persistence of the spots in typhus, and the disappearance of papules with the production of fresh papules in typhoid. It is to be borne in mind that in some cases of typhus, rose papules are intermingled with the characteristic *maculæ*. In typhoid fever the temperature reaches its acme at a later period than in typhus. The rise of temperature is more gradual and regular in typhoid than in typhus.

Corroborative diagnostic points are, the occurrence of peritonitis and hemorrhage from the bowels in some cases of typhoid, and the earlier occurrence of delirium, coma-vigil, and other ataxic symptoms in typhus.

[1] For facts bearing on this point, *vide* Murchison, *op. cit.*

[2] *Vide* Boston Med. and Surg. Journal, June, 1841.

If the eruption be present, typhus is generally recognized without difficulty. The eruption is not always present, and the diagnosis may then involve delay and difficulty. The prevalence of typhus and exposure to contagion are to be taken into account in doubtful cases.

Prognosis.—Of 18,592 cases aggregated by Murchison, occurring at the London Fever Hospital in 14 years, at King's College Hospital, the Edinburgh Infirmary, and at Glasgow, Scotland, the mortality was 18.78 per cent., or 1 in 5.27. This rate of mortality differs only by a small fraction from the rate in about the same number of cases of typhoid fever. The death-rate is found to vary, at different times and places, between 9 and 25 per cent., the variations being due to differences as regards an intrinsic tendency of the disease to a fatal result. In epidemics of typhus, as of other diseases, it has been often observed that the fatality is greatest at first, and decreases as the number of cases diminish. The ratio of fatality is greater among males than females. The fatality is less in early life than subsequently. It is greater under 10 years of age than between 10 and 20 years. After 30 years the fatality progressively increases, and after 50 years the proportion of deaths is nearly one-half.

Of the 63 cases which I have analyzed, 12 were fatal, that is, 1 in a fraction over 5, or a fraction over 18 per cent.

A fatal result is oftener due to the intensity of the fever, that is, occurring irrespective of complications, in typhus than in typhoid fever. Peritonitis, which destroys a certain proportion of patients with typhoid fever, does not occur in typhus. This is true, also, with respect to intestinal hemorrhage. Pneumonitis is less frequent in typhus, and there are no complications peculiar to the latter. Acute diffuse nephritis attended by uræmic symptoms, is more liable to occur in typhus than in typhoid fever. A fatal result appears to be oftener attributable to feebleness of constitution, or to causes which impair the power of resisting the disease, in typhus than in typhoid fever. Of 38 cases which occurred among the members of the resident medical staff and persons employed in Bellevue Hospital, 17 ended fatally, whereas, of 1428 patients admitted with fever during the same period, the number of deaths was 243, or 1 in 5.87. This difference in the mortality in the two classes of cases is the more remarkable because the resident physicians and persons employed in the hospital were treated for the disease under more favorable circumstances than the hospital patients. It is difficult to account for the greater fatality among the former class, except by supposing that living in the hospital involved exposure to nosocomial depressing influences which rendered the system less able to resist the disease.

In general, the symptoms pointing, on the one hand, to a favorable, and, on the other hand, to an unfavorable, prognosis, are the same in both typhoid and typhus fever.

CHAPTER III.

CONTINUED FEVERS—(Concluded.)

Treatment of Typhus and Typhoid Fever. Relapsing Fever—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Erysipelatous Fever. Epidemic Fever characterized by mild Erythematic Pharyngitis.

THE general principles of treatment in typhoid and typhus fever are essentially similar, and, indeed, are applicable to all the fevers. It will suffice to notice, incidentally, indications pertaining exclusively either to typhus or typhoid fever, without considering the treatment of each fever separately.

It must be admitted that the known resources of therapeutics do not afford reliable means for the arrest of these fevers, nor even for shortening the duration of the febrile career. Quinia, so potential in arresting malarial fevers, has no abortive potency in the continued fevers. Emetics were thought by James Jackson to be sometimes successful either in arresting or affecting favorably the progress of typhoid fever. This was the opinion of Trousseau, and it is held by Chambers, of London. Calomel, in doses of from ten to fifteen grains repeated daily for several days, has been recommended by Niemeyer, Liebermeister, and other German writers, as shortening the course of typhoid fever, diminishing the mortality, and sometimes causing the disease to abort. Iodine, or the iodide of potassium, has been thought to have a special influence over this fever. Liebermeister states that the iodide of potassium, in doses of a scruple to a drachm daily, given in more than two hundred cases, while it produced no appreciable effect upon any of the febrile phenomena, apparently diminished the rate of mortality. That the mineral acids, namely, the dilute phosphoric, hydrochloric, nitric, and nitro-hydrochloric, have a favorable modifying influence upon the disease there is abundant testimony. In 1863 and 1864 I instituted a comparison in the male fever-wards at Bellevue Hospital of the rate of mortality during six months without, and the same period with, the use of dilute sulphuric acid, eliminating all cases in which death took place within forty-eight hours after admission. Of 70 cases treated from Jan. 1 to July 1, 1863, without acid, the death-rate was 20 per cent.; of 78 cases treated with acid from July 1, 1863, to January 1, 1864, the death-rate was 10.25 per cent. The treatment in the two collections of cases was the same, exclusive of the acid.[1] My observations do not enable me to state which one of the mineral acids is to be preferred. They are generally relished by fever patients, if sufficiently diluted, with the addition of syrup of orange peel or simple syrup, and they may be given, not as a medicine, but as a drink. The death-rate, however, in the cases treated with the acid, was not below that in 307 cases treated by Dr. Cotting, of Boston, without drugs of any kind. The rate in these cases was ten per cent.

Prof. George B. Wood attributed a curative influence to the oil of turpentine in typhoid fever. He supposed the curative influence to be exerted upon the intestinal ulceration. He recommended the remedy as especially useful when the tongue is dry, and the abdominal symptoms marked, in

[1] *Vide* report by Dr. Irving W. Lyon, then one of the House-physicians of Bellevue Hospital, in American Medical Times, Feb. 1864.

doses varying from 5 to 20 minims, in mucilage, repeated every hour or two. The sulphites introduced by Prof. Polli, on theoretical grounds, have not been found to have any special influence. The same is true of carbolic acid and the carbolates.

Of all measures employed for an abortive or a curative effect, no one has in its behalf stronger testimony than that of Currie, a century ago, to the efficacy of water employed after his method of cold affusion. This method consisted in pouring over the naked body several gallons of cold water, provided the skin was hot and dry, and repeating the affusion whenever the febrile heat returned. He affirmed that most cases of fever were cut short if this treatment were resorted to early, and that if this effect were not obtained, the fever rarely ended fatally.

It is not an unreasonable expectation that an antidote or a parasiticide, as effective in typhus and typhoid fever as quinia in malarial fever, may hereafter be discovered, and such a discovery is a proper aim for continued experimental observations.

In the present state of our knowledge, the most important object of treatment with reference, not to arrest nor abridgment of duration, but to severity and danger to life, is the reduction of the body heat. There is ground for the belief that in typhus and typhoid fever, as well as in the other essential fevers, and, indeed, in all diseases in which there is a continued hyperpyrexia, the severity and danger are due directly, in a greater or less degree, to the increased heat of the body. The modern revival of the use of cold water for an antipyretic effect in typhoid fever, is attributable to a publication by E. Brand, in 1861. Bartels, Jürgensen, and Liebermeister are to be named as especially prominent in bringing to the test of clinical experience antipyretic measures of treatment. Foremost among these measures is the use of cold water; but they embrace quinia and other drugs. Liebermeister cites the statistics of the hospital at Kiel, showing a reduction of the death-rate by systematic cold-water treatment, from $15\frac{4}{16}$ to $3\frac{1}{10}$ per cent.; and in the hospital at Basle, comparing the death-rate in 1718 cases of typhoid fever without, and in 1121 cases with, systematic cold-water treatment, in the former it was 27.8 per cent., and in the latter 8.2 per cent. Now, making ample allowance for differences as regards the intrinsic tendency of the disease to death or recovery at different periods, this contrast shows a notable diminution of the mortality as a result of systematic cold-water treatment. I cannot claim to have had a large experience in the employment of water as an antipyretic agent in the treatment of typhoid fever; but my opportunities for observation have been considerable, both in hospital and private practice, and they have afforded to my mind conclusive evidence of the importance of the object of antipyretic treatment, as, also, of the efficacy of water and other measures. To be effective, antipyretic treatment must be carried out systematically and fully. To judge of its effectiveness, if it be not thoroughly tried, is unfair. It is proof of effectiveness that the temperature of the body is maintained at only one or two degrees above the normal maximum.

The method of refrigeration practised by Currie, namely, affusion, has not been revived. The methods now in vogue are the bath, sponging the body, and the wet sheet with sprinkling. The bath is the method chiefly employed by German physicians. This method is objectionable on the score of the inconveniences attending its use, together with the fatigue for the patient, and the excitement which it is apt to occasion. It may be superseded by the other methods. These can be made to secure all the antipyretic effect to be derived from the bath.

Sponging is the simplest method, involving the least inconvenience to the

patient and others. It should be first employed, and in a large proportion of cases it will suffice. Sponging either the whole body at once, or different parts in succession, with water at a temperature not uncomfortable to the patient, for as long a period as it is unattended by discomfort, repeating the measure as often as indicated by a rise of temperature, will generally prove successful. If not conducted by a skilled nurse, it is difficult often to have this method properly carried out, in part, because persons cannot appreciate that so simple a measure can have much potency, and partly from the popular fallacy that there is danger of "taking cold."

The sponging should be resorted to when the axillary temperature is 103°, and that of the rectum 102½°. It should be continued until the temperature in the rectum falls to 100° or 101°, and repeated whenever it again rises. A little wine or spirits should be given if the patient manifest chilliness.

If this method prove ineffective, the wet sheet and sprinkling should be employed. The patient is placed on a cot, wrapped in a wet sheet, without any other covering, and the body sprinkled with cold water at short intervals. For sprinkling a common watering-pot is suitable. This may be continued for half an hour or even longer, according to the effect on the temperature and other symptoms. The thermometer must be introduced into the rectum. This method is to be repeated as often as the temperature rises. The temperature will often be found to fall after the patient has been transferred from the cot to the bed. A cot with arrangements for the drainage of the water is convenient. A sense of chilliness, feebleness of the pulse, and cyanosis contra-indicate the continuance of the sprinkling and are indications for wine or spirit.

The external use of water as an antipyretic agent should be commenced as early in the disease as the thermometer shows the temperature just named. The antipyretic treatment is, of course, indicated the more, the higher the temperature. It should be continued throughout the disease unless contra-indicated by intestinal hemorrhage, menstruation, sweating, feebleness of the heart's action, and, perhaps, pneumonia.

Of drugs which have an antipyretic effect, quinia holds the first rank. It should be given in a full dose, that is, from 20 to 40 grains, before the evening exacerbation. The effect is often a reduction of several degrees of temperature; but in a certain proportion of cases the temperature is but little or not at all affected. Trial should be made of this drug, inasmuch as, if tolerated by the stomach, it is only objectionable on the score of annoyance from cinchonism. It may be given as accessory to the water treatment, and repeated in twenty-four or forty-eight hours.

Other drugs, less effective and reliable, are digitalis, veratrum viride, salicin, and salicylic acid. Trial may be made of these if quinia fail. The veratrum viride and salicylic acid are to be given circumspectly, in order to avoid their toxical effects.

Indications for treatment relate to particular symptoms or events and complications embraced in the clinical history of these fevers.

In the early part of the disease cephalalgia claims palliative measures. This symptom is relieved by ice-water, spirit and water, distilled vinegar, or cologne water freely applied to the head, and, if more efficient measures be required, the cold douche or ice-cap may be employed. As soon as the existence of either typhus or typhoid fever is declared, the hair should be closely cut. This renders the patient more comfortable, and facilitates local applications.

Insomnia is a symptom calling for treatment. To procure sleep is desirable, not only for immediate comfort, but as a means of averting ataxic symptoms. An opiate often proves beneficial. It may procure refreshing sleep

in place of pseudo-somnolence, or coma-vigil. The latter condition, not denoting a tendency to true coma, does not contra-indicate the trial of opium. Other remedies which may be prescribed are hyoscyamus, the bromide of potassium, either separately or in combination.

Delirium, if slight or moderate, does not call for remedies; but if prominent as a symptom, as shown by constant talking and attempts to get out of bed, it leads to other ataxic symptoms and to exhaustion. Opium, in some form, and other anodynes, are indicated. If these fail, the combination of antimony, in small doses, with opium, as recommended by Graves, will often prove efficacious. An eighth or a sixteenth of a grain of the tartrate of antimony and potassa may be given hourly or half-hourly until the patient becomes quiet, unless nausea or vomiting occur, when it is to be at once suspended. The remedies, in addition to opium, given for insomnia, are appropriate. The tincture of digitalis in half-drachm doses sometimes has a happy sedative effect upon the nervous system. The wet pack, that is, the body wrapped in a wet sheet and covered with a blanket, is a soothing measure which may often be resorted to with advantage. It is also an antipyretic measure, although less effective than continued sponging and the wet sheet with sprinkling. Insomnia, delirium, and other symptoms denoting disorder of the nervous system are less marked in proportion as the antipyretic treatment is effective. This statement is, probably, applicable in general to the complications and serious events liable to occur during the course of the disease, including, perhaps, perforation of the intestine and intestinal hemorrhage.

Nausea and vomiting seldom occur spontaneously in either typhoid or typhus fever to an extent to call for more than regulation of the ingesta. Diarrhœa in typhoid fever may require to be restrained, and, for this end, opiates and astringents, given by the mouth or rectum, may be employed. Mere looseness of the evacuations, without undue frequency, does not call for treatment. On the other hand, in typhus, and sometimes in typhoid, fever, constipation may furnish an indication for treatment. As a rule, cathartics, or even laxative remedies, are not required for constipation; simple enemata suffice, and are to be preferred. Evacuations may be delayed for two or three days, or even longer, without injury, if there be no evidence of discomfort, and the abdomen be not distended. Tympanites, if great or considerable, occasions discomfort, and embarrasses respiration by interference with the descent of the diaphragm. Large enemata may suffice to relieve this symptom. Turpentine should enter into the enemata. If these fail, a saline laxative may be given. A stomach-tube introduced into the rectum, and carried as far as practicable, sometimes occasions the discharge of gas in considerable quantity. Turpentine, given by the mouth, is supposed to relieve this symptom. Turpentine stupes to the abdomen are useful. Charcoal given freely is sometimes effective. Mechanical compression, by means of a band applied over the abdomen, sometimes affords relief.

Two important events connected with the abdominal lesions are liable to occur in cases of typhoid fever, namely, perforation of intestine followed by peritonitis, and intestinal hemorrhage. The probability of the successful treatment of the former is almost *nil*. The small chance of success depends on the free use of opium and measures to support the powers of life. Local depletion and blisters are not admissible. Peritonitis not dependent on perforation claims the same treatment, and is not so hopeless. Intestinal hemorrhage, if profuse, involves danger. This event calls for hemostatic remedies. The peristaltic movements should be arrested by opium. Ergotine may be given hypodermically. The acetate of lead, given by the mouth, is preferable to tannic acid or the astringent preparations of iron, as less likely to occasion

vomiting. Cold applications should be made to the abdomen. Rigid quietude is to be enforced.

Cough, although generally existing, is seldom sufficiently troublesome to require palliation. Pneumonia should not be treated with local or general depletion, blisters, or mercury, nor with nauseant sedatives. This, as well as other serious complications, contra-indicates depressing measures. Epistaxis is sometimes so profuse or persisting as to indicate local astringent remedies, and sometimes even plugging of the anterior and posterior nares.

Coma is to be treated by sinapisms or blisters to the back of the neck, and, if dependent on uræmia, by saline hydragogues, if they be not contra-indicated by the abdominal symptoms. If contra-indicated, reliance must be had on measures to produce copious perspiration. For the latter object the pilocarpine, administered hypodermically, may prove efficient. Strong coffee is useful as a palliative of undue somnolency or semi-coma apparently due to nervous exhaustion.

It is important to prevent accumulation of urine from retention, and to resort to the timely use of the catheter if required.

Bed-sores are to be guarded against by having the position of the patient often changed and by attention to cleanliness. If they occur, the ulcerated parts are to be relieved from pressure by air cushions, and treated with appropriate local applications.

Hygienic and supporting measures constitute a most important part of the treatment of typhoid and typhus fever. Hygienic measures indicated are, complete ventilation, cleanliness, regulation of temperature, which should be about 60° Fahr., changing frequently the position of the body, and the varied attentions involved in good nursing.

Foremost among the hygienic conditions for passing safely through the disease is an abundance of pure air. In private practice, the sick room should be large, and ventilated as completely as possible. In hospitals, fever-wards, in addition to ample provisions for ventilation, should not be crowded; 1500 cubic feet of air should be allowed to each bed. The evacuations should always be instantly removed. When practicable, it is advisable that the bed and body linen should be changed daily.

The importance of fresh air is shown by the reduced rate of mortality when patients are treated in sheds and tents, as compared with the death-rate in even well-ventilated hospital wards. Striking evidence of this was afforded by the transfer of fever-cases (mostly typhus) from Bellevue Hospital to tents on Blackwell's Island. A comparison of the mortality in 520 cases treated in tents from May 17 to November 1, 1864, with the average mortality in the Bellevue Hospital wards, shows a marked difference. The average death-rate in the hospital wards was 1 in 5.97; in the tents, 1 in 16.77, excluding the cases in which death took place within 48 hours after admission. Making the fullest allowance for the conjecture that the cases in the tents were milder than those in the hospital wards, it can hardly be doubted that the superior ventilation in the tents was the means of saving many lives.

In a paper communicated to the New York Academy of Medicine, in June, 1853, by Dr. John H. Griscom, an account is given of 82 cases of typhus transferred from an emigrant ship at Perth Amboy, N. J., to wooden shanties with sail "roofs." The ship brought over between three and four hundred passengers, and a number had died on the passage. There being no hospital nor other accommodations in the town, two shanties were erected, "thirty feet long and twenty feet wide, boarded on three sides about four feet up, and over them old sails were stretched." Eighty-two fever patients were transferred to these shanties, of whom twelve were in a state of insensibility when

removed. On the night after their removal there was a violent thunder-gust accompanied by torrents of rain, and the following morning the clothes of all were saturated with water. The medical treatment consisted "of an occasional laxative or enema, vegetable acids, and bitters were liberally administered, together with the free use of cold water, buttermilk, and animal broths." Four sailors who sickened after the arrival of the vessel were removed to an ordinary dwelling-house, and, of these cases, two proved fatal. Of the 82 cases treated in the shanties, not one proved fatal.[1]

Fever patients should not only be allowed to take water as freely as they may desire, but it should be systematically given when, from the blunted state of the perception, they manifest no desire for it. There is reason to think that death is sometimes attributable to an insufficient supply of liquid. The importance of this should not be overlooked by the physician, inasmuch as it is a popular notion that the free use of water in fevers is hurtful. Iced water is not objectionable. It may be acidulated with lemon or orange juice, if rendered thereby more agreeable to the patient.

The importance of support is based on the plain fact that, typhus and typhoid fever being self-limited diseases, if the patient can be kept alive, after three, four, or more weeks, recovery will take place provided there be no serious complication. In a case of severe uncomplicated fever, the patient is in a situation not unlike that of a person in danger of drowning not far from, or perhaps very near, the shore; if he drown, it is because his strength gives way before the shore is reached. As a person in this situation requires only to be buoyed up by some support, so the fever patient, in a similar emergency, may only need supporting measures to live until the disease ends. Death may take place at a juncture when, could it have been averted a few days, or, perchance, even a single day, the period of danger might have passed.

Supporting measures embrace tonic remedies, alcoholics, and alimentation, more especially the two latter. Of tonic remedies, the most efficient and convenient of administration is quinia, which may be given in doses of two to three grains twice or thrice daily.

Alimentation ranks first in importance. It is desirable for the patient to take as much nutritious food as will be digested and assimilated. Innutrition in cases of fever, as of other affections, enhances and adds to the morbid phenomena belonging to the disease. Graves uttered an important truth in saying that a great object of treatment is to prevent patients from dying from starvation. In the early part of the disease there is generally a repugnance of food, and afterward, owing to the mental state and the condition of the mouth, taste and appetite are wanting. Under the latter circumstances food is to be given although not desired by the patient, and even when there is a disinclination to take it. The indifference to food may proceed, measurably, from an unwillingness to be disturbed and a reluctance to make any exertion.

The supporting diet should be in a liquid form embracing the necessary variety of alimentary principles. The animal broths, eggs and milk, with the addition of some farinaceous preparation of food, fulfil these requirements. Different articles should be given in alternation, and at regular intervals. The intervals should be from two to four hours. It is injudicious to give food every half hour or hour, or after even shorter intervals, as is not infrequently done. The amount of food given at a time must vary according to circumstances, the object being to give as much as can be given without risk of either vomiting, discomfort from over-accumulation in the stomach, or indigestion. If

[1] Transactions of the New York Academy of Medicine, vol. i. part ii., 1853.

the patient be in a condition to feel and express a choice for particular kinds of food, the preference should, as far as practicable, be consulted. The physician should have an oversight of the preparation of food, lest, through ignorance or carelessness, it be unpalatable, innutritious, or improperly served. Precise directions and attention to the details of dieteties form an important part of the physician's duty, not only in fevers, but in all cases of disease in which supporting treatment is indicated. Of the different articles of food just named, milk is by far the most valuable as entering into the fever diet. It is taken, if not with relish, at least with less reluctance than other articles; and it has the great advantage of embracing, in proper combination, all the alimentary principles required for nutrition. The "beef tea," as it is often prepared, is little more than warm water flavored with the meat. The different so-called meat extracts contain little or no nutriment. It has been considered, indeed, that they are injurious from the amount of excrementitious principles entering into them. Prepared in any mode, and as carefully as possible, the essence of meat or broths are vastly inferior, in nutritive value, to milk. They should, therefore, never be relied upon to the exclusion of the latter. If the same article of animal diet, for example, beef broth, be given day after day, the patient acquires for it, after a time, an intolerable disgust. The form should, therefore, be varied, beef, mutton, and chicken broth being given in alternation. They may be rendered more nutritious by the addition of barley or some other farinaceous article, and by adding the yolk or albumen of eggs. It is desirable that from one to two quarts of milk *per diem* should be ingested; but, since the value of a milk diet in fevers has come to be appreciated, its use has frequently been pushed to an injurious excess. I have met with instances in which an abundance of hard curds was passed from the bowels, after much abdominal distress and general disturbance. Coffee or tea if acceptable to patients is allowable. They may be made nutritious by a large addition of milk.

Alcoholics have entered largely into the treatment of fevers in this country during the last thirty years. That they have been used too freely and indiscriminately can hardly be doubted. As a natural consequence, there is perhaps at the present moment a tendency to undervalue their importance. It does not follow that they are never useful because in mild cases, or those treated under most favorable hygienic conditions, the rate of mortality is small although they were not used. Observation of their immediate effects in certain cases shows their utility often in a very striking manner. Indiscriminately and excessively used, they are not useful, but used with proper application and moderation, they form an essential part of the supporting treatment of fevers, as well as of all other diseases which destroy life by asthenia.

The supporting effect of alcoholics is directed chiefly to the circulation. Hence, the indications respecting their use are derived especially from symptoms relating to the heart. Feebleness of the circulation, as denoted by the pulse and the heart-sounds, calls for their use, and they are to be given, as regards quantity, in proportion to the degree of feebleness of the circulation, and according to their effect. The characters of the pulse denoting feebleness of the heart's action are smallness and compressibility, frequently combined with considerable or great frequency. A pulse in the adult exceeding 120 per minute never denotes strength, and, above this number, it is feeble in proportion to frequency. Above 130, the pulse always denotes a degree of feebleness of the circulation rendering supporting measures highly important. The heart-sounds also constitute a good criterion for estimating the degree of feebleness of the heart's action. In proportion as the action of the heart is weakened, the intensity of the first sound over the apex is diminished; it is

shortened and in quality resembles the second sound. If the heart be notably weakened, the first sound may be inappreciable over the apex. Stokes was the first to direct attention to these changes as criteria for the administration of alcoholics.

Alcoholics are rarely indicated in the early part of either typhus or typhoid fever. They are oftener and earlier indicated in typhus than in typhoid fever. Brandy, or some form of spirit, and wine, sherry or Madeira, may be employed. Commencing with a moderate quantity, half an ounce of spirit or an ounce of wine, the effect on the circulation and other symptoms should be observed. A good effect is shown by increased force, with diminished frequency, of the pulse, perhaps some reduction of the temperature of the body, diminution of delirium, etc. The intervals should vary, according to the urgency with which this supporting measure is indicated, between six or eight hours and each successive hour. The quantity given at a time should rarely exceed that just stated. Guided by the true indications and by the effect, alcoholics will not do harm, and will often do much good in the treatment of typhus and typhoid fever. I have repeatedly tried their suspension for a few hours in cases in which they appeared to be urgently indicated, in order to become fully satisfied of their utility, and have found the pulse become more frequent, with increase of delirium and other ataxic symptoms, until their use was resumed. While a certain proportion of cases do well without them, and they are, therefore, not always indicated, I cannot doubt that I have seen not a few cases in which life was saved by their employment.

In these fevers, as in some other diseases, the tolerance of alcohol is often notably greater than in health. A patient may take from one to two pints of spirit per day, who in health could not have taken one-fourth of this quantity without inebriation. The excitant or toxic effects of alcohol should never be produced in cases of fever. If these effects be produced, the indications for alcohol are not present or it is too largely given. In extreme cases an ounce, or even more, of spirit, given hourly, may be necessary, but, in the majority of the cases in which alcoholics are indicated, not more than six or eight ounces in the twenty-four hours are needed.

During convalescence alcoholics should be given moderately. If they have been used freely during the career of the fever, when convalescence begins their excitant effect may be for the first time apparent. Frequently malt liquors or light wine are best suited to convalescence. Solid food should be allowed as soon as convalescence is declared. The processes of digestion and assimilation are usually active, and the appetite is apt to be voracious. The cautions to be observed relate to the kinds of food and the quantity taken at one time. The patient should be restricted to plain, wholesome, well-cooked articles of diet, and excess may be avoided by taking food at shorter intervals than in health. Convalescence from typhoid, more than from typhus, fever, requires care as regards diet, in view of the probable existence of intestinal ulcerations. Gestation in the open air may be allowed early in the stage of convalescence, and, as soon as their strength will permit, patients may walk out of doors. Care with respect to much muscular exertion is important in convalescence from typhoid fever, in consequence of a liability to intestinal perforation.

The prevention of typhus fever, except among those who are necessarily exposed to infection in rendering medical and other aid to patients in fever wards or hospitals, is attainable by proper hygienic reforms. If overcrowding be prevented, and free ventilation secured, the fever is not likely to be communicated. One of the great objects to be accomplished by improved sanitary regulations, especially in large towns, is the prevention of typhus. In view of the risk of the diffusion of the disease, patients with typhus should not be

treated in hospital wards with other cases. This statement does not apply to patients affected with typhoid fever; there is no risk of the diffusion of the latter among other patients. The custom of transferring to fever wards with cases of typhus, patients affected with typhoid fever, is objectionable in view of the risk of the latter contracting typhus during convalescence. Repeated instances in which this has occurred have fallen under my observation.

Typhoid fever is prevented by proper protection against the use of drinking water polluted with human excrement, and against emanations from waste pipes, drains, cesspools, etc. In every case of typhoid fever, it should be traced to its source, and continued exposure of the patient and others to the cause prevented. Drinking water should be boiled if there be any ground for suspecting its purity. In order to prevent diffusion of the disease, the intestinal dejections should be disinfected by adding a solution of the sulphate of iron and carbolic acid, and they should not be thrown into privies or water-closets, but buried so as to avoid the possibility of their infecting either drinking water or the atmosphere. Articles of clothing or bed linen soiled by intestinal dejections should be at once plunged in boiling water, or disinfected.

Relapsing Fever.

A form of continued fever, heretofore known by a variety of names, but now called *relapsing fever*, received very little attention in this country prior to 1870. It has never been indigenous in this country. In June, 1844, fifteen cases were admitted into the Philadelphia Hospital presenting the characters of relapsing fever, this name, however, at that time not being in use. These were, probably, the first cases reported in this country. The patients were Irish immigrants, all coming over in the same vessel. The cases were observed by Dr. Meredith Clymer, and were reported in his treatise on fevers.[1] In addition to these, so far as I know, the only cases observed are a few reported by Dr. A. Dubois, in 1848,[2] and fifteen cases which came under my observation in 1850–51, an account of which is contained in my "Clinical Reports on Continued Fever."[3] The cases reported by Dr. Dubois and by me were among recent Irish immigrants. It is highly probable that other cases have occurred among immigrants, which have not been reported, and which may have been confounded with typhus and typhoid fever. In the winter of 1869–70 the disease was imported by foreign immigrants, and it prevailed, to a considerable extent, in New York, during this winter and the following summer. It prevailed, also, to some extent, in other of the large cities of this country. At this time, the wards of Bellevue Hospital afforded an ample opportunity for the clinical study of it; and my observations were the basis of a lecture published in the spring of 1870, to which was appended a statistical report of 103 cases, prepared, at my request, by Dr. Thomas J. Moore, then one of the house physicians of the hospital.[4]

It is not long since the distinctive features of relapsing fever have been pointed out, and its claims to be considered as a distinct species of fever established. It is by no means, however, a new disease, and there is evidence of its having existed from a very early period in the history of medicine. In modern times it has prevailed, at different epochs, more especially

in Ireland, Scotland, and England. It prevailed as an epidemic in Upper Silesia, a province of Prussia, in 1847, and among the troops in the Crimea during the war of France and England with Russia. In 1863 it again appeared in Russia, and in 1865 there was a great epidemic in St. Petersburg. Since this date there have been several epidemics of relapsing fever in Russia, and in North Germany, particularly its eastern part. At present (1880) the disease is prevalent in Berlin. Its claims to be considered as a distinct species of fever rest on the following facts: It does not present either the anatomical characters or the diagnostic events of typhoid fever, and, as regards its non-identity with typhus, the two diseases are separately communicable, but neither communicates the other, nor does the occurrence of either secure an immunity from the other; each disease appears to have its own special cause. Relapsing and typhus fever, however, are apt to prevail together. Among the different names heretofore applied to the disease are the following: Febris recurrens, typhus recurrens, spirillum fever, "five day fever," "seven day fever," "short fever," "mild yellow fever," "famine fever," "hunger-pest." The name relapsing fever is based on one of the most striking of the peculiarities of the disease, and involves no hypothesis; it is, therefore, to be preferred to any of the other appellations. The disease described by Griesinger as bilious typhoid fever is a severe form of relapsing fever.

Anatomical Characters.—The lesions are those of an acute infectious disease. They have been studied with especial care by Ponfick.[1] The *spleen* is enlarged, of a dark red color, and of soft consistence. The enlargement is in many cases extreme, and resembles that of typhoid fever. In a few instances rupture of the spleen has taken place. Hemorrhagic infarctions in this organ are not rare. Abscesses also occur, but are less frequent. The Malpighian follicles are indistinct, although often swollen. They are sometimes the seat of small abscesses and of necrotic softening. The enlargement of the spleen is due to congestion and hyperplasia of lymphoid elements. Ponfick observed a considerable number of large granular cells containing molecules of fat, and sometimes inclosing red blood-corpuscles. The presence of these cells is not peculiar to relapsing fever. The *liver* is also enlarged, and of reddish-gray or yellowish-brown color. It is the seat of parenchymatous and often of fatty degeneration. The *kidneys* are swollen, especially the cortex, and often beset with small hemorrhages. The epithelial cells of the cortical tubes undergo granulo-fatty degeneration. Ponfick observed lymphoid cells in the interstitial tissue. These are the changes of an acute diffuse nephritis. They are not present in all cases, but they are not rare. There is usually a moderate degree of inflammation of the *intestinal tract*, the mucous membrane being congested, swollen and coated with mucus. The solitary follicles are somewhat enlarged. Ponfick attributes the icterus often present in relapsing fever to gastro-duodenitis. *Ecchymoses* are often met with in the stomach. Sub-pleural and pericardial ecchymoses are not uncommon. Small hemorrhages have also been found in the brain. Petechiæ of the skin are present in about 10 per cent. of the cases. The striated *muscular substance* is the seat of parenchymatous and of waxy degeneration as in typhoid fever. The degeneration is frequent and of especial importance in the muscular substance of the *heart*. The myocardium may be affected with a fatty degeneration almost as intense as that in phosphorus-poisoning. This degeneration may be the immediate cause of death. Ponfick observed in some cases

[1] Ponfick, Anatomische Studien über den Typhus recurrens, Virchow's Archiv, Bd. 60, p. 153, 1874.

changes in the *marrow of the bones.* These changes were partly diffuse and partly circumscribed. The diffuse changes consist in the appearance of large cells filled with fatty granules (resembling those found in the spleen), especially in the course of the small arteries, and in an increase in the number of lymphoid elements. Another alteration of the marrow occasionally found, is the presence of circumscribed foci of necrotic softening. The *blood* is dark in color and fluid, or imperfectly coagulated. When examined during life, the number of white corpuscles is often notably increased (1 white to 50–20 red). The same large, granular, fatty cells observed in the spleen have been discovered by Ponfick and by Heydenreich in the blood. Fatty endothelial cells have also been detected occasionally in the blood. Both of these abnormal cells have been found in the blood in other diseases. There seems to be an unsual number of small, round granules in the blood of relapsing fever patients.

In 1873, Obermeier, in Berlin, discovered a spiral-shaped bacterium in the blood of relapsing fever patients. This parasitic organism is called the spirillum Obermeieri, or the spirochæte of relapsing fever. It belongs to the group called spiro-bacteria (page 96). This parasite has been found in the blood in no other disease than relapsing fever.[1] The spirilla are sometimes, but not usually, found in the blood after death, and, if found, are motionless. These spiral organisms are extremely delicate, and are readily seen only with the high powers of the microscope. The diameter of a spirillum is about that of the finest fibrils of fibrin ; its length varies from ten to forty micromillimetres, or, according to Obermeier, from one and a half to six times the diameter of a red blood-corpuscle. In a drop of blood drawn during life the spirilla are in rapid motion, which resembles somewhat that of the spermatozoa. The parasite has been found only in the blood, and not in any of the other fluids or in the organs of the body. It differs from most bacteria in the readiness with which it is destroyed by the action of various reagents. It is found almost invariably during the febrile paroxysms, and disappears during the intermission. It is occasionally found during the intermission, especially for a few hours after the crisis, and for a few hours preceding the relapse. We are ignorant as to the life-history of this organism. Attempts to cultivate it artificially have failed. We do not know how it gains access to the body, nor in what relation it stands to the phenomena of the disease. It is held by many writers that the spirillum develops from spores which are present in the body during the intermissions. This view is based on facts known concerning the development of the bacillus anthracis, the parasite of malignant pustule (charbon, Milzbrand) or splenic fever.[2]

Among the complications of relapsing fever, in addition to those already mentioned, the most frequent are pneumonia (both lobular and lobar), hemorrhagic infarctions of the lungs, pulmonary œdema, œdema glottidis, pseudo-membranous laryngitis and pharyngitis, pleuritis, peritonitis, dysentery, suppurative parotitis, hemorrhages and abscesses in the muscles, thrombosis, arthritis. In some epidemics, affections of the eye have been observed from one to four weeks after the termination of the disease. Of six cases observed

[1] The spirillum Obermeieri resembles, but does not seem to be identical with, the spirochæte plicatalis discovered by Cohn in mucus from the mouth, and a spirochæte previously discovered by Ehrenberg in water. Similar spiral-shaped bacteria have been found by Billroth in fluid from noma, and by Manassein in the contents of a cyst in the antrum Highmorianum.

[2] Albrecht observed the development of spirilla in blood taken from relapsing fever patients, which at first did not contain these organisms. He considers that the blood contained spores from which the spirilla developed, and describes small round and oval bodies as such spores. (Centralbl. für d. med. Wissenschaften, May 22, 1880.)

by Litten, in which this sequel occurred, in three there was iritis, in one choroiditis, in one opacity of the vitreous humor, and in one phlyctenular conjunctivitis. Epidemics differ as to the extent and severity of the lesions and the characters of the complications and sequelæ. Only a small number of patients are affected with any of the complications which have been mentioned.

Clinical History.—Under this head I shall state succinctly the symptomatic features which are characteristic of this fever. These relate to two or more successive paroxysms of fever, separated by an apyrexial period or intermission. The recurrence of the paroxysm of fever, or the relapse, is the distinctive feature whence the name of the disease derives its significance.

Abruptness of invasion characterizes the disease. The attack is sudden. There is no prodromic period. The seizure is almost always marked by a well-pronounced chill which is immediately followed by febrile movement. Usually, the patient at once takes to the bed; but, in some cases, one, two, or three days pass before there is this evidence of yielding to the disease. Moderate perspiration occurs shortly after the fever begins, in a considerable proportion of cases. The perspiration in some cases is abundant, and it may recur repeatedly during the continuance of the febrile paroxysm.

The fever attains quickly to either considerable or great intensity, as denoted by the pulse and axillary temperature. Thus, of two cases in which the disease was developed in Bellevue Hospital, in one, the pulse on the first day was 120, and the temperature 103°; in the other case, the pulse on the first day was 130, and the temperature was 103°. During the continuance of the first paroxysm, the pulse and temperature generally denote a persistent intensity of fever, the pulse ranging, in different cases, from 100 to 140, and the temperature from 100° to 105°. The oscillations are rarely great, and those which occur are irregular in their occurrence.

The cessation of the fever is as abrupt as the accession. The pulse and temperature quickly fall to nearly or quite the normal standard. The transition from high fever to complete apyrexia takes place, often, in a few hours; usually this is accompanied by profuse perspiration which continues for several hours, and even an entire day. Not infrequently, the pulse and temperature fall below the standard of health. I have observed the pulse to fall as low as 54, and the temperature as low as 95°. In a day or two both the pulse and temperature rise again to the normal standard. Symptoms of collapse sometimes occur soon after the fall of temperature. They are usually of short duration.

The duration of the primary paroxysm, in the majority of cases, is from five to seven days. Exceptionally, it is sometimes only two days, and it may be twelve days.

During the apyrexial period, or intermission, the absence of fever is complete. It is incorrect to call this period a remission; the fever does not remit, but it intermits. The average duration of this period is about seven days; but it may not exceed two or three days, and it may extend to twelve days, or even more.

The relapse, like the primary attack, is sudden. It is generally ushered in by chilly sensations, but not so constantly by a well-pronounced chill as the first paroxysm. The fever in the relapse quickly becomes more or less intense. The intensity may exceed that of the first paroxysm. But, in the majority of cases, the intensity is less. The relapse also ends suddenly, and in most cases with profuse perpiration.

The duration of the relapse varies between three and five days. It is sometimes, however, only twenty-four hours, and it may extend to ten days.

It is to be borne in mind that the relapse does not always take place. On the other hand, a second, a third, and even a fourth and a fifth, relapse have been observed. In some epidemics there have been two relapses in the majority of cases, in others a second relapse has been the exception. The duration of the second intermission is about eight or nine days, and that of the third paroxysm about three days. The duration of the disease averages about twenty-five days, but is longer if more than two febrile paroxysms occur. In none of the cases which I have seen has there been more than a single relapse.

The foregoing points are those most highly distinctive of relapsing fever. It remains to notice other points, belonging to the clinical history, which are more or less characteristic.

Of symptoms referable to the digestive system, nausea and vomiting occur sufficiently often to be somewhat distinctive, especially when this disease is contrasted with typhus and typhoid fever. Not infrequently, these symptoms are prominent and persistent during the febrile paroxysms. The matter vomited is green or yellow from the presence of bile. The tongue is generally coated, and in most cases moist. This moisture of the tongue in connection with high fever is somewhat distinctive of this disease. The tongue may, however, become dry and fissured. The vomiting of blood presenting the character of "black vomit" has been observed; but it is a very rare symptom. It is generally associated with hemorrhage in other situations, and it is to be considered as an accidental event, not as an element of the disease. Epistaxis is a more frequent form of hemorrhage, and is observed especially during a crisis. In some epidemics a moderate diarrhœa has been the rule; in others, constipation. There is nothing characteristic as regards the condition of the bowels. Meteorism, in a moderate degree, is not uncommon. Tenderness on pressure over the epigastric region is frequent. Slight tenderness in the iliac region is not uncommon. Notable tenderness exists in most cases over the liver and spleen; and enlargement of these organs is determinable by palpation and percussion. I have not observed a craving for food during the paroxysms, which, according to some writers, is distinctive of this form of fever. The appetite, however, returns during the intermission, and the digestion may be active in this stage.

The occurrence of jaundice may be mentioned in this connection. This event occurs in a small proportion of cases, but its infrequency in the other continued fevers renders it somewhat distinctive of relapsing fever. It is doubtful if the statement that this event is an element of gravity be correct. The event is much more frequent in some epidemics than in others. The name "mild yellow fever" derives whatever pertinency it has from the occurrence of jaundice sometimes in a considerable proportion of cases, and also from the occasional occurrence of black vomit.

A symptom referable to the nervous and the muscular system is highly characteristic of the disease under consideration. I refer to arthritic and muscular pains, more especially the latter. During the first paroxysm, pains in the loins, the calves of the legs, and the muscles in other situations, are generally much complained of. They are never wanting, although, as regards intensity, they differ considerably in different cases. The muscular pains do not cease with the ending of the paroxysm, but they continue during the intermission; they are more or less prominent during the relapse, and they are apt to persist into convalescence. The pains are sometimes referred to the bones. Ponfick thinks that this may be explained by the changes in the marrow which he observed.

The mental condition, perhaps, in a measure, accounts for the suffering from these pains. The perceptions are not blunted in this disease as they

are in typhus and typhoid fever. This is a negative point of distinction in contrast with the fevers just named. Another negative point is the absence of the delirium which characterizes typhus and typhoid fever. Delirium is by no means absent in all cases of relapsing fever; but the delirium is such as is apt to occur whenever there is high febrile movement, whether the fever be essential or symptomatic, and it is generally manifested only at night. In the daytime the mental faculties are generally intact. The condition known as coma-vigil does not belong to the clinical history of relapsing fever. This statement is also true of subsultus, carphologia, and other ataxic symptoms which occur in grave cases of typhus and typhoid fever. Deafness is also a rare symptom in relapsing fever.

A distinctive point, in comparison with typhus and typhoid fever, is the absence of a characteristic eruption. In most cases there is no eruption. Sudamina or miliary vesicles are sometimes observed at the time when profuse perspiration occurs; but this eruption is incidental to various affections. The same is true of petechial spots which occur in some cases of relapsing fever. Other kinds of eruption are sometimes accidentally associated. Even the rose papules of typhoid fever sometimes occur in this as they do in various other diseases.

The physiognomy presents nothing distinctive. The face is more or less flushed, as in cases of symptomatic fever. There is not that degree of capillary congestion, marked especially on the cheeks, which exists in typhoid fever, nor the dingy complexion which characterizes typhus. The expression of indifference, vacuity, or stupidity, which is a notable characteristic of the fevers just named, is rarely observed in relapsing fever.

The urine during the paroxysms is usually concentrated, dark in color, and rich in urates. In some epidemics albuminuria has been a not uncommon symptom. Blood-corpuscles and hyaline casts have also been found. But in the majority of cases neither albumen nor casts are present. Great diminution, and even suppression of the urine, however, are sometimes observed, uræmic coma and convulsions taking place, but these cases are exceedingly rare.

It may be stated, as a point somewhat distinctive of relapsing fever, that there is very little liability to serious complications. In this fact we have an explanation, in part at least, of the very small rate of fatality from the disease.

What has just been stated with respect to complications holds true as regards sequels. As a rule, important sequels do not occur. A peculiar form of ophthalmia, which was described as following the cases reported by Dr. A. Dubois, of this city, in 1848, is an exception to the rule. It has been repeatedly observed as a sequel of relapsing fever. This sequel, however, has not occurred in any of the cases which I have observed. Relapsing fever, when it attacks pregnant women, almost always leads to miscarriage or abortion. The mother almost invariably recovers, but the child, no matter how near may be the end of gestation, as a rule, is either stillborn, or dies shortly after birth.

Diagnosis.—The distinctive features of relapsing fever are such as to leave hardly any room for doubt concerning the diagnosis after the disease has ended. Whatever difficulty in the diagnosis exists, relates to the discrimination during the primary paroxysm.

The diagnosis involves certain distinctive characters which belong to the primary paroxysm; but it is to be based, also, on negative points; in other words, on reasoning by way of exclusion. The distinctive characters are the abruptness of the invasion, the rapid increment of fever, the frequent

occurrence of moisture on the skin, or perspiration more or less abundant, without any marked abatement of the fever, the prominence of muscular and arthritic pains, and, in certain cases, the occurrence of jaundice. These are the positive points which are diagnostic. The fevers to be excluded are the eruptive fevers, febricula, remittent fever, typhus and typhoid fever. Scarlet fever and measles are readily excluded by the absence of the eruption and of the characters which are distinctive of these fevers during the period of invasion. Smallpox is excluded after the third day by the continuance of fever and the absence of the eruption. It is not always practicable to decide at once that the disease is not a febricula; but the intensity of the fever and the notable muscular pains do not belong to the latter. Doubt, however, is soon removed by the persistence of the fever. Typhoid fever is excluded by the absence of a prolonged access, and the absence of the abdominal symptoms, before sufficient time has elapsed for the appearance of the eruption, and of the characteristic mental condition. Typhus is excluded by the absence of the eruption, which appears earlier than in typhoid fever, by the absence of the dusky complexion, and by the absence of the mental condition —the latter also being apparent earlier than in typhoid fever. Remittent fever is excluded by the absence of remissions, these being determinable by a notable diminution of the axillary temperature in some cases in which they are not distinctly denoted by the pulse. Of course, the prevalence of relapsing fever is taken into account in arriving at the diagnosis.

Causation.—Relapsing fever is undoubtedly communicable from the sick to the well. This statement rests on facts derived from the different sources of evidence, exclusive of inoculation, which establish the contagiousness of other diseases; for example, typhus fever. Of those who are attacked during the prevalence of the disease, a large proportion are known to have been brought into contact with, or close proximity to, patients affected with it. The disease is diffused in hospitals among fellow-patients and those who have charge of the sick. During the period in which cases were received in Bellevue Hospital, after the disease began to prevail in this city, namely, between November 14, 1869, and February 6, 1870, twelve persons contracted the fever in the hospital. These twelve persons were especially brought into contact with patients affected with the disease, and in no instance did it attack one who had not been thus exposed. One of the senior assistant physicians residing in the hospital had it. The orderly in one of my wards contracted it; and his wife, who came to nurse him, was attacked by it. The disease has often been diffused in localities in which it did not previously exist, after the importation of a case.

Facts, however, go to show that it is not a highly contagious disease. Considerable exposure is, in general, necessary. The area of the infection appears to be limited, and it remains to be ascertained whether it may be transported by fomites. Some facts, cited by Murchison, render it probable that it may be diffused in the latter mode. It is especially communicable when the miasm is derived from a number of patients in the wards of a hospital, or in close apartments. The disease is not likely to be contracted from single patients in well-ventilated rooms. The investigations of the Metropolitan Board of Health in this city, during the prevalence of the disease, showed that it is diffused chiefly among those living in overcrowded, ill-ventilated tenement-houses. Of the propriety and importance of removing these patients to hospitals or wards devoted specially to cases of this disease, there can be no doubt.

Destitution, deprivations, and especially deficient alimentation, are power-

ful auxiliary causes. Of this fact, the past history of the disease, at different times and places, furnishes abundant evidence. The significance of the names "famine fever" and "hunger-pest" relates to this fact. Statistics do not show any notable etiological influence pertaining to age, sex, or season.

Although its diffusion involves generally, and perhaps always, a contagious principle, the history of the disease in other countries shows that it occurs as an epidemic, and, after continuing for a certain time, it disappears completely. Thus, in the city of London, for the fourteen years preceding the winter of 1868–'69, there had been no cases of the disease. The complete disappearance of the disease for so long a period goes to show the necessity of co-operating causes in conjunction with the special poison on which the production of the disease depends. The effective means for arresting the spread of the disease are, thinning the population of overcrowded tenement-houses, dispersing the occupants of insalubrious dwellings, relieving destitution, especially as regards food, and promptly removing patients to hospitals devoted to cases of relapsing fever. An attack of this disease does not exempt from subsequent attacks. The period of incubation in more than one-half of the cases in which it is determinable does not exceed five days. It rarely exceeds nine days. Occasionally, as in typhoid and typhus fever, the symptoms commence almost immediately after the exposure.[1]

At the present time, relapsing fever derives much interest from the presence in the blood of organisms which are characteristic of the disease. Obermeier discovered, in 1873, that organisms, which from their corkscrew-like appearance are called spirilla, are invariably found during the febrile periods, and are almost invariably absent during the intermissions or apyrexial periods. His observations have been corroborated by those of others, so that the fact just stated may be considered as established. Another important fact is—these organisms are not found in the blood of patients affected with other fevers. In view of these facts, it must be admitted that these organisms have an essential pathological connection with the disease. That they or their germs constitute the contagium, and that the phenomena of the disease are due to their presence in the blood, are conclusions vastly more probable than that they are either effects of the fever or accidentally associated with it. Accepting these conclusions, their importance is not limited to the etiology and pathology of relapsing fever. If it be true that this fever depends on the introduction and reproduction within the body of peculiar organisms which have been discovered, we may logically conclude that other fevers depend severally upon organisms which remain to be discovered.

In accordance with the germ theory, the first paroxysm of relapsing fever is due to a brood of spirilla. Their existence terminates in about a week, as a rule, and the first febrile paroxysm then ends. In a small proportion of cases the conditions required for the production of a second brood of these organisms are wanting, and the disease then consists of a single paroxysm of fever. But in the great majority of cases these conditions are not wanting; hence the germs remaining in the body give rise to a second brood; hence the relapse of the fever. In rare instances a third and a fourth brood are produced, but in most persons the conditions therefor are extinguished after a second paroxysm of fever. The conditions, however, are never permanently extinguished, as in cases of typhus and typhoid fever, yellow fever, small-pox, and the other eruptive fevers, for, after a certain period, they who have

[1] *Vide* Murchison, St. Thomas's Hospital Reports, vol. ii.

had relapsing fever are again susceptible to the contagium. The extinction of the conditions for the development and reproduction of spirilla within the body is only temporary.

The contagium is probably contained in the breath and cutaneous exhalations. There are no facts going to show that the intestinal dejections have any part in the diffusion of the disease.

Prognosis.—It is, at first view, remarkable that a fever of such intensity, and prevailing especially among a class of persons whose powers of tolerance are impaired by previous hardships and want, should have such a small rate of mortality. The mortality, in different collections of cases, varies from two to eleven per cent. Dr. Moore, in his statistical report, states that, of one hundred and three cases admitted into Bellevue Hospital between November 14, 1869, and February 6, 1870, only two proved fatal. In some epidemics the mortality has been as high as ten or eleven per cent., but, as a rule, it has not exceeded two to four per cent. In epidemics with the higher rates of mortality, the complications have been many, and the disease has presented the so-called bilious type. What is the explanation of the low rate of mortality? An explanation, which perhaps is sufficient to account for the fact, has been already given, namely, the disease is very rarely accompanied by any serious complications. The comparatively much greater fatality of typhus and typhoid fever is due mainly to complications. These fevers rarely kill *per se*, that is, death is not purely an effect of the intensity of the disease.

Of the fatal cases of relapsing fever, the death, in a certain proportion, is attributable either to complications, such as pneumonia and dysentery, or to antecedent affections, for example, disease of the kidneys and chronic alcoholism. But this fever may destroy life irrespective of any important complications or antecedent affection. Several observers have reported cases in which sudden death occurred apparently from syncope. Dr. Moore's report exemplified this fact. The death in one case was sudden and unexpected during the night, on the seventh day of the disease. At the time of death, the primary paroxysm seemed about to end, free perspiration having taken place. Neither coma nor convulsions occurred, and, so far as information could be obtained, the dying was by syncope. The fatty degeneration of the heart explains, in many cases at least, death by syncope.

Suppression of urine followed by uræmic coma and convulsions is sometimes a cause of death. This fact was exemplified by one of the two fatal cases occurring in Bellevue Hospital. These symptoms are due to acute diffuse nephritis, which is one of the recognized complications of relapsing fever.

Treatment.—There are no known means which can be relied upon for cutting short a relapsing fever. With our present knowledge, there are no remedies which, employed in the intermission, will prevent the relapse. Quinia has been used freely, but with no success. Its inutility, as a prophylactic, has been abundantly shown by different observers. The treatment, with our present knowledge, must be expectant, meaning, by this term, that it is to consist of palliative measures, and those addressed to the particular indications in individual cases.

The intensity of the fever during the paroxysms may be lessened by sponging the body with water, and by the wet sheet. Cold water may be taken into the stomach freely. Ice-cold carbonic-acid water is an acceptable and useful drink to allay thirst. Cephalalgia may be relieved by cold applications to the head. The bowels should be kept open by saline laxatives. The muscular and arthritic pains call for the use of opium, especially if it produce

no unpleasant after-effects. Irrespective of the pains, opiates are indicated to relieve sleeplessness.

The dietetic treatment is important, more especially in the cases in which deficient alimentation has been an auxiliary cause of the disease. In this fever, as in other fevers, when alimentary support is indicated, milk is the form of diet to be preferred. And it is to be borne in mind that, as in most diseases, there is never any danger of the over-appropriation of nutriment; the only risk is in the ingestion of more food than can be digested. It is desirable that, during the paroxysms, from one to two quarts of milk should be taken daily. In the intermission, when the appetite returns, as much substantial food as can be digested should be allowed; and the more food is appropriated in this stage, the better is the patient enabled to tolerate the relapse. Tonic remedies are indicated throughout the disease, and especially in the intermission. Quinia in small doses, and some preparation of iron, are the tonics to be preferred.

If the symptoms denote asthenia, alcoholics are indicated. The occasional occurrence of death from syncope renders it important to watch carefully for this indication. When there is room for supposing that alcoholics may be useful, they should be given tentatively and continued, or not, according to the effect, especially on the pulse and temperature. They are, of course, urgently indicated if the symptoms denote danger in the direction of asthenia.

Attention to the urine is important. It is to be recollected that a cause of death is suppression of urine. If the urinary excretion be deficient in quantity, or if, the quantity being sufficient, there be a deficiency of urea, diuretics are indicated. If the kidneys do not respond to diuretics, hydragogue cathartics are indicated, with a view to eliminate urea through the alimentary canal. Active hydragogues are, of course, indicated, if uræmic coma or convulsions supervene.

It is stated that convalescence from relapsing fever is notably slow, patients remaining for a long time much enfeebled, and tolerating with difficulty affections which may occur before the recovery is complete. This has not been a marked peculiarity in the cases which have come under my observation. It is doubtless more likely to be marked in the cases in which there had been impairment of the vital powers from innutrition and hardships before the fever was contracted; and, also, it is more likely to be marked where abundant alimentation and the judicious use of alcohol have not entered into the treatment of the disease.

Erysipelatous Fever.

Erysipelas, considered as a local affection, belongs to surgery rather than to medicine; for an account of this form of inflammation the reader is referred to surgical works. It occurs as an occasional complication of the continued fevers which have been considered. A form of continued fever distinct from the fevers which have been considered, is characterized by the frequent occurrence of erysipelas, and hence it is called *erysipelatous fever*. As a distinct form or species of fever, this is to be distinguished from erysipelas occurring as a local affection and accompanied with more or less febrile movement. The fever in the latter is symptomatic, whereas, in erysipelatous fever it is primary or essential. On the other hand, erysipelatous fever is to be distinguished from typhus, typhoid, and relapsing fever, with erysipelas as a complication.

Erysipelatous fever occurs as a sporadic and as an epidemic disease. As a sporadic disease it is rare, and has not been as yet sufficiently studied by means of the analysis of recorded cases. The invasion is either abrupt or

there is a forming stage of variable duration. The erysipelas may be developed within a few hours from the attack, or after the lapse of one, two, or three days. The head is oftenest the seat of the erysipelas, but it may be developed in any part of the body. Different parts may be successively invaded; I have known it to travel over the whole surface of the body. The febrile movement is more or less intense. Passive delirium and other ataxic symptoms are not infrequently developed; in other words, the typhoid state exists. The abdominal symptoms of typhoid fever are wanting; the career of the disease is shorter than that of typhoid fever. The symptoms are modified, and the disease, as regards duration and danger, is affected materially by the degree of intensity, the extent, and the local results of the erysipelas. The general principles of treatment are the same as in other of the continued fevers. In the existing state of our knowledge of this fever, I shall pass it by with this brief notice. It is sometimes classed among the eruptive fevers, but the erysipelas is hardly to be considered as a cutaneous eruption.

Epidemic erysipelatous fever, I shall also notice very briefly. It prevailed extensively in this country from 1841 to 1846. It was not confined to a particular section, but prevailed in certain districts in the New England, Middle, Western, and Southern States. In some localities great numbers were affected, and the mortality was large. It was commonly known in certain parts of the country as the "black tongue," from an appearance of the tongue occasionally observed. The medical journals of this country during the years just named and afterward, contained many articles relating to the prevalence of the disease in different localities. Of these, an article by Drs. Hall and Dexter, giving an account of the disease as it prevailed in Vermont,[1] and a paper by the late Dr. Bennett, of Bridgeport, Conn., are especially deserving of notice. The latter gives an analysis of various articles contained in different medical journals.[2]

The epidemic prevailed in isolated sections. It did not appear to migrate or to be transported from place to place. Its course was "irregular and erratic." Dr. Bennett, however, states that it sometimes appeared to follow the direction of rivers, small streams, and lakes. The attack was sometimes sudden and sometimes preceded by premonitions; the latter rarely existing longer than twenty-four hours, and being the same as those belonging to the access of other fevers. A pronounced and frequently prolonged chill, with or without rigor, ushered in the disease, accompanied often by pains in the extremities, and in some cases by great prostration. Pharyngitis was at once or speedily developed; this local affection was constant. It varied much in intensity in different cases. Not infrequently it was attended with great swelling of the tonsils, and sometimes sloughing occurred. The inflammation sometimes involved the larynx, and in a certain proportion of cases death was due to either laryngitis or œdema of the glottis. The lymphatic glands of the neck became more or less swollen, the swelling in some cases being very great, and occasionally suppuration taking place.

Erysipelas was far from being constant. The frequency of its occurrence varied at different times and places. Dr. Bennett observed it in only one-sixth of one hundred and fifty cases. In view of the fact that erysipelas occurs in only a certain proportion of cases, the propriety of calling the disease erysipelatous fever rests upon the absence of any other and better name. The erysipelas was seated in different parts. It was apt to lead to suppuration, gangrene, and sloughing. The danger and protractedness of the disease depended on the degree, extent, and local results of the erysipelas.

[1] *Vide* American Journal of the Medical Sciences, January, 1844.
[2] *Vide* New York Journal of Medicine, July, 1853.

The febrile movement was more or less intense. Erratic pains, like those of neuralgia and muscular rheumatism, were common during the course of the disease. Typhoid delirium and other ataxic symptoms occurred in severe cases. Petechiæ were sometimes observed. Abscesses, without erysipelas, occurred in some cases. The disease was not infrequently complicated with inflammation of serous membranes—the pleura, peritoneum, and the cerebral meninges. Pneumonitis was an occasional complication.

Different cases differed much as regards the gravity of the disease. In many cases the disease was mild and ended in five or six days. The severity and danger were generally due to the complications. Of the cases complicated with laryngitis, or œdema of the glottis, extensive erysipelas, serous inflammations, and pneumonitis, a large proportion ended fatally, the duration being indefinitely prolonged.

Puerperal peritonitis prevailed in conjunction with this epidemic so uniformly as to show a pathological relationship between these two affections. The opinion was generally held that the former was caused by a virus or miasm carried by the obstetrician from patients affected with the latter. Assuming this to be true in certain cases, puerperal peritonitis was by no means uniformly to be accounted for in this way. A rational explanation in many, if not in all, cases is that labor acted as an exciting cause and determined the situation of the local affection in those predisposed to the disease from the action of the epidemic influence. Many, if not most, practitioners held that the disease was communicable. Its contagiousness, however, cannot be considered as established.

As regards treatment, there was a diversity of opinion. Some practitioners advocated bleeding and other of the measures called antiphlogistic. But the majority, before the epidemic ceased to prevail, were convinced of the impropriety of these measures. In view of the symptoms, the nature of the disease, the tendency to suppuration and gangrene in the cases in which erysipelas occurred, and the other complications which were liable to occur, there can hardly be a question as to the propriety of measures of an opposite character. Tonic remedies, alimentation, and alcoholic stimulants, in other words, supporting measures of treatment, were indicated. Mild cases required little or no treatment; but in grave cases, were applicable the principles which should govern the management of other essential fevers with serious local complications.

Epidemic Fever Characterized by Pharyngitis.

In the winter and spring of 1857 an epidemic fever prevailed in the western part of the State of New York, in the adjacent parts of Pennsylvania, and in Canada, characterized by inflammation of the pharynx, of a mild grade of intensity, and unaccompanied by either diphtheritic exudation or much submucous infiltration. I reported the results of an analysis of 23 cases which I observed and recorded. A report of this epidemic, based upon notes of 37 cases, was at the same time made by Prof. Rochester.[1] The different cases presented great uniformity as regards the general and local symptoms. The fever commenced with a chill without rigor. The febrile movement, in all the cases, was considerable or marked. The severity of the disease was generally sufficient to keep the patients in bed for several days. The lymphatic glands of the neck were in most cases moderately enlarged, but without suppuration. Soreness of the throat was not a prominent symptom, even when the pharyngitis was marked. There was in no case an

[1] For both reports, *vide* Buffalo Med. Journal, 1857.

eruption. Vomiting did not occur, and generally the bowels were constipated. There were no symptoms of importance referable to the pulmonary and nervous system. The duration of the fever was from three to six days. It affected persons of either sex, and of all ages. The epidemic continued about two months, reaching its acme gradually, and gradually declining. In no case under my observation did it prove fatal.

The disease was not scarlatina, as shown by its affecting persons who had had that disease, by the fact that scarlatina did not prevail at the time, by the absence of an eruption in all the cases, by the non-occurrence of dropsy as a sequel in any case, and the fact that middle-aged and aged persons were attacked as well as children and infants. There were no cases of epidemic pharyngitis with exudation, or diphtheria, in that part of the country. The fever resembled the mild cases of erysipelatous fever which occurred during the epidemic prevalence of that disease, but erysipelas was not developed in any case. The cases bore a close analogy to those of influenza, except that the local affection was seated in the pharynx, and not in the Schneiderian and bronchial mucous membrane.

Dr. Harvey E. Brown, Asst. Surgeon U. S. Army, kindly communicated to me an account of an epidemic similar to that just described, which prevailed among the United States troops, stationed at Hart's Island, Long Island Sound, in January and February, 1866.

Palliative measures of treatment only were indicated.

CHAPTER IV.

PERIODICAL FEVERS.

Intermittent Fever—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Pernicious Intermittent Fever.

THE periodical are distinguished from the continued fevers by the occurrence of febrile paroxysms or marked exacerbations in a regular order of succession, thereby exemplifying a law of periodicity. This distinction applies more especially to the fevers called intermittent and remittent. Yellow fever is generally included among the priodical fevers, and belongs perhaps more appropriately here than in any other nosological division. The intermittent and remittent fevers are often distinguished as *malarial fevers*. These fevers will be found to present many striking points of difference, as contrasted with the fevers which have been considered in the preceding chapters. They differ not only in the events of the clinical history, but as regards the laws governing their causation, duration, complication, sequels, and the extent to which they are controllable by known remedies.

Intermittent Fever.

An intermittent fever is characterized by the occurrence of febrile paroxysms in regular succession, and by the absence of febrile movement between the paroxysms. The intermission is the distinctive feature of this form of fever, as its name implies. Popularly, the disease is known as "fever and

ague," "chill fever," "the shakes," and, by names expressive of the locality in which it is produced, as, in Louisiana "swamp fever," "Panama fever," "Chagres fever," etc. Although essentially the same disease, intermittent fever, as ordinarily presented in practice, is unattended with danger to life, but occasionally it is one of the most dangerous of maladies. I shall consider first simple or ordinary intermittent fever, and afterward, the grave forms of the disease under the head of *pernicious intermittent fever.*

Anatomical Characters.—Bronzing of the liver, spleen, and brain, which is found after death from remittent and pernicious intermittent fever, together with the presence of dark pigment in the blood (melanæmia), may be supposed to exist in more or less of the cases of simple intermittent fever in which the disease ends in recovery. These anatomical changes will be considered in connection with remittent fever. Aside from these and enlargement of the spleen, there are no known lesions which are characteristic of intermittent fever.

Clinical History.—The clinical history will embrace an account, *first*, of the paroxysm, and, *second*, of the intermission.

In the majority of cases the attack is sudden. In a certain proportion of cases, however, there are premonitions for a variable period. The premonitions are not very distinctive of this disease, consisting of pain in the head, yawnings, indisposition to exertion, loss of appetite, and general malaise. Although not very definite, they sometimes suffice to lead patients who have been repeatedly affected with intermittent fever, to anticipate an impending attack.

A paroxysm, when complete, consists of three distinct periods or stages, namely, the cold, the hot, and the sweating stage.

Cold Stage.—This stage commences with a feeling of chilliness, beginning in the loins and extending thence over the back and limbs. The chill is more or less intense, in some cases consisting of a slight creeping sensation of coldness with shiverings, and in other cases extremely severe. Muscular tremor commonly known as rigor may or may not accompany the chill. I have met with a single example of distinct rigor without a sensation of chilliness. During the chill, bristling of the hairs over the body, or horripilation, and the appearance familiar as "goose-skin" are often observed. Notwithstanding the sensation of coldness which the patient experiences, and the feeling of coldness when the hand is placed on certain parts, the thermometer in the rectum shows an increase of the temperature of the body. The thermometer, however, applied to the extremities, shows a decrease of temperature below that of health. The increase of the temperature of the body begins prior to the paroxysm. The sensation of coldness is sometimes limited to a part of the body, as the back, or to the extremities. During the rigor frequently the teeth chatter, and the movements of the body and limbs are sufficient to shake with considerable violence the bed on which the patient lies.

During this stage the patient frequently sighs, the pulse, which is usually accelerated, is small and feeble, the countenance has an expression of anxiety, the prolabia and face are pale, or frequently livid, and lividity is often marked at the roots of the nails. The general appearance is as if the person had been exposed to intense cold. The circulation is sometimes completely suspended in the fingers, which are waxy in appearance, devoid of sensibility, and bleed less than usual if wounded. Other symptoms are, mental irritability, a sense of oppression referred to the præcordia, pain in the head and limbs, and palpitation.

The duration of this stage varies from a few moments to two hours or even longer. The average duration may be estimated at from a half to three-

quarters of an hour. The transition to the next stage is sometimes abrupt, but generally gradual; flushings of heat are felt, the rigor ceases, the coldness, as it were, melts away, febrile movement is developed, and the cold stage is then ended.

The cold stage is not infrequently wanting, the paroxysm beginning with the hot stage. I have known a state of intense nervousness to take the place of the cold stage. Gastralgia or gastric irritability, as denoted by pain or incessant vomiting, are other morbid conditions which sometimes occur instead of this stage; also drowsiness or stupor and a condition resembling hysterical coma. Veritable coma is liable to occur, in this stage, in a form of the disease which will be noticed separately under the head of *pernicious intermittent fever*. In young children convulsions are apt to occur in the cold stage.

Congestion of internal organs is necessarily involved in the cold stage, inasmuch as there is less blood in the vessels of the surface, and the whole mass of blood is not diminished. But the primary and essential morbid condition underlies the congestion, and it is probable that the latter is an effect of an active contraction or spasm of the peripheral vessels, the blood accumulating in the internal organs in consequence of its being driven from the surface of the body. That the congestion incident to this stage does not stand in a causative relation to the other stages, is shown by the fact that the cold stage is sometimes wanting, and that the other stages in these cases are not less marked than when the cold stage occurs.

Hot Stage.—This stage is characterized by more or less intense pyrexia. The skin becomes hot, the pulse is accelerated and full or bounding, the face is flushed, the cephalalgia continues, but the pain in the limbs and the præcordial oppression disappear. The axillary temperature rises notably, usually reaching 105° or 106° Fahr. Thirst is usually a prominent symptom. The intensity of the pyrexia varies considerably in different cases. The duration of this stage is from three to eight hours. It is evident that in this stage the spasm of the vessels of the periphery, which existed in the cold stage, has ceased, and that in place of that morbid state, the distributing vessels of the surface of the body are abundantly dilated.

Sweating Stage.—Perspiration appears first on the face and afterward on the trunk and extremities. The pyrexia gradually abates, and at length disappears. The heat of the surface, cephalalgia, thirst, restlessness, etc., cease. The thermometer indicates a rapid defervescence, the heat falling to the normal standard. The patient obtains refreshing sleep. With this stage the paroxysm ends. As regards the amount of sweating, cases differ; it is sometimes profuse, and sometimes slight. The duration of the sweating stage is variable, the average duration being three or four hours. The sweating is evidence that the pyrexia is about to end. That it is the means of bringing the paroxysm to a close is by no means certain; it is a sign of the approaching intermission, and it may be an effect, rather than a cause, of the decrease of the pyrexia. During and succeeding the paroxysm, urea, uric acid, and the chlorides in the urine are increased. The urine is not infrequently albuminous, and occasionally there is hæmaturia.

The intermission, called also the apyrexial period, is the space of time between two successive paroxysms. The period from the beginning of one, to the beginning of the next, paroxysm, is called the interval, in distinction from the intermission. The duration of the interval is the basis of a division into varieties commonly known as the different types of the disease. Each variety or type observes a law of periodicity in the succession of paroxysms. There are three simple types of intremittent fever, namely, the *quotidian*, the *tertian*, and the *quartan* type. In the *quotidian* type the interval is

about twenty-four hours, or the paroxysm recurs daily, as the name imports. In the *tertian* type the interval is about forty-eight hours, or the paroxysm recurs on the third day, reckoning the days on which two successive paroxysms take place. In the *quartan* type the interval is about seventy-two hours, or the paroxysm recurs on the fourth day. As a rule, the paroxysms are uniform in each individual case as regards the occurrence of the cold stage, the duration of the several stages respectively, the severity of each, etc.; but they present considerable diversity in different cases. Of the three simple types, the quotidian and tertian type are by far the most frequent. Examples of the quartan type are comparatively rare. Of 98,237 cases of intermittent fever in the United States army, only 1757 were of the quartan type.[1]

As regards the relative frequency of quotidian and tertian cases, either variety may predominate at particular seasons. In the same locality the majority of cases are, at one season, of the quotidian, and, at another season, of the tertian, type. In an aggregate of cases occurring in a series of years, the quotidian type predominates. Of 98,237 cases in the United States army, 51,623 cases were of quotidian, and 44,857 cases of tertian, type.[2] Cases have been observed in which the paroxysm has recurred on the fifth, sixth, seventh, and eighth day, and hence there may be a quintan, a sextan, a heptan, and an octan type of intermittent fever. Such cases, however, are among the rare curiosities of clinical experience. In some cases, during the continuance of the disease, the type changes, the quotidian succeeding the tertian, or *vice versa;* such cases, however, are rare.

Cases are observed occasionally in which one of the simple types is duplicated; that is, two sets of paroxysms of the same type co-exist. Thus, one compound type is called a *double quotidian*, two paroxysms occurring daily. Another compound type is a *double tertian*. In a double tertian a paroxysm occurs daily, but the paroxysms on successive days take place at different hours, and may differ in various ways, whereas on alternate days they occur at the same hour, and correspond in other respects. Again, a tertian is doubled or duplicated when two paroxysms occur on alternate days. Another compound type is a *double quartan*. In this type a paroxysm occurs on two successive days, and on the third day there is no paroxysm. Finally, a *triple quartan* is a compound type in which a paroxysm occurs on three successive days, the paroxysms on these days presenting notable points of difference, but each paroxysm corresponding with that which recurs on the fourth day. These compound types, except the double tertian, are extremely rare, and merely interesting as curiosities of clinical experience. The double tertian is not very infrequently met with.

Paroxysms may occur at any hour of the day. They rarely occur during the night. In a large majority of the cases of the quotidian and tertian type, the paroxysms occur before noon; quartans are as likely to occur after, as before, the middle of the day. In infants the type is almost uniformly quotidian. As a rule, the successive paroxysms recur precisely or nearly at the same hour; but sometimes there is a variation from this rule, and the variation is in accordance with a law whenever the paroxysms are said to be either anticipating or retarding. They are anticipating when each successive paroxysm recurs earlier, by the same period, than the last. Thus, they may regularly anticipate half an hour, an hour and a half, etc. The paroxysms are retarding when each successive paroxysm is, in like manner, delayed. This variation in the time of recurrence is generally evidence that the disease is about to end.

[2] Ibid.

During the intermission there is much difference, in different cases, as regards freedom from ailments. In some cases the patient complains only of a certain amount of debility; the appetite and digestion are good, and there is no apparent disorder of any of the functions. In other cases marked prostration follows, the appetite and digestion are more or less impaired, and various disturbances exist.

Enlargement of the spleen is an occasional complication. The enlargement is often sufficient for the organ to be readily felt through the abdominal walls, constituting what is commonly known as the "ague cake" in districts where the disease prevails. The organ in some cases becomes enormously enlarged. This complication is not very frequent. It occurs in some cases when the disease has been of short duration, and it is by no means developed in the majority of the cases in which the disease has existed for a long period. Its pathological connection with the disease is not understood. It may continue for a considerable period after the paroxysms cease.

Anæmia is incident to the disease, especially if it have been of considerable duration. The pallor of the face in cases in which the disease has been protracted, or in which frequent relapses have taken place, is often associated with a yellowish or sallow tint, and with more or less œdema, giving rise to a characteristic facies. These characters denote what is called the *malarial cachexia*. General dropsy is an occasional concomitant or sequel. Notable anasarca with effusion into the serous cavities, is sometimes incident to the disease, and does not, therefore, necessarily denote either a cardiac or a renal affection. An herpetic eruption about the mouth is a frequent concomitant.

The duration of the disease is indefinite. It not infrequently ends spontaneously after a few paroxysms, but in many cases it continues for weeks and even months, if not arrested by curative means. Its indefiniteness of duration is a striking point of difference as contrasted with the continued fevers; its self-limitation is not, as in the latter, restricted within a certain period. Another not less striking point of difference relates to the liability to relapses. Subsequent attacks occur in the great majority of cases. The liability to relapse remains for many years. In some cases successive attacks occur regularly after a certain period, showing that in these cases the relapses take place in accordance with an intrinsic tendency, that is, irrespective of external causes. The notion was formerly entertained that the tendency to relapse was lessened if the disease be left to end of its own accord, or "wear itself out." So far from this being true, I believe that clinical experience shows a diminished tendency to relapse in proportion as the paroxysms are speedily interrupted by therapeutical interference. After the paroxysms have ceased to recur, either spontaneously or from the use of remedies, thermometric observations may show more or less increase of the heat of the body at the time when the paroxysm was to be expected. So long as these fluctuations of temperature occur, the disease has not completely disappeared, and relapses are liable to occur.

Physicians in malarial districts become familiar with cases which may be called cases of *latent intermittent fever*. In these cases paroxysms are not fully developed, but the patient complains of indefinite ailments, to which the term *bilious* is frequently applied. The appetite is impaired or lost; there may be nausea and occasional vomiting, with pain in the head, indisposition to exertion, etc. The tongue is frequently covered with a thin and very white coating. A close examination will sometimes disclose evidence of periodicity in an increase of ailments at regular periods on successive days or on alternate days, and slight manifestations of the several stages of a paroxysm may be observed. The thermometer in the axilla is useful as a means of diagnosis, in these cases, showing a periodical rise of tempe-

rature when the surface of the body may not show increase of heat, and the pulse is but little accelerated. In a case under observation at Bellevue Hospital, at the time of writing, the morning temperature in the axilla was 105° Fahr., the pulse being only 80, and at evening the temperature was 100°. Under the free use of quinia, the daily increase of temperature rapidly diminished, and in a short time ceased. The prompt relief afforded by treatment addressed to a suspected malarial condition, shows the correctness of the suspicion, and this treatment may be resorted to tentatively in cases of doubt. The affection, in these cases, is sometimes called *dumb ague*. This term is also applied to paroxysms in which rigors are wanting.

Intermittent fever is said to be *masked* in certain cases in which it is associated with other affections. It may exist in combination with various affections—bronchitis, pneumonitis, dysentery, etc. The association may render the periodical disease irregular, and interfere with the full development of the paroxysms. In these cases, it is not correct to apply to the associated affections the term malarial, meaning thereby that these affections are due to malaria. They are simply accompanied by phenomena proceeding from malarial disease existing in combination. In malarial districts the influence of malaria is apt to pervade all affections, and claims special measures of treatment. Of this fact practitioners in these districts become fully aware. Paroxysms of neuralgia sometimes appear to take the place of the paroxysms of intermittent fever, recurring with the same regularity after intervals corresponding to those in the different types of intermittent fever, and a cure is effected by the remedies which are efficacious in the latter disease.

Causation.—The causation involves a special morbific agent, commonly known as *malaria*. The existence of a special cause is logically inferred from the peculiar character of the disease, its limitation to certain localities called malarial, and the fact that it is controlled by remedies having a specific operation. The production of the special cause was attributed to vegetable decomposition in marshy localities, and called *marsh miasm*, in 1717, by Lancisci, an Italian writer. This doctrine, and the name, have since been very generally adopted. But that something more than ordinary vegetable decomposition is requisite for its production, is sufficiently proven by the disease being indigenous in certain localities, whereas, in certain districts and countries in which vegetable decomposition must take place abundantly, the disease never occurs. Observation shows that it is produced especially in marshy situations, but its production is not confined to such situations, and, hence, the name marsh miasm is inappropriate. The production of the special cause requires a temperature above 60° Fahr. In so-called malarial districts it is more abundantly produced when a dry follows a wet period. Turning up of the soil is apt to be followed by an increase of its production. It often disappears after the cultivation of soil for several years, so that highly malarial districts may, after a time, be free from malaria. On the other hand, the area of a malarial district is sometimes greatly enlarged by a gradual extension. During the last twenty years, the district surrounding the city of New York has extended far upward on the banks of the Hudson River, eastward into the State of Connecticut, and along the banks of the Connecticut River into Massachusetts, periodical fevers, until lately, not having been endemic in these situations for a long period.

The telluric source of malaria is proven by the fact of its being endemic in certain localities. Facts show that its specific gravity keeps it near the surface of the earth. Persons sleeping in an upper story may escape, when those sleeping on a level with the ground become affected. It is more abundant in the night-air than during the day, and hence the disease may often

be avoided by avoiding exposure in the evening, night, or early in the morning. The special cause of this disease is never reproduced in the bodies of those affected; that is, the causation never involves a contagium. Facts abundantly prove that the disease is not communicable from one person to another. The malarial fevers, therefore, belong among those distinguished as purely miasmatic.

Salisbury, in a paper published in 1866, claimed to have demonstrated the special cause of malarial fever to be certain species of algoid plants, called *palmellæ*. To these species he applied the names *gemiasma* and *ague-plants*. Among other points involved in the demonstration was the presence, in the salivary secretions and mucous expectorations of persons living in a malarial district, of the cells or spores of palmella, and their absence in persons residing in a situation not malarial.[1] It is stated, however, that these cells or spores are found in the secretions and mucous expectorations of healthy persons in Alpine regions and other situations entirely free from malaria.[2] Klebs and Tommasi-Crudeli have recently made some experiments in the vicinity of Rome, which are considered by these observers to prove that the special cause of malarial disease is a low vegetable organism. These observers did not confirm Salisbury's conclusions as to the kind of organism. They produced in rabbits, by the injection of watery extracts of marshy soil from a malarial situation, phenomena during life and appearances after death which they considered as characteristic of periodical fever, and these effects were not produced when extracts of soil from a situation not malarial were injected. They have isolated and cultivated a vegetable organism which they call *bacillus malariæ*, and which they suppose to be the special causative agent of malarial fever. It is stated that the spores and bacilli have been demonstrated in the spleen, the marrow of the bones, and the blood in cases of death from pernicious fever.[3] Further facts are necessary before we are warranted in accepting as an established truth that the special cause of malarial fever is a particular vegetable organism. Meanwhile, it may be said that this view is not only consistent with, but best explains, well-known facts relating to the causation, namely, the production of the disease in the summer season; its prevalence in marshy situations; the absence of the cause when parts known to be malarial are submerged, and the abundance of the cause in these parts in a dry season; the fact that certain countries and sections are never malarial, etc.

The period of incubation is indefinite; it may be a few days only, or a few weeks, but it is not infrequently many months, and perhaps years may elapse after the reception of malaria before its morbid effects are manifested. Auxiliary causes appear to be often necessary to give efficiency to the special cause. An attack is apt to occur after exposure to cold, over-exertion, excesses in eating or drinking, etc. The activity of the special cause is also often awakened by the occurrence of some other affection. The disease occurs especially in the spring and autumn, probably in consequence of the action of auxiliary causes in these seasons. The vernal intermittents are in general milder than the autumnal.

The disease shows no preference for either sex, and it affects all ages.

If the paroxysms be caused by the development and multiplication within the body of vegetable organisms, it is to be supposed that a crop sufficient to occasion an attack either dies or is eliminated when the paroxysm ends; and

that, from germs remaining in the system, other successive crops are produced after definite periods of time, corresponding to the different types of the disease. These different types would seem to imply different varieties of the ague-producing organism.

Diagnosis.—In well-marked cases the diagnosis offers no difficulty. The type is to be determined by the duration of the intervals and a comparison of the paroxysms. Latent and masked intermittents are not so easily recognized, and in arriving at a positive diagnosis the effect of treatment is sometimes to be considered. Febrile paroxysms resembling those of intermittent fever are sometimes observed in connection with pulmonary phthisis; they may present the three stages well marked, and recur at regular intervals. They oftener occur in the afternoon than in the forenoon, whereas the reverse obtains in intermittent fever. The co-existence of phthisis is to be taken into account in making this differential diagnosis, also the known exposure to malaria or otherwise. The treatment appropriate to intermittent fever will sometimes arrest the paroxysms connected with phthisis. Chills connected with suppuration in some of the internal organs may suggest, as probable, the action of malaria in malarial districts. The irregularity of their occurrence, the inefficacy of treatment specially directed to a malarial affection, and the discovery of the local affection will in time clear up the diagnosis. Happily the remedies indicated in malarial diseases are rarely hurtful in the cases in which intermittent fever is incorrectly supposed to exist. Operations on the urinary passages, such as catheterism and lithotrity, are apt to produce paroxysms resembling those of intermittent fever.

Prognosis.—Ordinary or simple intermittent fever, as regards immediate danger, is not a grave affection. Whenever the disease involves immediate danger, it is to be considered as pernicious, and not therefore belonging under the head of ordinary or simple intermittent fever. An important fact is that an intermittent fever at first devoid of immediate danger may become pernicious. An ordinary or simple intermittent may prove remotely serious, if it continue long or recur frequently, by inducing anæmia, general dropsy, or the malarial cachexia. The remote effects of the disease, however, are rarely in themselves fatal. Death may result from the association of intermittent fever with other affections. It has been supposed that this disease exerts a protective influence against the development of pulmonary tuberculosis; so far from this being true, there is reason to believe that it promotes the development of the affection just named in those predisposed to it. It is not a small calamity to contract intermittent fever on account of the liability to relapse, and to its recurrence in connection with other diseases.

Treatment.—For the cure of intermittent fever, medicine possesses specifics, if any remedies be entitled to this appellation. This statement applies especially to the salts of quinia, of which the sulphate and the bisulphate are almost universally used in this country. The salts of quinia will promptly interrupt the recurrence of the paroxysms of intermittent fever in the vast majority of cases. It is always desirable to arrest the disease as speedily as possible. Its morbid effects are less in proportion as it is quickly arrested, and the liability to relapses is diminished. There is no need of preparatory treatment. This position was taken by the author in an article published nearly 40 years ago.[1] An experience embracing many hundred cases in

[1] *Vide* American Journal of the Medical Sciences, October, 1841. This article contains a series of observations on the employment of quinia in single doses of from 20

different climates, since the date of that publication, has abundantly confirmed the correctness of this position. Aside from the delay in arresting the disease, the measures heretofore employed to prepare the system for quinia or other special remedies, were injurious. These measures were mercurial cathartics, emetics, and sometimes bleeding. They are not indicated in the treatment of intermittent fever. A consideration of no small importance, as enforcing an immediate employment of the abortive treatment, is the possibility of an intermittent fever, at first simple or ordinary, becoming, after several paroxysms, pernicious.

With respect to the time of giving the anti-periodic remedy, my experience has led me to the conclusion at which Bretonneau, Graves, Briquet, Trousseau, Murchison, and others have arrived, namely, that it proves most effective when given as near as possible to the paroxysm which has passed. It is probable that if it be given in the sweating stage, the chances of preventing the next paroxysm are greater than if the administration be delayed until after this stage. As regards doses, the most effective plan is to give the remedy so as to produce evidence of cinchonism as speedily as possible. This object may be accomplished by giving at a single dose the quantity supposed to be required. This quantity for an adult is from ten to twenty grains. A dose of from ten to twenty grains is generally tolerated by the stomach as well as smaller doses. An objection, however, to this method is that the quantity estimated as sufficient may not be large enough, or it may be larger than is required. A preferable method, therefore, is to give the remedy in smaller, but not in small doses, which are to be repeated at intervals of two or three hours until cinchonism is produced. The latter is indicated by *tinnitus aurium*, and this effect is, in general, evidence that a sufficient quantity has been administered. For an adult, five grains may be given at a dose, and repeated, after four hours, once, twice, or thrice, if necessary for the effect just stated. By this method of treatment, in a case of quotidian type, the chances that another paroxysm will or will not occur are about even. In a case of tertian type the chances that another will not occur predominate. If another paroxysm occur, the same method of treatment is to be repeated.

As regards the form in which the sulphate of quinia may be administered, it is most effective when given in solution, its solvency being secured by the addition of a minim of the aromatic sulphuric acid for each grain of the salt. Owing to the greater solubility, if given in pills, powders, capsules, or wafers, the bisulphate is to be preferred to the sulphate. If, owing to the irritability of the stomach, the remedy be not retained when given by the mouth, it may be given *per enema*. It is readily absorbed from the intestine; and the opinion has been held by some that it acts more efficiently when thus given. According to most observers, however, the quantity when given by the rectum should be larger than when given by the mouth.

The plan of treatment just described is almost invariably successful. If it fail, there is always reason to suspect that the preparation of quinia employed is spurious or adulterated. A difficulty, in some cases, relates to an intolerance of the remedy. Some persons are affected very unpleasantly by even small doses of a salt of quinia. This intolerance is not infrequently imaginary, but it is sometimes real. In such cases small doses must be given, or some one of the remedies to be presently mentioned substituted.

to 40 grains. At that time this treatment was novel and bold. The author believes that he was the first in this country to make observations in respect of the treatment of intermittent fever by large, single doses of quinia, without preparatory measures, and given at different periods in the paroxysm.

As a rule, small doses are curative in the cases in which the remedy is tolerated only in small doses. On the other hand, some persons are affected by the remedy only when full or even large doses are given; and, as a rule, such persons require larger doses than others. Cinchonism is the test of the requisite quantity having been given, but this need not be produced except in a slight degree. The co-existence of any affection does not contra-indicate the plan of treatment which has been described. In all cases in which intermittent fever is complicated with other affections, the primary object of treatment is to interrupt the paroxysm as speedily as possible. In children and infants the doses are to be less than in adults in proportion to the age. In young children, owing to the difficulty of administration by the mouth, the remedy may be given *per enema*. It may also be employed effectively by inunction, an ointment containing it being rubbed into the axilla, groins, and over the abdomen.

The hypodermic injection may be resorted to in cases of ordinary intermittents, when the remedy is not retained either by the stomach or rectum. This mode of administration has the advantage of economy as regards the quantity of the remedy required, experimental observation appearing to show that the effect is three or four times greater when thus administered than when taken into the stomach. The effect is also more quickly induced. It is, however, in cases of pernicious intermittent that the hypodermic injection of a solution of quinia is of special value, by reason of the certainty and promptness with which cinchonism may be induced by this mode of administration. In simple intermittents the risk of abscesses at the places where the injections are given renders them unadvisable. Binz states that pure amorphous hydrochlorate of quinia, lately introduced into commerce, is especially adapted for subcutaneous injection, dissolving in an equal weight of water, and not giving rise to abscesses.

After the paroxysms are interrupted, the remedy should be continued in small doses, from four to eight grains daily, for a considerable period. It is desirable to continue it for several weeks. If anæmia exist, a chalybeate should be conjoined. Relapses are prevented by this after-treatment. The diet should be nutritious, and a little wine with meals is advisable. Cathartics are to be avoided; given before the interruption of the paroxysms, they conflict with that object. If there be constipation, it should be remedied by mild laxatives or enemas.

The germ theory affords a rational explanation of the specific efficacy of quinia in this disease. This drug is destructive to certain low organisms; its efficacy is due to its action as a parasiticide. This statement will probably apply to other remedies which have a controlling influence over the disease.

Preparations of cinchona other than the sulphate of quinia are more or less effective in arresting intermittent fever. The sulphate of quinidia appears to possess an anti-periodic power not less than that of the sulphate of quinia. It has less bitterness and is more soluble. The sulphate of cinchonia and cinchonidia are much less effective. Amorphous quinia, called quinoidia, chinoidine, or the precipitated extract of bark, must be given in doses of double the size of the sulphate of quinia.

There are several succedanea of the preparations of cinchona which are capable of arresting the disease. Salicin is successful in a certain proportion of cases. From 40 to 60 grains are to be given in an intermission. The sulphate of bebeerine is frequently successful, and it has been claimed in behalf of this remedy that it does not produce the unpleasant effects which are sometimes caused by the preparations of cinchona. From 15 to 30 grains are to be given in the apyrexial period. The ferrocyanide of iron or Prussian blue I have found an efficient anti-periodic in doses of from one to two drachms.

Patients take it with reluctance, its appearance suggesting the idea of poison. Strychnia and nux vomica often succeed. Chloride of sodium, given to the extent of from eight to ten drachms in the apyrexia, effects a cure in a certain proportion of cases. Piperine sometimes proves curative. Many practitioners give this remedy in combination with the preparations of cinchona. Arsenic is, probably, next to the preparations of cinchona, the most reliable. Fowler's arsenical solution is the form generally employed, given in doses of five to ten drops three times daily to an adult. The muriate of ammonia, in doses of a drachm in the intermission, appears to exert an anti-periodic power. Nitric acid in doses of from 8 to 10 drops continued during the intermission and paroxysm, once in six hours, has been found to be efficacious. The iodide of potassium has proved successful, in some cases, when the disease has resisted quinia. To the foregoing are to be added the eucalyptus globulus and hydrastia. This list might be extended. It is to be borne in mind, in judging of the effect of remedies in this disease, that it tends intrinsically to end after a few paroxysms in a certain proportion of cases. All the known remedies which may be employed as succedanea of the preparations of cinchona are much inferior to the latter. None are to be preferred except in some cases in which, from an idiosyncrasy, the preparations of cinchona are not tolerated. They may sometimes come into play where the preparations of cinchona cannot be procured, and they have the advantage of being less costly than the latter.

Prof. Polli, of Milan, reported cases in which the sulphites proved curative. It is not claimed that they arrest the disease like quinia, but that the severity of the paroxysms is progressively diminished, and that the disease ends in a short time. He recommended the sulphite of magnesia as the most efficacious, which may be taken to the extent of an ounce or an ounce and a half in the twenty-four hours, in divided doses. Several American physicians of large experience in malarial situations have reported highly successful results from the employment of the sulphite and hyposulphite of soda.[1] In order to test fairly the efficacy of these remedies, I employed them faithfully, in 1868, in twenty successive cases in Bellevue Hospital, an ounce of the sulphite of magnesia being given daily. A report of these cases was made, at my request, by Dr. D. C. Chandler, then one of the house physicians of the hospital.[2] Of the 20 cases, in only 2 did the paroxysms cease under the use of the remedy. In 4 cases there was improvement while the remedy was continued. In 14 cases there was neither an arrest of the paroxysm nor any improvement.

The administration of pilocarpin at, or shortly before, the commencement of the paroxysm, has been found by Dr. Gasper Griswold to prevent or arrest the paroxysm, and in many instances there is no recurrence.[3] The remedy acts with most certainty if administered hypodermically. The dose for hypodermic use is one-fifth of a grain of the muriate of pilocarpin dissolved in ten minims of distilled water. Given by the mouth, the dose is one-fourth of a grain. For feeble patients these doses should be somewhat reduced. This method of treatment has sometimes succeeded in effecting a cure when the disease had resisted other measures. The efficacy of this treatment establishes the fact that to prevent a paroxysm, or to render it abortive, may be sufficient for the cure. A full opiate at the beginning of the cold stage often appears to shorten and modify the severity of the paroxysm. It sometimes, indeed, acts as an abortive measure, and may even effect a cure of the disease. I have known a sinapism applied over the whole length of the spine, at the

[1] *Vide* Am. Journ. of Med. Sciences, April, 1857, and January, 1868.
[2] *Vide* N. Y. Med. Record, 1869.
[3] *Vide* N. Y. Med. Journal, Aug. 1880.

commencement of the cold stage, to arrest the paroxysm and effect a cure. This result has been obtained by dry cups applied to the spine, and by friction with the spirits of turpentine. The method of McIntosh, namely, bleeding in the cold stage, was sometimes effectual, but, for obvious reasons, it is not to be recommended. A paroxysm appears to be sometimes warded off by taking to the bed before the hour when it is expected, and keeping up warmth of the body by bottles of hot water or other means. External warmth is useful in the cold stage, and stimulants may be given internally, if tolerated by the stomach. The internal use of chloroform has been highly recommended. Given in drachm doses (either alone, followed immediately with cold water, or suspended in mucilage), at the commencement of the paroxysm, it has been found to arrest the chill and induce a refreshing sleep, from which the patient awakens without prostration. The duration and severity of the paroxysm appear to be lessened by this treatment.

During the hot stage, relief is procured by sponging the body with cold or tepid water. Pieces of ice, ice-water, or carbonated water may be taken freely. During the sweating stage, comfort is promoted by wiping the body with warm flannel, and changing the linen and bedclothes.

Anæmia and general dropsy, occurring as sequels, claim tonic remedies, into which the preparations of cinchona and iron should enter, with nutritious diet and other hygienic measures calculated to restore the strength and invigorate the body. Enlargement of the spleen is to be treated with the sulphate of quinia or other preparations of cinchona, and a belladonna plaster or anodyne embrocations applied over the enlarged organ. If these measures fail, the iodide of potassium may be tried. Faradization and the cold douche applied to the region of the spleen have been found useful.

The preparations of cinchona, and other anti-periodic remedies, are efficacious as prophylactics. Taken in small doses daily by persons exposed to malaria, they ward off attacks of intermittent fever, and they prevent relapses. There is no foundation for the popular notion that the prolonged use of the sulphate of quinia, in small or moderate doses, is prejudicial to health. I have known an instance in which two or three grains had been taken daily for twenty years, the person having found by experience that by this means he was exempt from relapses of intermittent fever. Other means of prophylaxis have been already stated in treating of the causation.

Pernicious Intermittent Fever.

Simple or ordinary intermittent fever, as regards immediate danger, is not a grave disease. But the disease is sometimes presented in forms attended with more or less immediate danger, and it may prove fatal within a few days or hours. These forms of the disease are to be considered apart from simple or ordinary intermittent fever, and, collectively, they constitute a variety of the disease called *pernicious*, *malignant*, and *congestive*. Of these names the first is commonly adopted by writers. The term congestive, although much used in the southern and western portions of this country, is objectionable, as implying that the primary or essential pathological state is congestion, a doctrine which is probably incorrect.

Pernicious intermittent fever occurs in isolated cases wherever the simple or ordinary variety of the disease prevails; happily, such cases are extremely rare. But it prevails at certain epochs in malarial regions. Of the cases of intermittent fever which occur at these epochs, the proportion in which the disease is pernicious is more or less large. In some seasons the fatality from the disease is very great, and it constitutes one of the most formidable of the maladies which the physician has to encounter. In this country it has

chiefly prevailed in the Southern and Western States. Drake states that, of the interior valley of North America, the regions in which it has most frequently prevailed are, "the level portions of Alabama, Mississippi, and Louisiana, the southern shore of Lake Michigan, from Chicago around to St. Joseph River, and of Lake St. Clair and Lake Erie, from Lake Huron to Lake Ontario, near the estuaries of the creeks and rivers."[1] In view of the great danger attendant on pernicious intermittent fever, and of the fact that the success of prompt and efficient treatment is perhaps more conspicuous in this than in any other malady involving an equal amount of danger, the disease is one of great importance. It will, however, suffice to notice the symptomatic features by which the different forms are distinguished from simple or ordinary intermittent fever, together with the therapeutical indications.

Different observers agree that in many, if not in most, cases, a pernicious paroxysm is preceded by one or more paroxysms not characterized by any symptoms denoting gravity of disease ; hence the vast importance, especially whenever cases of the pernicious variety are known to have occurred, of resorting in every case at once to prompt and efficient measures to interrupt the paroxysms. But, in a certain proportion of cases the pernicious character of the disease is manifested in the first paroxysm, and death may take place in that paroxysm. Drake states that the pernicious character is sometimes foreshadowed by some slight anomaly in the first paroxysms, such as "a partial numbness or coldness of the great toes, instead of a regular chill, or a disposition to sleep at the access of the paroxysm." According to this author, in the cases in which the pernicious character is gradually developed, the cold stage in the early paroxysms is not strongly marked, the hot stage is imperfectly developed, and in the intermissions the patient may be pursuing his usual avocations. Both patient and physician are apt to be thrown off their guard by the mildness of the paroxysms preceding the one which is pernicious.

The symptomatic features of pernicious paroxysms vary much in different cases, and from these diversities this variety of the disease may be considered as embracing several forms. More or less complete coma characterizes some cases ; these cases are distinguished as *comatose*, *soporose*, or *apoplectic* intermittents. Other cases are characterized by delirium preceding coma. The delirium is sometimes active, the patients requiring to be restrained. Examples have fallen under my observation. Epileptiform convulsions occur in some cases. Intense jaundice appears early in the so-called *icteric* variety. A form called *algid* is characterized by notable reduction of temperature, the extremities becoming cold as marble, or the coldness being like that of a cadaver. Profuse sweating characterizes some cases. Vomiting and purging are, not infrequently, prominent symptoms, leading to a state of collapse like that in cases of epidemic cholera. The secretion of urine is sometimes suppressed, and albuminuria is not infrequent. In a form which may be called *asthenic*, there are great restlessness and prostration, with a notably small, feeble, and irregular pulse. The development of well-marked febrile movement, with a full, regular pulse and heat of skin, is evidence that the patient will struggle through the paroxysm. The danger to be apprehended from another paroxysm is proportionate to the severity of that from which the patient emerges with safety ; if the latter have involved very great risk, the next will be likely to prove fatal. The prostration in the intermission is in proportion to the severity of the paroxysm.

A form claiming distinct notice has prevailed in different parts of the Southern States of this country during the last twenty years. Its most dis-

[1] On the Principal Diseases of the Interior Valley of North America, 2d series, 1854.

tinguishing feature is hæmaturia. It has been called *hæmaturic malarial fever*. The term hemorrhagic is, however, to be preferred, inasmuch as, not infrequently, the hæmaturia is accompanied by hemorrhage in other situations, and the latter is sometimes the case without the presence of blood in the urine. Hemorrhagic malarial fever is not to be confounded with intermittent or paroxysmal hæmaturia and hæmoglobinuria, which have been considered (*vide* page 923). The disease described by Féraud under the name *melaneuric bilious fever*, as observed by him in Africa, has been supposed to be identical with hemorrhagic malarial fever. The two diseases, however, are essentially different, the urine in the former containing bile, but no blood, and hemorrhage not occurring elsewhere.

As described by Michel, McDaniel, Norcum, Webb, and other observers in the Southern States, *hemorrhagic malarial fever*, in the first, second, or third paroxysm, presents the characters of a simple intermittent. The pernicious paroxysm commences with a severe rigor. At the commencement of the hot stage, urine is voided, containing, in greater or less quantity, blood. The presence of blood-disks has been ascertained in recently emitted urine, but after decomposition of the urine these may disappear, and blood-pigment only be found. It is, however, as yet an unsettled question whether blood-disks are invariably present before decomposition has taken place; in other words, if hæmoglobinuria do not exist instead of hæmaturia. The amount of blood in the urine is sometimes considerable. Hemorrhage sometimes takes place, also, in other situations, namely, the stomach, bowels, uterus, nose, gums, blistered surfaces. It may occur in some of these situations without hæmaturia, but the instances are rare. Following the hemorrhage, the skin and other vessels of the body assume a bright lemon or a bronzed-yellow color. Some observers attribute this coloration to the presence of bile-pigment (hepatogenous jaundice), and others to altered hæmoglobin (hæmatogenous jaundice). The pulse is frequent and soft. Nausea, vomiting, and thirst are usually prominent symptoms. Restlessness and prostration are marked. Suppression of urine and uræmic poisoning occur in a certain proportion of cases. Delirium and coma sometimes take place without being referable to uræmia; but, as a rule, the mental faculties are preserved.

The association of hæmaturia or hemorrhage in some situations, and other symptoms denoting more or less danger to life, with malarial paroxysms of either the quotidian, double quotidian, tertian or double tertian type, suffices to distinguish this form of pernicious intermittent fever from paroxysmal hæmaturia, hæmoglobinuria, and yellow fever. From the so-called melaneuric bilious fever or malarious yellow fever, it is distinguished by the occurrence of hemorrhage. It is to be noted that, in a certain proportion of cases of hemorrhagic malarial fever, the urine contains bile, as well as either blood-disks or hæmoglobin.

The disease is always to be considered as dangerous, and, if the paroxysm be not at once interrupted, the danger is very great. Delirium and coma are almost fatal symptoms.

The diagnosis of all the forms of pernicious intermittent fever is aided by the fact that, as a rule, the dangerous paroxysm is preceded by at least one paroxysm, and, it may be, two or three paroxysms, devoid of any symptoms denoting danger, and by the fact that the pernicious paroxysm occurs in accordance with the type of the disease. In the forms characterized by coma, delirium, or convulsions, cerebral meningitis and uræmia are to be excluded. The former is excluded by the absence of symptoms of cerebral inflammation exclusive of those just named, and the latter is excluded by an examination of the urine. Microscopical examination may show the presence in a drop of

blood of black pigment. Enlargement of the spleen also has diagnostic significance.

Of the pathology of the several forms of pernicious, as compared with simple or ordinary, intermittent fever, all that can be said, with our present knowledge, is that the essential morbid condition existing in the latter variety in a degree not involving immediate danger, exists in the former variety in such intensity as to prove highly dangerous. Intermittent fever is not the only affection which, without any essential change in the nature of the disease, is in some cases extremely mild, and in other cases extremely formidable. Scarlet fever may be cited as another striking example. The difference as regards symptomatic phenomena and gravity, between pernicious and simple or ordinary intermittent fever, is not explained by lesions found after death.

Pernicious intermittent fever is often preventable, and many lives are saved by timely efficient treatment. It is doubtless prevented by promptly interrupting paroxysms before they assume a pernicious character. In seasons when pernicious cases prevail, there is much risk of lives being sacrificed by the delay in arresting the disease, incident to the employment of the so-called preparatory measures of treatment. In these seasons, especially, the curative treatment should be resorted to at once in all cases of intermittent fever, and the disease arrested as speedily as possible. When the disease has become pernicious, there are two great objects of treatment. One of these is to carry the patient safely through an existing paroxysm, the other is to prevent another paroxysm.

With reference to the first of these objects, the indications differ according to the differences of form which pernicious paroxysms assume, and according to the symptoms whatever may be the form. Enfeebled action of the heart always calls for stimulants, alcoholic, ethereal, and aromatic, severally or collectively. In many cases the danger of the disease is manifested chiefly by the symptoms referable to the circulation. In these cases the all-important indication is to strengthen the heart's action. Coma, unaccompanied by augmented force of the circulation and increased heat, does not call for bloodletting. Bloodletting has been employed in the cold stage of pernicious paroxysms of intermittent fever. That patients have recovered under this treatment by no means proves that it is devoid of danger. It is admissible only when the symptoms denote active cerebral congestion. Coldness of the surface is an indication for the external application of heat by means of warm blankets, bottles of hot water, etc., and for internal stimulants. Vomiting and purging are to be restrained by opiates given by the mouth or rectum. Opiates are also indicated by restlessness, delirium, and convulsions. In connection with the latter, the kidneys are to be interrogated with reference to the existence of uræmia. Emetics given at the commencement of the paroxysm, although they have been much used, are of doubtful utility, and cathartics should never be given. Chloroform, in drachm doses, deserves further trial as a means of abridging the cold stage. The doses should be repeated until the hypnotic effect of the remedy is obtained. Pilocarpin, administered hypodermically, will become an invaluable remedy if it prove as successful in arresting a pernicious paroxysm as it is in cases of a simple intermittent fever.

The second object, namely, to prevent another paroxysm, should enter into the treatment before the paroxysm, attended with more or less immediate danger, is ended. With reference to this object, nothing can take the place of the preparations of cinchona. The succedanea of these preparations are not to be relied upon if the latter can be obtained. The sulphate, bisulphate, or the muriate of quinia should be given during the paroxysm, and given in larger doses than in cases of ordinary intermittent fever, in view of the vastly

greater importance of arresting the disease, and because the tolerance of the remedy is often much greater. It is to be given during the paroxysm, not for its immediate effect, but to render more sure the prevention of another paroxysm. A scruple of the sulphate of quinia may be given at once, by the mouth, to an adult, and a larger quantity if given by the rectum. After three or four hours, if there be no evidence of cinchonism, the dose may be repeated. It is to be continued after the patient has emerged from the paroxysm, in doses of from ten to twenty grains, the intervals between the doses being sufficient to judge of the effect of each dose. Cinchonism should be produced and maintained during the intermission without reference to the quantity required; but to produce this effect the enormous doses which have sometimes been given are never necessary. Promptness and boldness are important, but excessive cinchonism is not advisable, and it is to be borne in mind that permanent blindness and deafness have resulted from the use of quinia in enormous doses. By pursuing the plan just stated, the remedy may be employed as freely as may be necessary to obtain, to the fullest extent, its remedial effect, without incurring much risk of injury from its toxical effect. In a case in which it was considered that the life of the patient depended on the prevention of another paroxysm, one hundred and twenty grains of quinia were given, in divided doses, in about twenty-four hours. The paroxysm was prevented, but suddenly, without having previously had symptoms of much cinchoism, he became completely blind and almost completely deaf. As may be imagined, great anxiety was felt; but happily, at the end of eight hours both the blindness and deafness had disappeared, and the patient recovered without any further untoward symptoms.

The administration of quinia by means of hypodermic injections has been found effective in cases of pernicious intermittent characterized by coma and inability to swallow. It may be resorted to when, from irritability of the stomach, the remedy will not be retained if given by the mouth.

The nostrum called Warburg's tincture is highly recommended by many East Indian physicians in the treatment of pernicious, as well as of simple, intermittent fever.

A pernicious paroxysm having been experienced, at the time when another paroxysm is to be expected, provided the type be known, and on the second and third day, if the type be not ascertained, the patient should be in bed at the hour when the recurrence is likely to take place, the body kept warm by artificial heat, and hot, stimulating drinks. An opiate will render more sure the prevention of the dreaded paroxysm.

After the interruption of the paroxysms, some one of the preparations of cinchona should be continued in tonic doses, with a nutritious diet and other restorative measures. After both the pernicious and simple variety of intermittent fever, if the malarious cachexia remain in spite of appropriate measures of treatment, removal without the sphere of the malarious influence during the season when this influence is rife, is to be advised.

CHAPTER V.

PERIODICAL FEVERS—(Concluded.)

Simple Remittent and Typho-malarial Fever—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Pernicious Remittent Fever. Yellow Fever—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment.

A FORM of periodical fever is distinguished by the occurrence of remissions instead of intermissions, and, hence, is called *remittent fever*. It is also known as *bilious remittent* or *bilious fever*. The term bilious is superfluous, and, so far as it has any significance, tends to perpetuate a pathological error. Between simple remittent and intermittent fever there is a close relationship. They are mutually convertible into each other, they undoubtedly involve the same special cause, and they are controlled by the same specific remedies. The propriety of recognizing remittent, as distinct from intermittent, fever is denied by some writers. Bouillaud calls it a "real nosological superfœtation!" There is, however, a practical convenience in considering the two forms as separate affections, admitting that they are essentially identical.

Remittent fever and typhoid fever may be associated. Not only may the former present typhoid phenomena or the typhoid state, but the two diseases occur not infrequently in combination. This statement embodies an opinion held for a long time by practitioners in malarial sections of this country and inculcated especially by Prof. Dickson. The late Dr. Drake maintained this opinion, calling the combined affection remitto-typhus fever.[1] I have for more than thirty years advocated this opinion in medical teaching.[2] More recently it has been proposed to employ a name denoting the union of the two affections, and the term *typho-malarial fever* has been introduced by Dr. Joseph J. Woodward.[3] I shall adopt this name, and consider remittent and typho-malarial fever conjointly. The facts which show the blending of remittent and typhoid fever will be noticed under the head of pathological character and causation.

Simple Remittent and Typho-Malarial Fever.

By the term simple remittent fever is meant remittent, not associated with typhoid, fever, and not accompanied by symptoms of gravity entitling it to be called pernicious. Pernicious remittent fever will claim a brief, separate notice. Typho-malarial fever will be considered in conjunction with simple remittent fever.

Anatomical Characters.—The characteristic lesion of remittent fever consists in the presence of dark pigment-granules in the blood and in various

[1] *Vide* The Principal Diseases of the Interior Valley of North America, vol. ii. p. 557.

[2] *Vide* article by the author in the Buffalo Med. Journal, 1857.

[3] *Vide* Outlines of the Chief Camp Diseases of the United States Army, etc. By Joseph Janvier Woodward, M.D., Assistant Surgeon U. S. Army, etc., 1863.

organs of the body. The parts chiefly affected are the spleen, the liver, and the marrow of the bones. When contained in the circulating blood, the pigment may be found in the bloodvessels of any part of the body. The presence of the pigment in the blood constitutes the condition called *melanæmia*. The pigmentation of organs is sometimes called *melanosis*. Melanæmia and melanosis attend remittent fever, pernicious malarial fevers, long-continued intermittent fever, and sometimes the malarial cachexia. The degree of pigmentation depends upon the duration and the severity of the malarial affection. It is, therefore, most intense in connection with the severe malarial infection of warm climates.

During a paroxysm of malarial fever the spleen is enlarged from hyperæmia. This swelling at first subsides during an intermission; but, under the influence of prolonged malarial infection, the organ becomes permanently enlarged, constituting the so-called ague-cake. The color of the swollen spleen varies from dark red or brownish to bluish-black in proportion to the amount of pigment present. The consistence is soft when the enlargement is recent, or when death has occurred during a febrile paroxysm; if there have been no recent attacks the consistence is firm. The swelling at first is due to hyperæmia; subsequently there is hyperplasia of the cellular elements of the spleen, with new formation and thickening of its connective-tissue framework. The pigment is in the form of granules and of larger masses, and is contained mostly within cells. In recent cases its color is reddish-brown—later it becomes black. The pigment is in the splenic pulp, and is also accumulated about the bloodvessels, especially around the veins. It is contained also within the splenic veins. Little or no pigment is found in the Malpighian bodies in most cases. The cells containing the pigment are chiefly the lymphoid cells, which constitute the principal cellular elements of the spleen. Pigment is also contained in larger and more granular cells, and in long fusiform cells which are considered to be endothelial cells of the veins.

The liver in most cases is enlarged, but in cases of long duration it may be atrophic. The consistence is usually more or less softened. The organ presents a bronze, chocolate, or slate color. It is called the bronzed liver and the pigment liver. It is usually hyperæmic. The pigment granules are found both in the interlobular tissue and within the lobules. They are inclosed chiefly within cells. They exist partly within the bloodvessels and partly in the extravascular tissue. The pigment is found mostly within lymphoid cells, but also in fusiform, and sometimes in stellate, cells. The fusiform cells are considered by many writers to be derived from the spleen, as similar cells exist there, and as the same cells are found in the blood of the splenic and portal veins. The melanæmic pigment does not exist within the hepatic cells. These cells, however, usually contain a considerable amount of yellowish-brown pigment derived from the biliary coloring matters. According to Kelsch, there is an increased number of lymphoid cells in the interlobular tissue. This writer also maintains that a form of cirrhosis may be produced by malarial affection of the liver.

Pigment is found in the marrow of the bones both outside of, and within, the bloodvessels. It is contained in lymphoid cells. Pigmentation of the brain forms a marked lesion in some cases of melanæmia. The change in color is most evident in the gray matter which acquires a dark gray or slate color contrasting markedly with the white matter. When the change is intense the white matter also has a dirty grayish tint, and presents many puncta vasculosa. In some severe cases capillary hemorrhages have been found in large number. These extravasations have been attributed to plugging up of the small cerebral bloodvessels with pigment. In melanæmic brains the pigment is present mostly within the small bloodvessels. It is also found in

the walls of the vessels and in the perivascular spaces. According to Arnstein, the pigment does not exist in large amount in the brain unless it is also present in the circulating blood. If pigment be present in the kidney, it is met with chiefly in the glomeruli. The accumulation of pigment in other organs than those named is not great. It may be found in lymphatic glands, in the spinal cord, in the lungs, in the pancreas, in the skin, in mucous membranes, etc. In these situations it is contained within the blood-vessels.

The characters of the pigment in the blood, the source of the pigment, and the relations between the pigmentation of organs and the presence of pigment in the blood, are subjects which have been discussed in the article on melanæmia in Part First (page 82).

After death from remittent fever, more or less congestion and inflammation of the stomach and of the intestine are frequently found. The mucous membrane of these parts may present ecchymoses. The solitary glands and Peyer's patches may be swollen. The latter often present the shaven-beard appearance.

The same parenchymatous and pseudo-waxy degenerations which have been described under typhoid fever, have also been found after death from severe malarial fevers.

Acute nephritis, dysentery, and pneumonia are rare complications of this disease.

In typho-malarial fever, in addition to appearances characteristic of malarial disease, the abdominal lesions which are essentially those characteristic of typhoid fever are found after death.[1]

Clinical History.—Under this head I shall present a brief sketch of simple remittent fever, as regards especially its distinctive features, and, afterward, of typho-malarial fever.

Simple remittent fever often commences abruptly, but, in a certain proportion of cases, it has a brief forming stage, the prodromes being the same as those attending the development of other fevers. The febrile career commences with a chill, more or less pronounced, either with or without rigor. During the chill, as in the cold stage of an intermittent paroxysm, the temperature of the body is actually raised, as shown by the thermometer in the axilla. The attack is oftener before than after mid-day. Febrile movement follows, varying in intensity in different cases, accompanied with cephalalgia, pain in the loins, etc. The thermometer in the axilla shows an increase of temperature from 2° to 10° above the range of health. The febrile movement continues unabated for 6, 12, 18, 24, and even 48 hours, and then notably subsides; the pulse falls in frequency, the skin becomes moist, the patient is comparatively comfortable, and may obtain refreshing sleep. The febrile movement, however, does not disappear, there is not apyrexia; there is a remission, not an intermission. The temperature in the remission, as compared with the exacerbation, is notably decreased, sometimes falling nearly to the normal standard. The remission is apt to occur during the night. The degree of abatement of febrile movement varies in different cases, sometimes approximating to apyrexia, and sometimes the remission being slight. The duration of the remission varies from two to three hours to one or two days. At the end of the remission, another chill may occur, but it is often wanting, and, if present, is generally slight; the febrile move-

[1] Woodward formerly believed that the intestinal ulcers of typho-malarial fever present certain peculiarities which distinguish them from those of ordinary typhoid fever. Extended studies have led him to abandon this view.

ment is renewed with as much or more intensity than before the remission. A series of remissions may ensue, recurring in regular succession, and, as regards the intervals, corresponding to the quotidian, tertian, or, frequently, the double tertian type of an intermittent fever. In a case under my observation, the double quotidian type was represented by the remissions, that is, two distinct exacerbations occurring daily. The remissions sometimes recur irregularly. Different cases differ as regards the number of remissions. There may be but a single remission, or, on the other hand, remissions may occur regularly through the whole course of the disease. The latter is rare; in general the remissions cease to be distinct after a few days, and, sooner or later, the fever becomes continuous. The febrile career ends during the second or third week. It eventuates in intermittent fever in a certain proportion of cases. In some cases, the disease is preceded by intermittent fever, remissions taking the place of the intermissions. During the remissions there is a marked abatement of the temperature of the body, the temperature during the exacerbations being notably increased. In this respect remittent fever differs from typhoid fever exclusive of the period of defervescence in the latter disease. The fall in temperature, as shown by the thermometer, may denote evidence of remissions which are not rendered apparent by the general symptoms.

Early in the fever, nausea and vomiting generally occur, and are frequently prominent symptoms, continuing more or less throughout the febrile career. The matter vomited is greenish or yellowish in color. Pain or uneasiness is usually referred to the region of the stomach, and there is tenderness on pressure over the epigastrium. Diarrhœa, tympanites, and iliac tenderness are wanting. Sordes is rarely observed. Delirium is rarely a prominent feature, and when present is due to the intensity of febrile movement. The urine is scanty, its coloring matter is increased, and its specific gravity is high. It is rarely albuminous. Jaundice occurs in a certain proportion of cases.

If simple remittent fever be protracted, certain symptoms denoting the typhoid state may appear, namely, low delirium, sordes, subsultus tendinum, etc. These symptoms are not sufficient to show the union of typhoid fever and remittent fever. They are liable to occur in all fevers and in various other affections.

In typho-malarial fever, the symptoms distinctive of typhoid fever are intermingled with those of periodical fever. The symptoms referred to are those connected with the abdominal lesions of typhoid fever, namely, diarrhœa, tympanites, and iliac tenderness. These symptoms become more or less marked during the second week of the career of the disease. The characteristic eruption of typhoid fever may be observed. The ataxic symptoms belonging to the typhoid state, namely, low delirium, deafness, subsultus tendinum, etc., occur more frequently, earlier, and are more marked than in connection with simple remittent fever. Enlargement and suppuration of one or both parotids are sometimes observed in cases of typho-malarial fever. This form of fever is preceded by a forming stage longer than in cases of simple remittent fever. The duration of the febrile career is longer, and the gravity of the disease is greater. Perforation of the intestine is liable to occur. Bronchitis is a common complication, and pneumonitis is developed oftener than in simple remittent fever. Convalescence is apt to be protracted in cases of typho-malarial fever. In different cases of the latter, the phenomena of typhoid fever and of periodical fever are intermingled in varying proportions; in some cases the periodical, and in other cases the typhoid, phenomena preponderate. In proportion as the phenomena of the one or the other disease predominate, cases will approximate, on the one hand, to simple remittent, and, on the other hand, to typhoid fever.

Pathological Character and Causation.—Simple remittent fever, as regards its essential pathological character, does not differ from intermittent fever. Both are due to the special poison known as malaria. True remittent fever is never contracted elsewhere than in malarial situations. The distinction between the two diseases is nosological rather than pathological.

Typho-malarial fever is caused by the combined action of malaria and the special cause of typhoid fever. Practitioners in malarial situations have been accustomed to say that remittent becomes converted into typhoid fever. This mode of expression is not accurate; there is not a metamorphosis of the one disease into the other, but a combination of both diseases, the phenomena of the one or of the other disease predominating in different cases. Typho-malarial fever is not a distinct type of fever. It is, however, of great importance to recognize the combination of typhoid and of malarial fever.[1]

Cases of typho-malarial fever occur in most, if not all, malarial regions. This fact shows that the special cause of typhoid fever is not held in abeyance by the prevalence of malaria, and produced only after the latter disappears. The extinction of malaria is followed by cases of unmixed typhoid fever, and hence it has appeared as if the latter follows in the wake of the periodical fevers. The typho-malarial fever prevailed largely among the United States troops in certain situations, during the recent civil war, especially in the Army of the Potomac, in the Peninsular campaign of 1862, when it was known as the *Chicahominy fever*. It was called elsewhere, during the war, *camp fever*.

Simple remittent and typho-malarial fever prevail especially in the autumnal season. Persons of all ages are liable to be affected with simple remittent fever. There is no evidence that this fever is ever contagious, nor that the malarial poison producing it is portable. Its occurrence affords no protection against its recurrence.

Diagnosis.—Simple remittent fever is readily discriminated from simple intermittent fever by the occurrence of notable remissions, instead of intermissions. The thermometer in the axilla may show the occurrence of these when they are not distinctly manifested by symptoms aside from the temperature of the body. A notable variation in temperature at different periods of the day in the early part of the disease, the mercury rising to a high point at one period and falling nearly within the range of health at another period, warrants the exclusion of typhoid fever. Exclusive of remissions, the differential diagnosis involves the following points;—

The abdominal symptoms of typhoid fever are wanting in simple remittent fever, and in place of these are the gastric symptoms distinctive of the latter, namely, nausea and vomiting, with tenderness over the epigastrium. The ataxic symptoms of the typhoid state are either wanting in simple remittent fever, or they occur at a later period. The typhoid eruption is wanting. The access is much oftener abrupt, and accompanied by a more pronounced chill. Paroxysms of intermittent fever are liable to occur at the close of a remittent fever. Finally, remittent fever is developed only in malarial districts, or in persons who have been exposed to malaria. There can be no question as to this differential diagnosis in cases of disease occurring in a situation where malaria is known not to exist, and when the patient is known not to have been within a malarial influence.

Typho-malarial fever is discriminated, on the one hand, from simple remittent fever, by the characteristic events of typhoid fever, namely, the abdominal

[1] *Vide* article by Woodward on Typho-malarial Fever, in the Transactions of the International Medical Congress, p. 305, Philadelphia, 1877.

symptoms, the eruption in some cases, the earlier occurrence of ataxic phenomena, epistaxis, and occasionally intestinal perforation. It is discriminated, on the other hand, from unmixed typhoid fever, by the characteristic events of periodical fever, namely, remissions, gastric symptoms, jaundice, and the eventuation, in some cases, in intermittent fever.

PROGNOSIS.—Simple remittent fever, in itself, does not involve danger to life. In fatal cases the termination is due to co-existing affections. Of course, it is to be understood that cases of pernicious remittent fever are not included under the head of simple remittent fever. An attack of remittent fever leaves behind it a liability to subsequent attacks of intermittent fever, and is liable to be followed by the sequels of the latter disease, namely, enlarged spleen, anæmia, and general dropsy. This disease differs much in severity at different times and places, and in different cases at the same time and place. As a rule, it is apt to be more severe in tropical than in temperate climates.

Typho-malarial fever is a much graver affection than simple remittent fever; it is certainly not less grave than typhoid disconnected from malarial fever. Like the latter, the rate of mortality differs at different times and places, owing to differences as regards the intrinsic tendency of the disease and a variety of circumstances. Data for determining the average death-rate are not available, as it has not been customary to separate cases of this disease from cases, on the one hand, of simple remittent fever in which the typhoid state occurs, and, on the other hand, of typhoid fever without the combined action of malaria.

TREATMENT.—The first and leading object in the treatment of simple remittent fever, is the arrest of the disease by anti-periodic remedies, of which the preparations of cinchona are by far the most reliable, the sulphate, the bisulphate, or the muriate of quinia being the preparations to be preferred. As soon as the character of the disease is determined by the occurrence of a remission, one of these salts of quinia should be given in a full dose, namely, from ten to twenty grains to an adult. The remedy should be continued in doses of from five to ten grains after intervals of from two to four hours, until it produces slight deafness or ringing in the ears, suspending the remedy when these manifestations of cinchonism appear. If other preparations of cinchona be used, they are to be given, in equivalent doses, in the same manner. If the remedy be not tolerated by the stomach, it should be given *per enema*. If cinchonism be not produced during the remission, the remedy may be continued during the exacerbation of fever. This is preferable to waiting for another remission. In a case in which the practitioner is satisfied that a remission has already occurred, in other words, whenever the diagnosis is clear, the remedy should be given at once, notwithstanding the intensity of febrile movement, without waiting for a remission. Time need not in any case be lost in order to resort to cathartics or other measures preparatory to the administration of an anti-periodic remedy. In short, the treatment is essentially the same as in cases of intermittent fever. This plan of treatment will succeed, in a large proportion of cases, in promptly arresting the disease.

Aside from the treatment just stated, palliative measures are to be employed according to the indications in individual cases. The indications will relate to pain in the head, nausea and vomiting, vigilance and restlessness, heat and dryness of the skin, etc. The same measures are to be addressed to these symptoms as when they are present in other fevers. It is unnecessary to consider these measures in this connection. The treatment during con-

valescence is the same as after other fevers, except that a preparation of cinchona should be employed for some time, in conjunction with a chalybeate, as after an attack of intermittent fever.

The plan of treatment which has been sketched does not embrace measures heretofore considered important in this disease, namely, emetics, cathartics, bleeding, and the use of mercury. Emetics are contra-indicated by the condition of the stomach. Cathartics are not indicated by the disease *per se;* they are required only to overcome constipation, and generally simple enemata or mild laxatives will suffice for this object. Bleeding is called for only by active cerebral congestion or intense febrile movement with augmented power of the heart's action, the patient being robust and plethoric. Under the latter circumstances, sedative remedies, saline laxatives, and cold to the surface will generally be sufficient without the abstraction of blood. The external use of cold water is highly useful when the skin is notably hot and dry. The wet sheet may be employed as in cases of typhoid fever. Opium, given in pretty full doses early in the disease, appears sometimes to exert an effect beyond that of a palliative, by inducing a more marked remission. The pathological views which formerly led practitioners to employ mercury freely in this disease are not tenable, and clinical observation affords no ground for regarding this remedy as specially indicated.

In typho-malarial fever the periodic element claims the treatment indicated in simple remittent fever. The object is to eliminate this element by means of anti-periodical remedies. Aside from this object, the hygienic and medicinal measures indicated are the same as in cases of unmixed typhoid fever. To consider these measures here would be to repeat what has been presented in the chapter in which the treatment of typhoid fever is considered. The reader is, therefore, referred to that chapter.

It is highly important to recognize the existence of the malarial element in cases of typho-malarial fever, with reference to a continuation of anti-periodic remedies throughout the course of the disease. I have known death to occur from a paroxysm of intermittent fever when the symptoms had denoted convalescence from the typhoid fever; the autopsy also showing that restorative processes were taking place in the intestinal ulcers. Probably in this case quinia in anti-periodic doses, continued throughout the course of the fever, would have prevented the fatal paroxysm.

Pernicious Remittent Fever.

A brief notice of pernicious remittent fever will suffice. This fever is distinguished as pernicious under circumstances similar to those which constitute grounds for the application of the same name to intermittent fever, namely, circumstances giving to the disease unusual gravity and danger. This variety of the disease is also called malignant and congestive. Pernicious remittent fever presents the same diversities, as regards symptomatic phenomena, as pernicious intermittent fever. In cases in which death takes place quickly, it is impossible to determine whether the disease be intermittent or remittent; a fatal result may take place before either a remission or an intermission occurs. The occurrence of an intermission or of a remission is the chief differential point. The two forms of disease, in a pathological view, are essentially the same, and they claim the same treatment. The importance of pernicious remittent fever is by no means to be measured by this brief notice of it; but inasmuch as all that is of practical importance in relation to this disease is embraced in the consideration of pernicious intermittent fever, the reader is referred to that portion of the preceding chapter which treats of the latter.

Remittent fever, especially the pernicious variety, has received, in different parts of the world, a variety of names denoting its geographical relations, such as Walcheren fever, African fever, Hungarian fever, jungle fever, lake fever, etc.

Yellow Fever.

The fever to be now considered has received a great variety of names, but it is at this time everywhere known as yellow fever, a name, the significance of which is derived from the frequent occurrence of yellowness of the surface of the body. Although the name relates to a symptom not constantly present, and occurring occasionally in other fevers, it has the merit of not involving any hypothesis concerning the nature or causation of the disease.

Anatomical Characters.—The morbid appearances which are most frequent are situated in the liver, in the stomach and intestine, and in the kidneys. The liver may be somewhat enlarged, but generally presents no marked change as regards size. It is pale in color rather than congested. Its consistence is often diminished. The most characteristic change is the yellow color which the organ presents in most, although not in all, cases. The change in color may affect the whole liver, or may exist in a larger or smaller number of scattered patches. The abnormal coloration is due to the presence of fat, as was proven by Alonzo Clark in 1853. The fat is in the form of large and small drops in the liver-cells. According to some observers, fat is found also in the interstitial tissue. The process is to be regarded as an acute fatty degeneration of the liver.[1] Some writers describe an actual disintegration of some of the hepatic cells in yellow fever. The yellow color may be due in part to jaundice of the liver. The combination of bile-staining and of fatty metamorphosis produces the so-called saffron-colored liver. Small ecchymoses are often found upon the surface of the liver. Schmidt describes the occasional presence in the liver, as well as elsewhere, of reddish-brown stains which he attributes to extravasations of hæmoglobin.[2]

The mucous membrane of the stomach is usually swollen, softened, and congested. Small hemorrhages are found in the mucous and submucous tissues. The stomach often contains a dark, bloody fluid, which is of the same nature as the black vomit to be described under the head of the clinical history. The cells of the gastric tubules undergo parenchymatous degeneration. Changes similar to those of the stomach are found in the upper part of the small intestine, and may extend downward to a variable degree. The upper part of the intestine contains in some cases black matter similar to that found in the stomach. The Peyerian and solitary glands of the intestine present no morbid alteration.

The kidneys are usually enlarged and the seat of parenchymatous degeneration. They often contain small extravasations of blood. Acute diffuse nephritis is a frequent accompaniment of yellow fever. In this condition the cortex is swollen and presents a yellowish-white color, mingled with congested and hemorrhagic portions. The epithelial cells of the convoluted tubes con-

[1] The presence of large oil-drops is not a sufficient criterion of fatty infiltration in distinction from fatty degeneration. (Consult Part First, page 55, and the article on Fatty Liver, page 619.) It is incorrect to regard the hepatic changes in yellow fever as comparable in degree or extent with those in acute yellow atrophy of the liver. There is still less ground for the assumption that the essential symptoms of yellow fever are referable to an acute parenchymatous or fatty degeneration of the liver (Liebermeister, Schmidtlein).

[2] Schmidt, The Pathology of Yellow Fever, New York Medical Journal, vol. 29, p. 128, 1879.

tain fatty molecules. Red blood-corpuscles are found in the tubes as well as in the intertubular tissue. Collections of emigrated white corpuscles are met with between the tubes. Miliary abscesses have been seen exceptionally in the kidneys of those who have died of yellow fever.

It is a remarkable fact that in so acutely infectious a disease as yellow fever the spleen undergoes no enlargement as a rule. The lungs are often the seat of hypostatic congestion. In many cases hemorrhagic infarctions have been found in the lungs. The pleura as well as the pericardium and other serous membranes frequently presents small ecchymoses. Parenchymatous and fatty degeneration of the myocardium has been frequently seen in some epidemics. The brain and its membranes present nothing distinctive. No changes have been discovered in the blood other than those belonging to most essential fevers. The attempts to discover a specific organism in the blood and tissues have thus far met with no success.

Clinical History.—An attack of yellow fever is usually abrupt. In a minority of cases it is preceded, for one, two, or three days, by languor, lassitude, loss of appetite, pain in the head, and chilly sensations. The attack is generally denoted by a chill, with or without rigor; the chill, in most cases, is of moderate intensity. Fever follows, differing in intensity in different cases; the temperature quickly reaches its maximum which varies from 102° to 110° Fahr. The pulse seldom exceeds 100. The tongue is moist, and more or less coated. Vomiting occurs in a certain proportion of cases early, but it rarely is a prominent symptom until a later period. Tenderness on pressure over the epigastrium is more or less marked. The bowels, as a rule, are constipated. Cephalalgia, the pain especially referred to the supra-orbital region, is usually present and is sometimes intense. Frequently pain in the loins, and pain in the lower limbs, especially in the calves of the legs, are prominent symptoms. This fever bears an analogy to smallpox in the frequent prominence of lumbar pain. The mind is usually clear, but occasionally delirium is manifested, rarely violent or active, and sometimes mirthful. The eyes are reddened, irritable, watery or tearful; this is quite constant, and so marked as to constitute a diagnostic feature. Otherwise, the organs of sense are not disturbed. In general, there are no pulmonary symptoms.

The pyrexia continues for a period varying from a few hours to three days. Then follows either a marked abatement or entire cessation of fever. A remission is said to take place; but this term is not always accurate, inasmuch as there may be complete apyrexia, and, in a certain proportion of cases, there is no return of fever. The condition following the febrile paroxysm has been called "the state of calm." This is reckoned as the second stage of the disease, the first stage embracing the period of fever, the latter called the "febrile period," the "stage of excitement," or the "paroxysm." The first stage may be regarded as constituting the disease proper, and whatever may follow, as sequels of the disease; the disease is then a fever with a single paroxysm. In mild cases, convalescence takes place immediately after this stage.

In grave cases the cessation of fever is often deceptive; the pains, etc., may cease, and the patient may feel as if convalescence had begun. But after a period, varying from a few hours to twenty-four, or longer, there are new symptoms more distinctive of the affection than those during the febrile paroxysm. The pulse sometimes falls below the normal frequency; it has been observed to fall as low as 40, and even 30 per minute. It is sometimes small and weak, and sometimes vibratory. It is always notably compressible, and has been called a "gaseous pulse." The surface is usually cool, especially of the parts of the body which are exposed. In the few cases which I have

noted, capillary congestion of the skin existed in a marked degree. Lividity of the back, attributable to hypostatic congestion, is sometimes observed.

Of the symptoms referable to the digestive system, those most characteristic pertain to the stomach. Vomiting occurs, if not already present, and, if present, becomes more prominent. In a large proportion of fatal cases, and in a few of the cases ending in recovery, the black vomit occurs. This, taken in connection with other symptoms, is pathognomonic of the disease. Heretofore there has been much discussion respecting the nature of the vomited matter, but it is settled that the appearances are due to blood changed by the action of the gastric fluids. As regards the gross appearances, the matter vomited is a thin liquid of a reddish, brown, claret, or blackish color, with sediment resembling coffee-grounds. Occasionally the liquid is bright red, the blood having undergone but little change. It rarely has a greenish or yellowish tinge from the presence of bile. The secretion is acid, and it has an acid taste without bitterness. It is sometimes acrid, excoriating the throat, tongue, and lips. The microscope shows the sediment to contain disintegrated particles of food, mucus, epithelium, blood-pigment, and deformed blood-disks often decolorized. Fungus-spores are often found. A fluid resembling the black vomit may be produced artificially by adding an acid to blood out of the body. The bilious matter vomited in some cases of remittent fever presents somewhat similar gross characters, but chemical and microscopical examination show the presence of bile and the absence of blood constituents. The black vomit in different cases of yellow fever is more or less abundant. It is sometimes ejected with force, and sometimes by an act of regurgitation rather than of vomiting. It generally ceases for a period of from 12 to 24 hours before death. The black vomit rarely occurs until after the febrile paroxysm; it occurs at variable periods afterward, but generally not until toward the close of the disease. Blair described a matter vomited prior to the black vomit, limpid or slightly opalescent, which he termed the "white vomit." Tenderness over the epigastrium is more or less marked, and the tenderness is sometimes extreme. The tongue is frequently reddened, dry, and cracked; in some cases it is moist and covered with a creamy coating, and sometimes it preserves its natural appearance.

During the second stage, the evacuations from the bowels are frequently of a brownish, approaching to a black, appearance; they resemble sometimes tar or molasses. This appearance is due to the presence of blood, so altered, however, in its passage through the intestinal canal, that its morphological characters are not demonstrable. Uric acid and the triple phosphates may be found in the evacuations from the bowels. Sometimes blood but little altered is passed from the bowels. Diarrhœa in this, as in the first stage, is rare. The abdomen is soft and seldom meteorized. The melænic discharges generally precede the occurrence of black vomit; they have been called the "black vomit stools."

Albuminuria is of frequent occurrence in grave or fatal cases. Hyaline and granular casts, red blood-corpuscles, renal epithelium, and epithelium from the bladder are found in the sediment of the urine.[1] A scanty secretion of urine or suppression not infrequently precedes a fatal ending. Uræmia occurs in a certain proportion of cases. The urine in certain cases becomes of a yellow or orange color from bile-staining, and it is sometimes bloody.

Yellowness of the surface of the body, whence the disease derives its name, occurs after the febrile paroxysm. The conjunctiva becomes yellow, and this, with the redness, gives to the eye a striking and peculiar appearance.

[1] *Vide* The Urine in Yellow Fever, by Prof. J. W. Holland, in the London Practitioner, July, 1879, and the American Practitioner, Sept. 1879.

The yellowness of the skin is especially marked on the chest and upper extremities. The jaundice is probably hepatogenous, but it is considered by some as hæmatogenous. It exists in only a certain proportion of cases; it occurs in a much larger proportion of fatal than of non-fatal cases—in fact, it occurs in a small proportion of the latter. The yellowness continues after death and into convalescence.

Hemorrhage in various situations, other than the stomach, intestine, and the kidneys or bladder, to which reference has been already made, is often a striking feature of the disease. It occurs from the nostrils, gums, uterus, wounds or abrasions of the skin, and sometimes from the eyes, meatus auditorius, finger-nails, holes bored in the ears for ear-rings, etc. Petechiæ and vibices are sometimes observed.

As regards symptoms referable to the nervous and the muscular system, coma and convulsions are of occasional occurrence. They are probably dependent on uræmia. Delirium is observed, but frequently the mind remains clear. Delirium may exist during the fever, and disappear afterward. Generally there is notable muscular prostration, but to this rule there are remarkable exceptions. Patients sometimes do not take to the bed, but keep about their usual avocations, not thinking themselves much ill, often a few hours before death. These have been called "walking cases." Rush relates a case in which the patient stood up before a glass and shaved himself on the day of his death. In a case cited by Bartlett, the patient, a soldier, continued to do duty until black vomit took place. In another case, the patient dictated and signed a letter a quarter of an hour before death. Cartwright cited an instance of a shoemaker who nearly finished a shoe the day before his death. Fenner saw a patient quietly reading a book after the black vomit had occurred. These cases exemplify a kind of cheerful delirium, as it was called by La Roche, in which the patient fancies himself well or but little ill.

The physiognomy of patients is described by different writers with a good deal of metaphor, but nearly all state that it is characteristic. The face is flushed. The appearance of the eyes is described by different writers as injected, brilliant, transparent, fiery, and glassy. To the facies is applied the following terms: suffering, dejection, anxiety, anguish, despair, terror, stupidity, vacancy, astonishment, sullenness, etc. The diversity of these terms raises a suspicion that the peculiarity of the physiognomy is less distinctive than observers have generally supposed; at all events, it appears to be difficult to convey a clear idea of the characteristic appearance by language.

The duration of the disease after the febrile paroxysm is variable; it varies from twelve hours to three or four days. In cases of great gravity, the duration is brief, the disease running rapidly to a fatal termination.

Writers recognize a third stage in fatal cases, called the stage of collapse, or the stage of exhaustion. The collapsed condition is denoted by prostration, feebleness and irregularity of the pulse, coldness of the extremities, low delirium in some cases, the intellect remaining clear in other cases, mental indifference or apathy generally existing as in cases of epidemic cholera—these symptoms showing tendency to death by asthenia. Coma and convulsions sometimes occur in this stage, attributable, probably, to uræmia. In some cases this period is characterized by great restlessness, jactitation, and general distress; but in other cases the patient remains quiet and seems free from suffering.

If death do not take place, the third stage is the stage of convalescence. When the disease passes to the second stage, and presents the grave symptoms belonging to this stage, namely, black vomit, hemorrhage, etc., the recovery is always slow, and is frequently preceded by fever having more or

less of the phenomena of the typhoid state. Relapses sometimes occur after convalescence appears to be declared.

In mild cases the disease ends in convalescence directly after the paroxysm of fever. Whenever an epidemic prevails, there is a certain proportion of cases devoid of any gravity. In these cases a slight chill occurs, followed by moderate pyrexia continuing for one or two days, and recovery quickly takes place. These cases would not be recognized as cases of yellow fever, except from the fact of their occurrence during the prevalence of an epidemic. When this mild form of the disease occurs, it is not infrequently a matter of doubt whether patients have had the disease or not.

More severe cases are distinguished by the intensity of the pyrexia. The term inflammatory, often applied to these cases, is not correct, inasmuch as the intensity of the febrile movement is not due to inflammation, but to the fever *per se*. Malignant cases are those characterized by black vomit, or profuse hemorrhage in other situations, followed by collapse or exhaustion, and also cases in which coma or convulsions occur with suppression of urine.

The duration of the disease is variable. Shortness of its career is a distinguishing feature. In the shortest cases, death or convalescence takes place in from two to three days. According to La Roche, the duration varies from three to nine days. The average duration is less than a week.

CAUSATION.—The peculiar features of this disease, its limitation within certain geographical boundaries, and its occurrence as an epidemic, warrant the inference that it requires for its production a special cause. Does the special cause emanate from the bodies of those affected with the disease; in other words, is the disease contagious? This question has given rise to much discussion. Volumes have been written by contagionists and non-contagionists in defence of the two opposing doctrines. It is evident that the question is one of great importance in its bearing on commerce and quarantine laws, as well as on the precautionary measures respecting exposure in visiting or attending upon those affected with the disease. For a full consideration of this topic the reader is referred to works treating *in extenso* of yellow fever, and especially to the elaborate treatise by La Roche. I shall simply state the grounds which substantiate the non-contagiousness of the disease.

1. The disease is confined within certain territorial limits. In this respect it differs from most diseases the contagiousness of which is established. Even in localities in which it is prevailing as an epidemic, it is sometimes restricted to a circumscribed area.

2. The rise and progress of epidemics are not consistent with its diffusion by contagion. For example, Fenner, with great zeal and fidelity traced the first 30 or 40 cases in the epidemic at New Orleans, in 1853, and ascertained that the disease broke out in different places among persons who could have had no communication with each other. Fenner investigated the origin and spread of the disease in New Orleans for twelve years, and stated that he never found the least proof of personal communicability. This is alike true of epidemics in other places.[1]

3. In certain places within the yellow fever zone, sporadic cases occur almost every year. According to Fenner a summer never passes in which there are not a greater or less number of sporadic cases in New Orleans, but the disease prevails as an epidemic only in certain years. Were the disease contagious, it should be diffused more or less whenever there are any cases of it.

[1] *Vide* article on "Epidemiological Conclusions and Suggestions," in Brit. and For. Medico-Chirurg. Review, Oct. 1870, page 484.

4. When it prevails as an epidemic, it spreads too rapidly to be diffused by contagion.

5. Persons going from a district where it prevails into a district where it does not exist, and becoming attacked in the latter, do not communicate the disease. There is abundant evidence that this is the rule, and the apparent exceptions are so few, and of such a character, that it is most logical to explain them otherwise than by the supposition of contagion.

6. Persons brought into close contact with yellow fever patients—physicians, nurses, other hospital patients, etc.—do not contract the disease.

7. Epidemics run a certain course, as respects duration, and abruptly end, in this respect resembling epidemics of cholera. The disease should prevail longer and disappear more slowly, if propagated by contagion. Like other epidemics, the disease, as a rule, becomes milder by continuance; it appears to absorb other diseases while it continues, in this respect resembling epidemic cholera, and its prevalence is arrested by cold. These facts, especially the two latter, are not consistent with the doctrine of contagion.

8. The great majority of those who have had an extensive practical acquaintance with the disease believe it to be non-contagious.

9. Experiments to test the question of communicability, by inoculation, by swallowing the black vomit, and by the utmost possible exposure, have led to negative results. To cite one among many experimental observations, Dowler gives the following account: In 1805, Don Cabanellos, a Spaniard, slept at night with his children in beds, in the Lazaretto, in which yellow fever victims had died. For submitting the question of contagion to this personal test he was made physician to the Royal Household, with an annuity of 1200 dollars. A number of galley slaves who accompanied him had one year's imprisonment remitted. The whole party amounted to fifty, and no one suffered any harm.

10. Complete seclusion has proved ineffectual to prevent the disease.

In view of the foregoing considerations, to which others might be added, yellow fever is not produced by means of a contagium. Yellow fever, therefore, is a purely miasmatic infectious disease, using these terms as already defined (*vide* page 89). Another question arises in connection with that of contagion, namely, may not the infection be transported in clothing, merchandise, etc., and the disease be in this way imported? Facts establish the affirmative to this question. The special cause can in this way be distributed by vessels, railroads, and other conveyances. The fact of the disease being portable renders judicious quarantine restrictions of vital importance, but in view of its non-contagiousness, the restrictions need not include the detention of persons.

Of the nature of the infection we have not, as yet, demonstrative proof. Something, however, is known of the conditions under which it is produced. It is indigenous in warm climates. Yellow fever is rarely developed south of 20° (south) or north of 40° (north) latitude. It prevails more in the Eastern than in the Western Hemisphere, and in certain parts of Europe and America than in Africa. In the Western world it prevails especially in the commercial towns on the Atlantic coast south of Charleston, S. C., on the Gulf of Mexico, and in the West India Islands. It rarely prevails in rural situations. It prevails only in the summer season in other than tropical climates, and in the latter chiefly during the hottest months. A high temperature is essential to its causation, but in yellow fever localities epidemics do not always occur in the years in which the temperature is highest. Humidity has been supposed to favor the development of the disease, but this is not conclusively established. There does not seem to be ground for connecting the causation with any known meteorological conditions other than a

high temperature. As stated by Nott, the special cause is most active near the ground; persons on a ground floor are more likely to be attacked than those in stories above. The miasm is more active at night than in the daytime.

In localities where the disease prevails often, the conditions for its development do not uniformly exist during the hot seasons. Epidemics occur only in certain years. It would seem that the efficiency of the special cause is favored by the co-operation of other causes, and, hence, sanitary measures—drainage, sewerage, removal of filth, avoidance of overcrowding, etc.—contribute to the prevention of yellow fever epidemics.

Unacclimation is a condition pertaining to individual susceptibility. Natives of yellow fever localities are rarely attacked. Particular epidemics, however, have been characterized by a considerable number of cases among the native population. Not having experienced the disease is another personal condition. The disease having been once experienced, the susceptibility to the special cause, as a rule, is extinguished. The number of persons who have the disease more than once is probably not greater than the number of exceptions to the rule that smallpox and typhus render the system insusceptible ever afterward to the special causes of these diseases. Acclimation, as regards this disease, is complete only when the disease has been experienced.

It would appear that the negro race is singularly exempt from a liability to this disease. Statistics show the mortality among negroes to be insignificant. It is stated, however, by Fenner that the insusceptibility is not nearly as great as mortuary statistics would seem to show, in consequence of the fact that the disease in the negro is almost invariably mild, and not likely to prove fatal. The susceptibility is not affected by age; persons of different ages, inclusive of infancy, are liable to the disease. Statistics show a larger proportion of cases among males than females.

The special cause is destroyed by cold. It is a matter of common observation that an epidemic is arrested by one or two hard frosts. "It is killed like insects and plants by a temperature of 32° F."[1] Epidemics, however, have a self-limited duration. Fenner noted that, at New Orleans repeatedly, the disease disappeared before the occurrence of frost. An epidemic rarely continues longer than from 60 to 70 days. Barlow calculated the average duration of yellow fever epidemics, and finds it to be 58.33 days, being somewhat longer than the mean duration of epidemics of cholera.

Of the nature of the special cause, or infection, as already stated, positive proof has not, as yet, been obtained; but that the disease is produced by specific germs or organisms is as logically established as with respect to any of the infectious diseases the causes of which have not been demonstrated. Assuming the existence of yellow fever germs, the production of the disease by filth or any local conditions, without the presence of these germs, can only be considered as possible by those who hold to the doctrine of spontaneous generation. While, as already stated, certain obvious local conditions may have an auxiliary agency, that these conditions are essential is disproved by instances in which the disease is developed in situations as healthy as possible in a sanitary point of view. The multiplication of germs without the body, therefore, may take place irrespective of any apparent local causes. The organisms which furnish the yellow fever germs are exotic as regards most, if not all, parts of this country. The sporadic cases which appear in New Orleans in seasons when the disease is not epidemic, are probably due to germs which have escaped destruction, having been placed under circumstances favorable for retaining their vitality. This has been called the

[1] Nott, *op. cit.*

"laying over" or the "hibernation of germs." Germs attached to clothing, or other articles, under favorable circumstances, may probably retain their vitality and infective capability for a long period.

The period of incubation is variable. It varies between two and fifteen days, and in the majority of cases it is nearer the first than the second of these numbers. Campbell has reported an instance in which the period was nearly six weeks.[1]

Diagnosis.—The access of the disease, and the symptoms during the febrile or first stage, present nothing very distinctive. All observers agree that it is often difficult to arrive at a positive diagnosis during this stage. In a considerable proportion of cases, the disease at the end of this stage terminates in convalescence. These cases would not be considered as cases of yellow fever except during an epidemic. The disease in these cases presents the characters of a febricula. The symptoms which have diagnostic significance are, the abruptness of the attack, pains in the back and limbs, and suffusion or redness of the eyes.

In cases progressing beyond the febrile paroxysm, and presenting the grave events which are liable to follow, the diagnostic features are sufficiently distinctive. They are, yellowness of the conjunctiva and skin, black vomit, hemorrhages elsewhere than from the stomach, epigastric tenderness, slowness of the pulse in certain cases, coldness of the extremities, suppression or a scanty secretion of urine, and the phenomena denoting collapse. All these events are not present in every case, but generally enough of them to render the diagnosis positive. The march of the disease to a fatal issue from the end of the febrile paroxysm, or the first stage, in well-marked cases, is peculiar, and it can hardly be confounded with any other affection.

Prognosis.—The mortality from yellow fever varies much in different epidemics. The range of variation is from 10 to 75 *per centum*.[2] The average mortality, according to calculations by La Roche, is 1 in 2.32. The rate of mortality differs in different periods of the same epidemic, the rule being a decrease in the rate as the epidemic approaches its termination.

Unfavorable prognostics are, yellowness of the surface, black vomit, great diminution or suppression of urine, abundant hemorrhage in any situation, coldness of the extremities, jactitation, hiccough, delirium, convulsions, and coma. Of these symptoms, black vomit and suppression of urine are almost invariably forerunners of death. Coma and convulsions are fatal symptoms dependent on uræmia.

A favorable prognosis cannot be confidently entertained in any case of this disease. Unfavorable events are liable to occur when, up to the time of their occurrence, the symptoms appeared to be favorable. Black vomit, hemorrhage elsewhere, uræmic convulsions or coma, are liable to occur unexpectedly in cases which appear to be progressing favorably.

Exclusive of cases in which the immediate cause of death is uræmic coma, the mode of dying is by asthenia.

Treatment.—With reference to the treatment of yellow fever, it is to be premised that no specific remedy has been discovered; there is no known plan of treatment on which reliance can be placed to cut short the disease. Another consideration to be premised is, the disease, exclusive of malignant

[1] The Yellow Fever Germ on Coast and Inland, by Henry F. Campbell, M.D. Trans. of the Med. Association of Georgia, 1879.

[2] Da Costa, Medical Diagnosis.

cases, tends to recovery. Mild yellow fever is a very mild disease, not tending to destructive lesions of either the solids or fluids; nor does it tend to continue indefinitely, if not arrested, like intermittent fever.

A third preliminary consideration is that, in a considerable proportion of malignant cases, the disease is necessarily fatal. Hence, a large proportion of fatal cases is by no means proof of injudicious treatment. And a fourth consideration is that different epidemics differ as regards the relative proportion of mild and malignant cases. In some epidemics the majority of cases are mild, in others malignant. It follows that the ratio of recoveries under a certain plan of treatment may be no test of the superiority of that plan. Measures which appear to be eminently successful in one, may appear equally to fail in another, epidemic, the difference being due to variations as respects the tendency of the disease to a fatal issue.

In cases of mild yellow fever, no active interference is required. Quietude, restricted diet, ventilation, and other hygienic regulations, together with such palliative measures as particular symptoms in individual cases may indicate, suffice for the treatment. The palliative measures will embrace anodyne and refrigerant remedies, cold applications to the head, sponging of the body, laxatives in some cases, etc. It is, however, to be borne in mind that the disease may become malignant in cases which are at first mild in appearance. It is impossible always to distinguish at the outset the cases which will prove to be mild; hence, it is of vast importance to take every precaution to prevent the development of grave symptoms. For this end, hygienic measures are especially or chiefly important. Patients should at once give up to the disease and take to the bed. As complete rest of body and mind as practicable is to be enforced. The services of a faithful and experienced nurse are of more importance than any medication. Free ventilation, cleanliness, and other sanitary measures are not less important in this than in other forms of fever.

In cases characterized by intensity of fever during the febrile paroxysm, no one entertains at the present time the propriety of bloodletting. Antipyretic measures of treatment, namely, cold sponging and the wet sheet, are rationally indicated. Data are not as yet available for forming an opinion as to the efficacy of these measures in preventing the grave events of the disease and lessening its mortality.

Purgatives have been much employed in this as in most other diseases. Drastic or active purgatives do harm by increasing the gastro-intestinal irritation and producing exhaustion. Even if well borne, it is difficult to see what indication they fulfil which may not be equally fulfilled by mild laxatives or simple enemas. The latter are indicated by constipation. Purgation, except in some cases for the purpose of eliminating urea, is to be avoided. Emetics, which have also been much used, are contra-indicated by the gastric symptoms which belong to the history of yellow fever.

Mercury has been considered as important in this disease. Calomel in large doses has been much used, and it has been thought to be desirable to produce ptyalism. This practice has now but few advocates. Facts do not warrant the opinion that mercurialization is in any sense curative, and the testimony of most physicians who have had practical acquaintance with this disease, is adverse to the use of mercury in any form.

Measures to relieve gastric irritability are often indicated. For this end, counter-irritation over the epigastrium may be employed by means of small blisters, dry-cupping, sinapisms, and stimulating liniments. Anodynes, given either *per orem* or by the hypodermic method, are indicated for this end. Other remedies are, chloroform in small doses, prussic acid, and creasote. Ice swallowed in small pieces has been found useful in allaying irritability of

the stomach. To prevent black vomit, and with a view to arrest gastric hemorrhage when it has occurred, the acetate of lead with opium has been much extolled. With reference to this event, careful attention should be given to the ingesta. Milk with lime-water, not given in large quantity, is probably the best article of diet. If sustaining measures be not indicated, bland liquids only should be taken into the stomach.

Hemorrhages elsewhere call for local styptics if the source of the hemorrhage be accessible, and for ergot or other hæmostatics. In a case related to me by a former colleague, life was apparently saved by the transfusion of blood.

Great restlessness and vigilance call for opium or other anodyne remedies. Deficiency of the urinary secretion is an indication for diuretic remedies if they be tolerated by the stomach, and for measures to produce diaphoresis if diuretics be not borne or if they prove inoperative. If symptoms be present denoting uræmia, the hot air bath should be employed. Under these circumstances, elaterium or some other hydragogue may be advisable, if relief be not procured by diaphoresis.

Sustaining measures are indicated in proportion as a tendency to collapse or death by asthenia is denoted by the symptoms. The irritability of the stomach may interfere with the sustaining treatment. The forms of stimulus and nourishment are to be selected which, on trial, are found to be best borne. Alcoholic stimulants may be given *per enema*, if not retained by the stomach. Two of my colleagues in the New Orleans School of Medicine, who had experienced this disease in its severe or malignant form, attributed their recovery to the free use of alcoholic stimulants. In one of these cases, when a fatal termination was regarded as imminent, a favorable change occurred immediately after champagne had been given freely.

Measures for the prevention of yellow fever relate, 1st, to the removal of local conditions which favor the multiplication of the disease-germs, 2d, to quarantine regulations, and 3d, to disinfection. The first of these three divisions embraces all that pertains to public and private hygiene. The local conditions especially important as auxiliary causes are unknown, and, therefore, it can only be hoped that they will be reached by rendering sanitary measures as complete as practicable. But, be these measures never so complete, they do not make superfluous those of quarantine and disinfection. The object of quarantine regulations is that the disease-germs shall not be imported. To effect this object, either there must be non-intercourse with places in which the disease prevails, or all articles of merchandise, clothing, etc., brought therefrom must be thoroughly disinfected. To be efficient, quarantine regulations must include, not only vessels from infected parts, but inland transportation by railroads and other conveyances. There is no danger of the disease being carried by the living body after disinfection of the wearing apparel, nor by the bodies of the dead. Detention of the well or the sick is, therefore, a needless precaution, except to prevent groundless popular apprehensions. If importation of the germs have taken place, the houses with their surroundings in which cases occur, should be instantly and completely disinfected. The object now is to "stamp out" the disease. There is ground for the belief that this object may be effected if measures of disinfection be promptly and thoroughly carried out.

During the prevalence of an epidemic, unacclimated persons should avoid going within the infected area, except under a sense of duty, and they who are already within this area should leave it, unless there are motives for remaining which render the risk of life justifiable and praiseworthy.

CHAPTER VI.

ERUPTIVE FEVERS.

Variola, or Smallpox — Anatomical Characters — Clinical History — Causation — Diagnosis—Prognosis—Treatment. Varioloid, or Modified Smallpox. Vaccinia, or Cowpox. Varicella, or Chicken-pox.

THE fevers which remain to be considered are characterized by an eruption or exanthem, and hence they are called eruptive or exanthematous fevers. The continued fevers, typhus and typhoid, have also an eruption, but the eruption is less constant and less prominent than in the eruptive fevers. The eruptive fevers are *variola*, or smallpox, including the modified form known as *varioloid; varicella*, commonly called chicken-pox; *rubeola*, or measles; *scarlatina*, or scarlet fever; and *roseola*, or rose-rash. The eruption in two of these fevers is moist, that is, vesicular or pustular; this is true of variola and varicella. In the remainder the eruption is dry, and is properly an efflorescence or rash. To the latter kind of eruption the term exanthem is, strictly speaking, restricted.

The eruptive fevers were formerly considered as varieties of one disease, and the individuality of each was not fully settled much before the present century. Each is a distinct species of fever, having phenomena and laws peculiar to it, and its own special cause. All, with the exception of roseola, are propagated by special causes reproduced within the body; that is, they are communicable diseases.

The division of the career of the disease into stages is the same in all the eruptive fevers. The first stage is the stage of invasion or the access; this stage begins with the first manifestations of disease, and ends with the first appearance of the eruption. The second stage is the stage of the eruption, and extends from the time when the eruption first appears to its disappearance; this stage is subdivided in variola. The stage of desquamation, or desiccation, follows the eruptive stage, and either constitutes, or is followed by, the stage of convalescence. The consideration of these fevers will also embrace the periods of incubation, and certain events liable to occur after the disease, or sequels.

Variola. Smallpox.

The discovery of vaccination, by the immortal Jenner, toward the close of the eighteenth century, has divested this disease of much of the importance which it had in the two previous centuries, when it ranked first among the acute affections destructive of human life. It is not, however, so rare, even in its unmodified form, at the present day, but that cases are liable to come under the observation of every practitioner. The gravity and loathsomeness of the disease, together with its contagiousness, render highly important an early diagnosis and judicious management. I shall consider first unmodified variola, and afterward, under a separate head, the modified form of the disease known as *varioloid*. The latter head will embrace the consideration of variola produced by inoculation.

Anatomical Characters.—The characteristic lesion of smallpox is the eruption. The successive stages of the eruption are the macule, the papule, the vesicle, and the pustule. The pustule undergoes desiccation. The *macule* is a reddish, slightly elevated spot due to congestion of a circumscribed portion of the skin. The microscope shows that in this stage the capillaries of the papillæ of the corium are dilated, tortuous, and elongated. The connective tissue of the papillæ is slightly œdematous. The *papule* is due chiefly to swelling of the epithelial cells of the rete Malpighii, and to the appearance in the same situation of little cavities containing a clear fluid. It is to be noted that cavities holding fluid are present in the papule as well as in the vesicle, but in the latter they are so large that the vesicular structure is evident to the naked eye. The swelling of the epithelium and the small cavities are present chiefly in the middle layers of the rete Malpighii. According to many writers, the lowest layer of cells in the rete Malpighii is unchanged in this and in the vesicular stage of the eruption. Weigert,[1] however, has shown that in the centre of the pock the lowest cells of the rete Malpighii have undergone a peculiar metamorphosis, by which they are transformed into irregularly shaped, opaque masses devoid of nuclei. To this change he has given the name *diphtheroid metamorphosis*, as it resembles the change described by Wagner as occurring in the epithelium of mucous membranes in diphtheria. The metamorphosis belongs to the group of the coagulation-necroses described in Part First, pages 52 and 53. The body of the cell is changed into a substance which Weigert compares in its properties to fibrin, the nucleus disappears, and the altered cells present a variety of shapes, some being branched, and others formless clumps. Weigert regards this necrosis of cells in the rete Malpighii as the first and the characteristic effect of the smallpox poison upon the skin. The diphtheroid metamorphosis affects only a certain number of cells in the base of the pock.[2]

Another alteration which many of the epithelial cells undergo, is the formation in their protoplasm of spaces or cavities containing a clear, serous fluid. This alteration has been called *serous infiltration* and *vesicular or dropsical transformation* of the cells. The cells in the upper and the middle layers of the rete Malpighii are those chiefly affected. At first a clear ring forms around the nucleus; this transparent zone increases in size until nearly the whole cell is converted into a cavity, the wall of which is formed by the outer border of the cell. One nucleus and sometimes several nuclei may be found in the cavity, or the latter may contain nothing but a transparent or slightly turbid liquid. In this vesicular transformation the cell becomes swollen, so that the cavity may be larger than the original cell. The boundaries separating adjacent cell-cavities may become ruptured, so that by the coalescence of several cavities larger spaces with irregular walls are formed. In this way many explain the formation of the vesicle out of the papule (Wagner, Cornil, Leloir). According to this view, in the papule a large number of the epithelial cells in the upper Malpighian layers become swollen

[1] Weigert, Anatomische Beiträge zur Lehre von den Pocken, Theil I., Breslau, 1874.

[2] This is a fact which does not seem to have been considered by those who have failed to confirm Weigert's observations on this point. A perpendicular section through the periphery of the pock will often contain none of the necrosed cells. Every section of a series passing through the entire thickness of the pock must be examined before it can be said that a focus of diphtheroid metamorphosis is absent. Leloir, in his recent elaborate article on the formation of pustules and vesicles (Archives de Phys., 1880, p. 307), seems to be under the misapprehension that Weigert holds the opinion that every epithelial cell in the pock loses its nucleus and undergoes coagulation-necrosis.

and transformed into cavities, the walls of which are represented by the condensed peripheral layers of the cell. These cavities, by rupture of their walls, open into each other, and when large spaces containing a clear fluid have thus been formed, the appearance is that of the characteristic smallpox *vesicle.* The interior of the vesicle is subdivided by a network or reticulum composed of altered epithelial cells. But the vesicular transformation of cells is not the sole origin of the small cavities of the papule, or of the larger spaces of the vesicle. The serum which transudes from the capillaries of the corium penetrates the epidermis, and not only enters the cells, but also makes its way between the cells which are thereby pushed apart. Thus, spaces containing serum exist between the cells as well as within the cells. The extra-cellular accumulation of serum and the coalescence of intracellular cavities combine to form the spaces of the smallpox vesicle.

The manner in which the *reticulum* of the smallpox vesicle is formed, has been, and is still, a matter of controversy. The reticulum consists of coarse and of fine bands which stretch from the floor to the roof of the vesicle, and which interlace in the interior of the vesicle. It is generally admitted that these bands are composed of more or less altered epithelial cells. Weigert believes that the reticulum is formed in great part of irregular and branching masses (called by him Schollen) which represent cells that have undergone the diphtheroid metamorphosis or coagulation-necrosis. Cornil and Leloir are of the opinion that the reticulum is formed mainly by the borders of cells in whose substance cavities have appeared, these borders representing the partitions between the intracellular cavities. All, however, admit that at least some of the bands are composed simply of epithelial cells which have been compressed, elongated, and displaced by the accumulation of fluid between them.

The roof of the smallpox vesicle is composed of the stratum corneum, the stratum lucidum, and often some of the upper cells of the rete Malpighii.[1] The sides of the vesicle are formed of cells in the middle layers of the rete Malpighii; the floor of the vesicle is composed of the lowest cells of the rete Malpighii, some of which have undergone the diphtheroid metamorphosis. Some of the epithelial cells in the sides and in the base of the vesicle are enlarged, and often contain two or more nuclei. There is reason to believe that in these situations there is an active proliferation of epithelial cells.

A characteristic appearance of the smallpox vesicle is produced by a central depression in its roof. This depression constitutes the so-called *umbilication of the vesicle.* Not every smallpox vesicle is umbilicated. Vesicles in the palm of the hand and in the sole of the foot are not umbilicated. There have been various theories as to the cause of the umbilication. Some have attributed it to the existence of a sweat-gland or of a hair-follicle in the centre of the vesicle. The umbilication may, however, be present in vesicles which are not formed around hair-follicles or sudoriparous glands. The most plausible explanation is that which attributes the central depression to swelling and proliferation of the epithelial cells in the sides of the vesicles. The influence of this cause is aided by the presence of bands which pass from the centre of the roof to the floor of the vesicle. These bands, the existence of which has already been noticed, act as retinacula which hold down the central

[1] The different layers of the epidermis from without inward are: 1, stratum corneum, composed of non-nucleated horny scales; 2, stratum lucidum, composed of flattened, refractive cells, with nuclei or rudimentary nuclei; 3, rete Malpighii or stratum mucosum, composed of nucleated epithelial cells, the layer next to the corium being more or less cylindrical in shape. The upper cells of the rete Malpighii contain peculiar granules, and constitute the stratum granulosum of some histologists.

part of the roof, while the sides of the vesicle are swollen by the enlargement and proliferation of cells and by the accumulation of serum.

The smallpox vesicle is filled with serum, called, in this situation, lymph. The serum may be perfectly clear; it usually contains a few pus-cells and some granular material. Weigert and Cohn have demonstrated that some of the granular material consists of micrococci. The pus-cells are probably emigrated white blood-corpuscles. The presence of pus-cells in the intracellular cavities does not prove that they are produced by endogenous proliferation of the epithelial cells. They can wander into these cavities from without. A delicate network of fibrillated fibrin is sometimes found in the lymph of the vesicle.[1]

The lymph in the vesicles becomes more and more clouded by the presence of pus-cells. By the accumulation of these cells the vesicle is gradually transformed into a *pustule*. As the pus-cells increase in number the reticulum within the vesicle is destroyed, so that the fully formed pustule consists of a single cavity. The destruction of the reticulum causes the umbilication to disappear.

In hemorrhagic variola the vesicle becomes filled with red blood-corpuscles instead of emigrant white corpuscles. Between the corpuscles is a network of fibrin. Wagner has rendered it extremely probable that these red corpuscles escape from the capillaries in the corium-papillæ by diapedesis, and not in consequence of rupture of bloodvessels.

The microscopical examination of the corium during the vesicular stage of the eruption, shows that the papillæ corresponding to the centre of the pock are often much lengthened, while those at the periphery may be depressed. Pus-cells are found in the connective tissue of the corium, especially around the vessels of the papillæ. These pus-cells, which are undoubtedly emigrated white blood-corpuscles, are present in large number during the pustular stage. The pustule may extend in depth in consequence of suppuration of the upper layers of the corium. The cicatrices or pock-marks which follow an attack of variola, are extensive and deep in proportion to the extent in which the corium is involved in the suppurative process during the pustular stage.

During the stage of desiccation the contents of the pustule disintegrate and dry up. After the pustule ruptures and discharges its contents, brownish scabs are formed by the desiccation of the pustular contents. Beneath these scabs the epithelium is regenerated, the new cells being produced by proliferation from the intact epithelial cells (page 41).

In a number of cases of smallpox, Weigert observed colonies of micrococci in bloodvessels and lymph-spaces in the corium, as well as similar colonies in the vesicles.

The occurrence of the variolous eruption upon the mucous membranes of various parts of the body will be described in connection with the clinical history. Parenchymatous degeneration of the liver, heart, and kidneys has been observed in cases of smallpox. Weigert found, in a large number of cases, in the liver, the spleen, the lymphatic glands, and the kidneys, colonies of micrococci situated in the bloodvessels. The cells around these bacteria were at first unaltered, gradually they became necrotic (coagulation necrosis), and around these necrosed cells appeared emigrated white blood-corpuscles.

[1] This fibrin has nothing to do with the formation of the reticulum or bands which have been described. Some writers, however, think that the substance of the epithelial cells which form the bands is changed into a material resembling fibrin. The bodies of some of the cells in these bands seem to have undergone the metamorphosis into keratine which characterizes the cells in the upper layers of the epidermis.

These foci of coagulation-necrosis[1] are generally not visible to the naked eye before the pus-cells accumulate. The formation of abscesses is rare. The spleen is sometimes swollen. Ecchymoses are very frequently found in the mucous membrane of the renal pelvis and of the ureters. Pontick has emphasized the fact that in hemorrhagic variola, swelling of the spleen and parenchymatous degenerations do not usually occur, probably because death takes place at such an early period of the disease. Enlargement of the spleen is by no means constant in ordinary smallpox. In variola hæmorrhagica, hemorrhages are present in the interior of the body as well as upon the surface. They are found in the mucous membrane of the air-passages, in the lungs, in the mucous membrane of the alimentary tract, especially of the stomach and rectum, in the uterus, rarely in the Fallopian tubes and ovaries, or in the testicles. Punctate hemorrhages are present in the serous membranes and in the pia mater. The complications of smallpox, which are many, will be noticed under the clinical history.

Clinical History.—Differences pertaining to the eruption, and other events embraced in the clinical history, in different cases, are so great that writers have made several varieties of the disease. The division into *confluent* and *discrete* or *distinct variola* is generally adopted. In the latter variety the vesicles and pustules are separate or distinct from each other. In the former variety coalescence of the vesicles or pustules takes place. In cases in which coalescence exists to a greater or less extent, but not over the whole or the greater part of the surface of the body, the disease is said to be *semi-confluent*. When the eruption has a hemorrhagic character the disease is called *hemorrhagic* variola. Without considering these varieties under separate heads, I shall notice their distinctive features in connection with the symptomatology of the several stages of the disease.

Stage of Invasion.—The disease is ushered in by a chill in the great majority of cases, and the chill is usually more marked than in the other eruptive fevers. In some cases a series of chills occurs, alternating with flushes of heat. Febrile movement follows, accompanied generally by more or less perspiration. The latter is apt to continue, or to recur more or less frequently, up to the maturity of the eruption, a feature distinctive of this, as compared with the other eruptive fevers. The febrile movement is known as the primary fever. It is often intense, the thermometer sometimes showing a rise to 104° or 105°. Nausea and vomiting are often prominent symptoms in this stage. The tongue becomes coated. Pain is referred to the epigastrium, accompanied by tenderness on pressure, either with or without notable nausea and vomiting. Generally the bowels are constipated, but diarrhœa is sometimes present, especially in children. Cephalalgia, pain in the limbs, and general debility are more or less marked, as in the early part of other essential fevers; but in this fever pain in the loins is usually a marked symptom and possesses diagnostic importance. Incomplete paraplegia is occasionally observed, generally disappearing with the development of the eruption. Paralysis of the bladder, giving rise to retention of the urine, sometimes exists without paraplegia. Convulsions often attend the development of this disease in children, and sometimes occur in adults. Delirium is an occasional symptom.

[1] Weigert compares these necrotic foci in parenchymatous organs to the eruption on the skin. The first step in the latter he considers to be necrosis of the lowest cells in the rete Malpighii from the action of bacteria. The same necrosis, according to this pathologist, occurs from a similar cause in internal organs. The secondary result of the necrosis both on the skin and in the organs is a reactive inflammation.

If the symptoms in this stage be mild, the eruption will probably be discrete, but if the chill be notably marked, the pyrexia intense, the lumbar pain severe, etc., it may be expected that the disease will prove to be of the confluent variety.

The duration of this stage, as a rule, is two days. The eruption begins to appear on the third day after the attack. There are, however, exceptions to this rule. In some cases the eruption appears on the second or on the fourth day. The duration is sometimes extended to the fifth or sixth day, and occasionally even longer. The eruption, if it appear on the second day, may be expected to be confluent, and, on the other hand, in proportion as the appearance of the eruption is protracted beyond the third day, mildness of the disease is to be expected. Two events, relating to the skin, are of occasional occurrence in this stage. One of these is a cutaneous efflorescence or rash. The whole or the greater part of the surface of the body may be covered with this erythematic redness, resembling the appearance in scarlatina. The disease is liable to be mistaken for scarlatina when this occurs. In other cases the rash is in isolated patches, and it may then bear a resemblance to measles. The patches, however, are not elevated, that is, they are not papular. Small vesicles or sudamina are sometimes observed. The efflorescence appears on the second day and continues only eighteen or twenty-four hours, giving place to the eruption peculiar to the disease.

The other event is the appearance of petechiæ, that is, ecchymoses. These may be more or less abundant. They are sometimes very abundant, covering both the trunk and the extremities. In some cases these foreshadow subsequent hemorrhages; but they by no means have always this significance. They do not always denote severity of the disease; they are sometimes observed in mild cases. They continue during the greater part of the stage of the eruption.

Stage of Eruption.—The histological structure of the different forms of the eruption has already been considered. It remains to notice the clinical characters of the eruption. The eruption, as a rule, appears first on the face, especially about the lips and chin, and nearly at the same time on the neck and wrists; next on the chest and arms; then over the body, and last on the lower extremities. Its diffusion over the whole cutaneous surface occupies from one to three days. Exceptionally it is first observed on the genital organs, chiefly in young children, and on the loins or nates. It may appear first in the neighborhood of a blister or sore existing in any part of the body. Successive changes take place in the physical characters of the eruption, which, in different stages of its progress, represent nearly all of the cutanei. At first it appears in the form of small red spots or specks, sometimes having a purplish or livid color. It is now a maculated eruption. The central part of the *maculæ* becomes hard, slightly elevated, and pointed. A change has taken place from a maculated to a papular eruption. In this stage of its progress, the eruption is not unlike that of measles, and the disease is liable to be mistaken for the latter. The *papulæ* are smaller, rounder, and harder, and lack the crescentic or curvilinear arrangement which characterizes the eruption of measles. They feel like small shot under the skin. Next, a clear liquid becomes visible in the *papulæ* which now become *vesiculæ*. This change is observed 24 hours after the first appearance of the eruption. After 24 hours more, *i. e.*, 48 hours from the first appearance of the eruption, the vesicles have acquired considerable size. On the fifth day of the stage of the eruption, the vesicles have attained to nearly or quite their full development, measuring from $\frac{1}{4}$ to $\frac{1}{3}$ inch in diameter, and are raised from $\frac{2}{10}$ to $\frac{4}{10}$ inch above the level of the skin. More or less of the vesicles present a depression in the centre. They are said to be *umbilicated.*

This appearance is highly characteristic, indeed, almost pathognomonic. It is observed in no eruption other than that of variola, excepting the vaccine vesicle, and sometimes ecthyma. This umbilicated appearance may be discovered in some of the vesicles, often as soon as the latter are discoverable. The vesicles are multilocular, as has already been described. They contain an opalescent serum.

This is the history of the eruption up to the period when the vesicles reach the maximum of their development, if the eruption be discrete. In the confluent variety, a diffused redness of the surface precedes the appearance of papules and vesicles. This diffused redness is apt to lead to the error of supposing this disease to be measles. The vesicles when they first appear have not the determinate form of those in discrete smallpox, but run together or coalesce to a greater or less extent. At the end of the period for the full development of the vesicles, the face and other parts are covered with patches of greater or less size, in which the cuticle is uniformly raised by opalescent serum, resembling a blister. The whole of the face and the greater part of the cutaneous surface may be covered with coalescent vesicles.

After the full development of the vesicles, there is another important change in the eruption. The vesicles become pustules. In other words, suppuration takes place. With this change the external characters are altered. The pocks are more distended. The reticulum is broken up. The central depression is lost, and the pustules become pointed. This change from vesicles to pustules is accompanied by general symptoms which show it to be an important epoch in the clinical history of the disease. Hence, with this change begins another stage, namely, the *suppurative stage*, or the stage of *maturation*. This will claim consideration under a distinct head. It will be observed that, of the different forms of cutaneous eruption, all except the *squamæ* and *tuberculæ* are represented in the successive changes in the eruption of smallpox, namely, enumerating them in the order of their sequence, *maculæ*, *papulæ*, *vesiculæ*, *pustulæ*, and, in the confluent eruption, *bullæ*.

The eruption is not limited to the skin. Simultaneously with its appearance on the cutaneous surface, it may be observed, to a greater or less extent, on the mucous membrane of the mouth and throat. It appears here in the form of round opaque spots. As no stratum corneum exists upon the mucous membrane, the formation of typical vesicles and of pustules does not take place. Little erosions and ulcers rapidly form in the site of the eruption. The membrane surrounding the spots is swollen and inflamed. The spots are observed especially on the tongue and soft palate. They are liable to occur in the larynx, trachea, and bronchi; on the conjunctiva, leading sometimes to ulcers and destruction of the eye; within the nostrils, in the external meatus auditorius, and on the prepuce or vulva. The eruption does not occur upon serous membranes, and probably not on the mucous membrane of the stomach or intestine. In the larynx, the eruption may cause laryngitis which may prove fatal. An instance of this kind has fallen under my observation.

A striking feature of the disease pertaining to this primary fever, is either a notable remission, or complete apyrexia on the appearance of the eruption. The pulse falls to nearly or quite the normal frequency; the heat of the skin is but little or not at all above that of health, and the thermometer in the axilla shows a reduction to 100° Fahr. or lower. This is a highly diagnostic feature of smallpox, provided the eruption be not confluent. In the confluent variety this feature is either wanting or much less marked. As the eruption progresses, the febrile movement is gradually developed or increased.

Stage of Suppuration.—With the change of the eruption to pustules, usually on the sixth day after the first appearance of the eruption, there is a

recurrence of notable increase of pyrexia, constituting what is known as the *suppurative fever*, or the *secondary fever*. The pulse becomes more or less frequent, the heat of the skin is sensibly raised, and the thermometer denotes increase of temperature, especially in the evening as compared with the morning. The perspirations which up to this epoch are apt to occur, now cease. In mild cases of discrete smallpox, the secondary fever continues only for three or four days. But it continues longer in the confluent variety irrespective of any complication. The pyrexia is symptomatic of the affection of the skin, and its intensity, other things being equal, is proportionate to the degree of cutaneous inflammation. More or less redness and œdema of the skin are apparent in the spaces between the pustules. Tumefaction of the face occurs, and is often considerable. The swelling of the eyelids is often sufficient to close the eyes, as in cases of erysipelas. Swelling of the hands and feet occurs in severe cases, especially if the eruption be confluent. The redness and swelling are accompanied by a burning pain, as in erysipelas. Salivation is a frequent symptom. In severe cases of the confluent variety it is often very profuse, and accompanied with more or less swelling of the salivary glands. It is measurably or chiefly dependent on the eruption in the mouth and fauces. It is rarely observed in children. In severe cases delirium is apt to occur in this stage. The delirium is generally passive like that in most cases of typhoid fever, but it is sometimes active or maniacal. Other ataxic symptoms, namely, subsultus, carphologia, and coma-vigil, may also occur, denoting always a condition of gravity. Coma occurs in a certain proportion of fatal cases. Other symptoms are due either to complications or to anomalous occurrences which will presently be noticed. Diarrhœa is an occasional symptom, and is always an unfavorable omen. The duration of the stage of eruption is four or five days.

Stage of Desiccation.—This stage commences on about the twelfth day of the disease. The exceptional cases in which it commences much earlier or later are very few. The tumefaction and redness of the skin diminish. The pustules, for the most part, break, and the pus concretes into a thick scab. Over patches in which the eruption is confluent, there is a continuous scabby crust. The whole face, in severe cases, is covered, as if by a mask, presenting a hideous appearance, and the greater portion of the surface of the body may present a similar aspect. The diminution of the inflammation and the formation of scabs are first observed on the face, afterward on the trunk and upper extremities, and at last on the lower extremities. During this stage the skin exhales a sickening characteristic odor. In cases in which the eruption is confluent, the stench is extremely offensive, and may be perceived at a considerable distance. The spectacle in this and the preceding stage, and the fetor, render smallpox the most repulsive and loathsome of diseases. In mild cases the stage of desiccation is the stage of convalescence. The scabs fall off, leaving the skin beneath unbroken, but presenting a discoloration continuing for a long time, and especially apparent when the surface is exposed to cold. But in severe cases the skin beneath the scabs is excoriated or ulcerated, the scabs are liable to be renewed, and troublesome ulcerations sometimes follow. More or less pyrexia, in severe cases, continues into the stage of desiccation. In mild cases there may remain no permanent traces of the eruption, but in the great majority of cases, there are left cicatrices, either circular or linear, which are known as "pitting" or "pock marks." The amount of pitting will depend on the abundance of the eruption, the size of the pocks, and the depth of the ulcerations. Some of the pocks do not break, but harden, and their contents are absorbed. It is probable that in these the corium is not involved in the suppuration, or that the vesicles are not converted into pustules.

To recapitulate the relative duration of the several stages in the majority of cases: The duration of the stage of invasion is from 2 to 4 days, of the stage of eruption about 5 days, of the stage of suppuration 4 or 5 days, and of the stage of desiccation 6 to 10 days, making the duration of the disease, in cases ending in recovery, from 17 to 24 days. In mild, uncomplicated cases, the recovery is usually rapid, but convalescence may be indefinitely prolonged by ulcerations of the skin and other complications.

Various complications and anomalous events are liable to occur in the several stages of the disease. Pharyngitis, dependent on the eruption within the pharynx, is sometimes sufficient to occasion much pain and difficulty of deglutition. Laryngitis, dependent on the eruption within the larynx, is of not infrequent occurrence. It is denoted by huskiness of voice, or aphonia, with, in some cases, more or less difficulty of respiration. The laryngeal inflammation is sometimes diphtheritic. Œdema of the glottis is an occasional accident. Bronchitis, also from the eruption, occurs in a certain proportion of cases. Sometimes there is inflammation of the gastric or of the intestinal mucous membrane. This is rarely of the diphtheritic variety. Pneumonitis, pleuritis, and pericarditis are rare complications. Endocarditis, including the acute ulcerative form, has been observed as a complication. Furunculi, or boils, and subcutaneous abscesses are not uncommon, both as concomitants and sequels. Phlegmonous tonsillitis and suppurative inflammation of the cervical lymphatic glands and of the salivary glands occasionally occur. Erysipelas on the face, neck, limbs, or body is not very infrequent. Gangrene may occur on parts exposed to pressure, and sometimes in other parts. Ophthalmitis is an important complication, sometimes leading to permanent blindness from opacity or perforation of the cornea. The inflammation in the throat sometimes extends through the Eustachian tube and gives rise to median otitis which is liable to eventuate in deafness. Hemorrhage in various situations occurs in a certain proportion of cases. Epistaxis is an occasional early symptom, and does not betoken unusual gravity of the disease. Hæmaturia is sometimes an early and always a grave symptom. Hemorrhage occurring, at any period of the disease, from the mouth, throat, air-tubes, or bowels, accompanied by petechiæ or vibices, and sometimes by an extravasation of blood into the pocks, characterizes certain malignant cases. Hemorrhagic, scorbutic, and black variola are names applied to the disease as exhibited in these cases. In females, menstruation is apt to occur, and, if not irregular or profuse, it is not an untoward event. Metrorrhagia is apt to occur in hemorrhagic cases. Albuminuria is a symptom of not infrequent occurrence in severe cases. It is probable that the coma which occasionally occurs is sometimes due to uræmic poisoning dependent on acute nephritis. Orchitis and ovaritis are rare complications. Inflammation of the synovial membranes of the joints, sometimes with serous and sometimes with purulent exudation, is also an infrequent complication. Paralysis of the lower extremities and of the bladder has been known to be a sequel of smallpox. This is due, according to Westphal, to an acute disseminated myelitis.

Causation.—Smallpox is a highly contagious disease. It may be communicated by means of a virus, that is, by inoculation, and by means of inappreciable emanations from the body. The disease is readily transported by means of fomites which may retain the contagium in an effective condition for months and even years. A very transient and slight exposure often suffices for the production of the disease. Thus, it is not infrequently taken by passing in the street or meeting in public conveyances persons who either are, or have recently been, affected with it. It may be contracted in hackney-

coaches which have been used for carrying patients to hospitals. The disease is generally supposed to be communicable in all its stages, but undoubtedly it is most highly so during the stages of suppuration and desiccation. The contents of the vesicles and pustules and the crusts and scabs formed by desiccation contain the contagium; and it is probably contained, not only in the emanations from the cutaneous surface, but in the expired breath, and perhaps in the intestinal excreta. The disease may be communicated from the dead body by means, not only of a virus, but by inappreciable emanations. Thus it has been contracted in the dissecting-room from subjects dead with the disease. It is stated that a cadaver may retain the virus in a condition to communicate the disease for an indefinite period—even for several years.[1] The following instance is interesting as showing the communication of the disease from the dead body, death having taken place before the development of the eruption: "During the winter of 1848–49, a young man, a member of the medical class of New York University, died suddenly and unexpectedly in the night under the care of a physician who had not thought him seriously ill. I was invited to the autopsy, and observed, when the corpse was uncovered, a few dark red spots on the surface, which were supposed to be petechial; the principal symptoms of this attack having been gastric with great debility, as we were informed. The coffin was taken home to a New England village for burial, where, at the funeral, some of the relatives approached and opened it to see the face of the deceased before it was inhumed. Of this number, eight were attacked with smallpox, no other persons in the neighborhood being assailed."[2] Whether the disease be ever produced otherwise than by means of a contagium is, and must always remain, an open question; for, with respect to reported cases in which the disease has appeared to originate spontaneously, it can always be said that there may have been some unsuspected and untraceable exposure. This explanation is more rational than the supposition that the special cause is produced *de novo*.

The susceptibility to the disease exists in all ages, but it is greatest in children. Some persons are wholly insusceptible to it, exposing themselves as fully as possible, with impunity. Cases have been observed in which persons have become susceptible after having been insusceptible for many years. Unknown causes peculiar to certain times and places co-operate with the contagium in the diffusion of the disease, so that it prevails as an epidemic. Reference in these statements is had to the production of the disease in the natural way, that is, exclusive of inoculation. The disease as thus produced is distinguished as *natural smallpox*. The negro and Indian races are particularly susceptible to the disease. As a rule, the occurrence of the disease once, extinguishes the susceptibility ever afterward. Instances, however, are not extremely infrequent of the disease having been experienced twice, and it has been known to occur thrice.

Certain interesting facts relate to the susceptibility of the child *in utero*. A pregnant woman affected with the disease may, or may not, communicate it to the fœtus. The development of the disease before birth generally causes the death of the child, and cases have been reported of still-born children presenting the different stages of the eruption. The death of the child, however, does not always occur. Healthy children have been born presenting the evidence of having passed safely through the disease in the uterus. In some instances the disease has been contracted before birth, but not developed until several days after birth. Recovery has taken place under these circumstances. The disease may be communicated to the unborn child by the mother after the

[1] *Vide* Nouveau Dict., art. Contagion.

[2] *Vide* article by Dickson, American Journal of the Medical Sciences, July, 1862.

fourth month of pregnancy and perhaps before. Finally, the special cause may be received into the system of the mother, and the fœtus become affected without the mother experiencing the disease. This fact has been observed in cases in which the susceptibility of the mother had been extinguished, either by the disease having been experienced, or by vaccination.

The special cause of this disease remains for a certain period latent, that is, there is a period of incubation. The duration of this period varies from five days to nearly three weeks, the average duration probably being from twelve to fourteen days. Facts appear to show that the special cause of rubeola or of scarlatina may be in operation simultaneously with the operation of the special cause of variola; in other words, smallpox may be combined with either measles or scarlet fever. Cases, however, exemplifying these combinations are extremely rare.

During an epidemic prevalence of smallpox, cases are sometimes observed in which all the symptoms of the stage of invasion occur without being followed by an eruption. The disease appears to abort spontaneously at the end of the stage of invasion. These attacks resemble febricula, but it has been observed that persons who have had these attacks during the prevalence of smallpox are thereafter insusceptible to the disease, although not protected by vaccination. Hence, it has been considered that the disease sometimes occurs without an eruption; and writers have been accustomed to recognize as a variety of the disease, *variola sine variolis*.

The question in what consists the essential causative principle, the contagium, is one of great pathological interest. It is claimed by Weigert and by Cohn that the round bacteria or micrococci, which they have observed in lymph from the vesicles, as well as in other parts, represent the contagious germs of smallpox. The question is, however, *sub judice*.

Diagnosis.—The diagnosis of smallpox presents no difficulty after the characters of the eruption are fully manifested. It is not so easy at an early period of the stage of the eruption before the vesicles are distinct. In seeking to determine the character of the eruption, vesicles should be looked for, and, next, their umbilicated appearance. This appearance, it is to be borne in mind, is almost pathognomonic. The distinctive characters of the papules, as determined by the touch, are also to be borne in mind, namely, they are granular, hard, and deep-seated. The duration of the stage of invasion is to be considered, namely, from two to three days. The prominence of lumbar pain and vomiting, and especially either a remission or a cessation of febrile movement at the time of the appearance of the eruption, are important diagnostic features. It is to be remarked that lumbar pain is not in all cases a prominent symptom, so that its absence is not entitled to much weight in the exclusion of smallpox. An examination of the throat and mouth should not be omitted. The round, whitish, or ashy spots which are characteristic of the eruption on a mucous surface, are generally apparent here as soon as, or before, the eruption appears on the skin. The appearance of the cutaneous eruption successively, on the face or neck, the trunk and upper extremities, and the lower extremities, is to be recollected.

The diagnosis cannot be made with positiveness prior to the stage of the eruption. Pain in the loins with febrile temperature, taken in connection with the absence of the symptoms which attend the access of the other eruptive fevers, and of typhoid fever, should excite a strong suspicion of smallpox, especially if the patient be not protected either by vaccination or by having once had the disease. The exclusion of rubeola and scarlatina by the absence of the symptoms characteristic of the stage of invasion in these diseases, is an important step in the diagnosis prior to, and in the early part of, the stage of

eruption. When the eruption first appears, the differential diagnosis lies chiefly between these fevers. In rubeola the Schneiderian membrane and air passages, and in scarlatina the fauces, are prominently and early affected, as will be seen in treating of these fevers. Moreover, in rubeola the stage of invasion is longer, and in scarlatina it is shorter, than in variola. In neither rubeola nor scarlatina does the pyrexia remit or cease when the eruption appears. Other affections liable to be confounded with smallpox, are lichen, accompanied with pyrexia, and a secondary syphilitic eruption. The occasional occurrence of an efflorescence and of petechiæ, to which reference has been made, preceding the eruption proper, is to be borne in mind.

The diagnostic points should br fixed in the memory, as, in view of the danger of the diffusion of the disease by exposure before its character is ascertained, an early diagnosis is immensely important. As another inducement for being prepared to recognize the disease promptly, it may be added that the ability of the physician is thereby strikingly shown, while, on the other hand, delay or failure to recognize it brings upon him popular censure.

Prognosis.—Unmodified or natural smallpox is attended with much danger to life, the ratio of fatal cases being as 1 to 3 or 4. The mortality is very great in cases of the confluent, and considerably less in the discrete, variety, the ratio in the latter being as 1 to 10. The death-rate varies between wide limits in different epidemics. The disease is much more fatal to children than to adults, and is especially fatal in early infancy. It is also extremely fatal to aged persons. Death is sometimes attributable to the intensity of the disease *per se*. Life is then destroyed before the eruption is matured, and without any important complication having taken place. Instances of this kind are rare. If death take place before the stage of suppuration, it is generally due to some important complication. Complications which are likely to prove fatal are, acute laryngitis, œdema glottidis, pneumonitis, acute ulcerative endocarditis, and an affection of the kidneys involving uræmia. The latter is to be suspected in cases in which coma or convulsions occur.

Death not attributable to complications is generally due to inability of the powers of the system to support the cutaneous affection; hence, the danger, other things being equal, is proportionate to the amount of the eruption. Confluent smallpox involves a very extensive suppurative inflammation which is apt to lead to a fatal result by exhaustion. Unfavorable prognostics are, great prostration, frequency and feebleness of the pulse, typhoid delirium and other ataxic symptoms, absence or subsidence of redness and tumefaction of the face and extremities, cessation of salivation, diarrhœa, hemorrhage from the mucous membrane and extravasations on the cutaneous surface.

Death taking place during or after the stage of desiccation is attributable to ulcerations of the skin, boils, abscesses, erysipelatous inflammation, gangrene, continued diarrhœa, etc.

In pregnant women the disease in its severe form is apt to induce abortion or miscarriage, and, under these circumstances, the result is generally fatal.

Treatment.—The treatment of smallpox embraces measures having direct reference to the eruption, and those indicated by the phenomena of the disease, irrespective of the eruption; in other words, the treatment is local and general.

The general treatment involves the same principles as the continued fevers. There is no special treatment. The disease will run its course, and, hence, the expectant plan is to be pursued. During the stage of invasion, the intensity of the febrile movement may be lessened by the use of cold drinks, ice-water, lemonade, carbonated water, allowed as freely as the condition of

the stomach will permit, by refrigerant remedies, and sponging the surface of the body with cold or tepid water. If there be hyperpyrexia the wet sheet and sprinkling with cold water may be resorted to, as practised in cases of typhus and typhoid fever. Refrigeration is not objectionable on the score of interfering with the appearance of the eruption. Cathartics are not indicated, but constipation is to be removed by mild laxatives or simple enemata. Remedies to relieve nausea or vomiting and cephalalgia are frequently indicated in this stage. It has been claimed that the sulphites have a modifying effect upon the disease, lessening the severity and danger. Sansom advises the sulphite of sodium in doses from 20 to 30 grs. given every third or fourth hour. He also regards as a useful remedy the sulpho-carbolate of sodium given in the same doses and with the same intervals. I have met with practitioners of experience who, from their observations, attributed to the sulphites a favorable influence over the disease.

During the stage of the eruption prior to suppuration, palliative measures are indicated by continued nausea or vomiting, vigilance, restlessness, diarrhœa in some cases, etc. The various complications which are liable to occur will also furnish therapeutical indications. It is probable that the mineral acids are useful in this fever as well as in the continued fevers. Alimentation and supporting measures in some cases are important in this stage. These measures are important in the suppurative stage and the stage of desiccation in proportion as the eruption is copious and confluent and the general symptoms are indicative of asthenia. The principles which should govern the use of alcoholic stimulants and tonic remedies, in conjunction with concentrated nutriment, are the same as in all the essential fevers as well as other diseases in which danger in the direction of asthenia is more or less imminent.

All the hygienic conditions which are so important in the treatment of typhus and typhoid fever, are not less important in the treatment of smallpox; and, of these conditions, the freest possible ventilation is of especial importance.

The local treatment embraces measures to render the eruption abortive on the face, or to prevent the disfiguration caused by pitting. The treatment for this end is called *ectrotic*, this term signifying to miscarry. The ectrotic treatment, extending more or less over the body, has been supposed to be useful by limiting the amount of cutaneous inflammation, and thereby the degree of secondary fever and danger from exhaustion. Of the various ectrotic measures which have been tried, the following have been found measurably successful:—

1. The careful evacuation of the vesicles by means of a fine needle. This plan was advocated by Rayer. It calls for much patience on the part of the operator.

2. Evacuation of the vesicles and cauterization by means of a fine-pointed stick of the nitrate of silver. This, also, is a very tedious operation. It is highly recommended by Velpeau, Bretonneau, and others.

3. The application of the tincture of iodine, once or twice daily by means of a brush, while the eruption is papular. This plan was introduced by Crawford, of Montreal, and Samuel Jackson, of Northumberland, Pa. The effect was observed by Sargeant in thirty cases, the treatment being limited to one side of the face. There was but little swelling on the side on which the iodine was applied; the vesicles were flattened, and the pitting, although not prevented, was evidently diminished.

4. The exclusion of light and air was recommended as an ectrotic measure by the late Dr. Picton, of New Orleans. This is effected by covering the face with a plaster of some kind. Covering the face with gold-leaf, as prac-

tised by the Egyptians, according to Larrey, must be useful chiefly by excluding light and air.

5. The application of a mild mercurial ointment, spread on cloth, has been highly recommended by authors in different countries. The risk of producing the constitutional effects of mercury is an objection of considerable moment to this plan. Mercurialization is certainly not desirable in smallpox. In view of this risk, Bennett was led to substitute, for the mercurial ointment, calamine saturated with olive oil, and this application he found to be usually effective. Skoda and Hebra recommend the application of compresses dipped in a solution of corrosive sublimate (grs. ii–iv to water ℥vi). Niemeyer preferred a weaker solution (gr. i to ℥vi).

6. The application of the subnitrate of bismuth and prepared chalk, in equal parts, twice daily, after smearing the surface with sweet oil, is stated to be an effective ectrotic measure by Hamilton, of Illinois.[1]

7. Stokes advised the application of poultices over the face, as the surest method of preventing disfigurement. They should be applied at the earliest period and continued to an advanced stage of the disease. He thought that linseed meal is the best article for the poultice. It should be spread on a soft material, such as French wadding, and covered with gutta-percha paper or oiled silk.

8. The application of collodion, as an ectrotic application, was first suggested in a letter to me by the late Dr. Brinkerhoff, of California.[2] It was subsequently recommended by Aran, of Paris. The collodion is to be applied once or twice daily by means of a brush. To be successful, the application must be made either while the eruption is papular, or while the vesicles are quite small. Applied at a later period, it has seemed to me to increase the pitting. In the few cases in which I have seen this plan tried, the application was agreeable to the patient.

A solution of gutta-percha in chloroform was used by Stokes, Graves, and Wallace. The *modus operandi* of the gutta-percha is similar to that of collodion, the effect being produced by the exclusion of air and by compression.

9. Carbolic acid has been used with success by Lemaire and Sansom. The acid is to be liquefied by alcohol, and applied by means of a camel's-hair pencil brush, as soon as the contents of the vesicles begin to appear puriform.

10. The application of cold wet cloths to the skin is regarded by many as an efficient ectrotic measure.

Aside from ectrotic measures, the local treatment embraces evaporating lotions to abate undue heat, a weak solution of the chloride of lime as an antiseptic and to allay pruritus, soothing unguents in the suppurative stage, and absorbent powders. If ulcerations follow the falling off of the scabs, they require the same applications as ulcers occurring under other circumstances.

It should be an object of treatment to prevent the eruption from appearing on the conjunctival membrane. The continued application of compresses wet with cold water is advisable for this object.

With a view to prevent diffusion of the disease, patients should not be discharged from hospital, or, if treated at home, allowed to go abroad, until the surface is completely free from scabs, and repeated, thorough ablutions have been employed. All articles of clothing worn during the disease should be left at the hospital, or, in cases in private practice, destroyed. Fumigations, as a means of destroying the contagium, should not be relied upon. Physicians, after visiting patients affected with this disease, should not see other

[1] American Journal of the Medical Sciences, Oct. 1865.
[2] *Vide* Buffalo Medical Journal, vol. vi. 1851.

patients until after having been sufficiently in the open air for the contagium to be dissipated by free ventilation. The hands should be washed before leaving the hospital or house, and change of dress before visiting other patients, especially young children, is to be recommended, if not enjoined.

Modified Smallpox or Varioloid.

Thus far, smallpox has been considered as produced by infected emanations, or the contagium in fomites, that is, natural smallpox, in persons unprotected by vaccination. Materially modified, as respects the events of its clinical history, and its severity notably diminished, the disease is commonly known as *varioloid*. This term is not to be understood as applied to a disease essentially distinct from, although resembling, smallpox. The name would imply this. But in all cases to which the term varioloid is correctly applied, the disease is essentially variola.

Smallpox is modified, as a rule, in a remarkable degree when produced by inoculation, or, as it is also called, variolation. As a means of rendering the disease so mild as to be in a great measure divested of danger, and of preventing pitting, inoculation had been practised from time immemorial in China and Persia. Imported into Turkey, the practice was introduced thence into Great Britain by Lady Mary Wortley Montague, in 1721. It was not adopted in France until 1764. In the same year of its introduction into Great Britain, a large number of persons in Boston and the vicinity were inoculated by Zabdiel Boylston. Boylston was the first to note this important fact relating to variola produced by inoculation, namely, the average period of incubation is shorter, by several days, than in cases of natural smallpox. Hence, the production of natural smallpox may be anticipated and prevented by inoculation after known exposure to the miasm of the disease.

The eruption in cases of inoculated smallpox, or after variolation, is usually slight. The pocks rarely exceed 100. Many of them abort, that is, they do not proceed to suppuration. The secondary fever is slight or wanting. There is very little constitutional disturbance, and the disease leaves little or no pitting. These statements are true in the main. Exceptionally, when inoculation was largely practised, the disease was severe. The rate of mortality was exceedingly small, varying, according to Shattuck, in 23,000 cases, in Boston, from 5 to 30 deaths in a thousand. Transferring the virus from persons successively inoculated, the disease becomes progressively more and more modified, until at length, as a rule, to which there are exceptions, the eruption consists only of the pustule formed at the point of inoculation, with a few pustules developed around this mother-pustule.[1]

As a rule, variolation affords complete protection, ever thereafter, against smallpox. For those who availed themselves of it, therefore, it was a great blessing prior to the discovery of vaccination. But it contributed to the diffusion of the disease by multiplying the foci of contagion, and, since the discovery of vaccination, it has ceased to be resorted to as a means of avoiding the danger and disfigurement of natural smallpox. Under certain circumstances, however, the physician is not only justified, but it is his duty to practise inoculation. These circumstances are, the known exposure of persons who have never had the disease, and who are unprotected by vaccination, and an inability to obtain the vaccine virus. Inoculation should then be resorted to in order to secure the great advantages of modified smallpox. The late Prof. Dickson advocated a restoration of the practice of inoculation,

[1] *Vide* Trousseau, Clinique Médicale, tome premier.

in addition to vaccination, with a view to test the protective power of the latter, and destroy, as completely as possible, all susceptibility to the disease.[1]

At the present day, in most cases of varioloid the modification is due to vaccination. Vaccination does not always afford complete protection against smallpox, but, in general, the disease is materially modified.

In varioloid the primary or eruptive fever, in the stage of invasion, is often as marked as in cases of natural smallpox. The duration of this stage may be longer than the average duration in ordinary variola. The eruption is usually far less copious; a few pocks only may appear, and the eruption may even be limited to a single pock. The eruption passes more rapidly through the successive changes, the maturation being completed in five or six days. Frequently the eruption aborts to a greater or less extent. It may stop at the vesicular, and even at the papular, period. More or less of the vesicles dry up without breaking. The general symptoms, as a rule, are much milder than in most benign cases of natural smallpox. The secondary fever is either slight or wanting, and the convalescence is speedy. Exceptionally, cases are severe, and the disease proves fatal in a ratio varying from seven to ten *per cent.*

Smallpox is modified in a certain proportion of cases spontaneously, that is, irrespective of inoculation or vaccination. Cases presenting the characters of varioloid occurred prior to the practice of inoculation and the discovery of vaccination. They were, however, rare. Finally, modified smallpox or varioloid is apt to be the form of the disease when it occurs in those who have before experienced it. In all cases of varioloid, it is to be borne in mind that the disease is essentially variola or smallpox, and that, however mild may be the cases, they are capable of communicating to persons unprotected a severe and fatal form of the disease.

The diagnosis, in cases of varioloid, offers difficulties which do not obtain in cases of unmodified smallpox. The disease most likely to be confounded with varioloid is rubeola or measles. The different points will be stated in treating presently of the latter disease.

In cases of varioloid oftener than in ordinary variola, the eruption is liable to be preceded and accompanied by an efflorescence bearing considerable resemblance to scarlatina. Until the variolous eruption is developed, the disease may be supposed to be scarlatina. The occurrence of papules in the midst of the efflorescence, and the remission or cessation of pyrexia, are the differential points. Moreover, an examination of the mouth and throat may show the characteristic eruption here before its distinctive characters on the skin are apparent. The occurrence of a scarlatiniform eruption explains, in some cases, the supposed co-existence of variola or varioloid and scarlatina.

The treatment of varioloid does not claim separate consideration. The same principles are involved as in the treatment of ordinary smallpox. The comparative mildness, in the great majority of cases, renders active treatment unnecessary. Usually little is required except hygienic measures.

Vaccinia, or Cowpox.

Vaccinia and cowpox are names of a disease of the cow, which, communicated to man, destroys, in the great majority of cases, for a certain period, the susceptibility to smallpox, and, in the cases in which it does not offer complete protection against the latter disease, renders it, as a rule, mild and devoid of danger. Cowpox is transferred to man and from one person to another by the introduction of a virus, and never, at a distance, by infection.

[1] Am. Journ. of Medical Sciences, July, 1862.

The operation for its communication is called *vaccination.* For the employment of vaccination as a means of preventing smallpox, the world is indebted to the immortal Jenner. The discovery was promulgated by Jenner in 1798, after a series of observations and experiments which had occupied his attention for twenty years. The fruits of this transcendently important discovery have been the saving of an incalculable number of lives which would otherwise have been destroyed by one of the most loathsome of diseases, and the prevention, to an extent which cannot be computed, of the disfigurement and other distressing effects which smallpox is apt to produce when it does not prove fatal. Of all the benefactors who have ever lived, no one has conferred on mankind such immense, palpable, and time-lasting benefits. Yet, out of the ranks of the medical profession, how many are ignorant of the name of the discoverer of vaccination! The practice of vaccination met at the outset with much hostility, but Jenner lived to see it triumph over all opposition, and to witness the beginning of beneficent results which will accumulate from age to age until the end of the world. The practice was introduced into this country in 1799, notwithstanding a bitter popular prejudice, by Benjamin Waterhouse, of Boston, the first professor of medicine in Harvard University. Connected with vaccinia and vaccination are questions of great interest and importance, which have given rise to extended experimental and statistical researches, together with much discussion. They have occupied a considerable share of medical literature since the time of Jenner. Certain points are still unsettled and claim further investigation. The scope and character of this work allow of only a brief statement of facts and the opinions most consistent with existing knowledge, considered with direct reference to the practice of medicine.

Directing attention first to the descriptive history of vaccinia in man, on the third day after vaccination (the operation being usually performed on the arm near the insertion of the deltoid muscle), red points, slightly elevated, that is, small papules, are apparent at the spots where the vaccine virus was inserted. On the fourth day the papules are more developed and reddened. On the fifth day vesicles are discoverable. The vesicles increase, presenting an umbilicated appearance, and on the eighth day they attain to their full development, being elevated from two to three lines, and measuring one-third of an inch in diameter. The vesicles, like those of smallpox, are multilocular, flattened at the summits, and contain a transparent, viscid liquid called the vaccine lymph. On the seventh or eighth day a red areola is apparent, extending from one to three inches around the pocks, increasing in redness until the ninth or tenth day, and the contents of the vesicles become more or less purulent. At this time there is usually slight pyrexia with some local pain and pruritus. The lymphatics of the arm become swollen, and the glands in the axilla may become enlarged and tender. On the tenth or eleventh day the pyrexia subsides and the redness around the pocks diminishes. A dark spot soon appears on the centre and gradually extends over the whole of the pocks. The pustules desiccate, and by the fifteenth day they are converted into black hard scabs which fall off usually by the twenty-fifth day from the date of the vaccination. During the progress of the vaccine affection, vesicles having the distinctive characters of vaccinia have sometimes been observed in other parts of the body. It is probable that these are caused by the patient scratching the vesicles on the arm and carrying therefrom lymph containing the virus on the finger nails to parts where, owing to the abrasions of the skin, self-vaccination is the result. Experiments show that between the fourth and the ninth or tenth day, the characteristic vesicles may be multiplied at will by revaccinating with lymph from the vesicles produced by the

primary vaccination. Lichenous or vesicular eruptions, the latter lacking the distinctive features of vaccinia, not infrequently accompany or follow vaccination. Finally, permanent cicatrices denote the situation of the vaccine pocks. The cicatrix, provided the vesicle has pursued a regular course, and subsequent ulceration has not occurred, is characteristic, presenting a series of depressions or pits. The period of incubation in vaccinia is sometimes considerably protracted in consequence of the existence of some other affection, or from causes which are not apparent.

A most important practical point connected with vaccination is the discrimination of veritable and complete vaccination from an incomplete or a spurious affection. The development of vesicles of full size, the successive stages, and the duration of the affection, together with the characteristic appearance of the vesicles and the cicatrices, are the criteria for determining this point. Simple sores having no specific character may be the result of vaccination. Incomplete vaccinia, *vaccinoid*, as it was termed by Trousseau, is evidenced by the vesicles being developed more quickly and progressing to desiccation more rapidly, by their swollen size and conoidal form, and by the absence of cicatrices, or of the appearance distinctive of the true vaccine cicatrix. In view of the immense importance of a true and perfect vaccination to those who suppose themselves to be protected against smallpox, the responsibility of performing vaccination should never be undertaken by those not practically familiar with vaccinia. It is obviously far better that a person should not have been vaccinated, with a knowledge of the fact, than that he should incorrectly believe himself to have had veritable and complete cowpox, since this belief involves a false security leading to exposures which might otherwise be avoided.

Certain interesting questions relate to the nature and source of cowpox. Did it originate in the cow, or come from the human species? Does it affect other animals? What are its essential relations to smallpox? In the early editions of this work it was stated that vaccinia in the cow may be produced by inoculation with the smallpox virus taken from man; that the disease thus produced in the cow, transferred to man, gives rise to vaccinia in the latter, and that vaccine virus obtained in this way has been found effectual in preventing smallpox. These statements were made as the basis for the conclusion that the opinion held by Jenner that vaccinia and variola are essentially identical, is thereby verified. There are, perhaps, facts, supporting these statements, sufficient to warrant the foregoing conclusion; but the practical inferences are incorrect and dangerous. The virus obtained from the cow by inoculating with the smallpox virus (retro-vaccination as it is called), is not only unreliable, as affording protection against smallpox in man, but it has been found repeatedly to communicate the latter disease. Vaccine virus, thus obtained, is, therefore, never to be employed in vaccination.[1] Experiments have confirmed the correctness of the opinion held by Jenner that an affection sometimes seen in horses, known as *grease*, called by the French *des eaux jambes*, is identical with cowpox, and that vaccinia in man may be derived from this source. It is not, however, settled that, as supposed by Jenner, cowpox in the cow was derived from the horse. It has also been ascertained that sheep are affected with an epizootic disease, called by the French *clavelée*, which is analogous to, if not identical with, cowpox. As to the origin of the disease in these and perhaps other domestic animals, it is not certain that it was primarily a human disease, but this view is perhaps the most rational with our existing knowledge. The vaccine lymph

[1] *Vide* Journal of the Gynæcological Society of Boston, April and June, 1872. Report of discourse by Dr. Henry A. Martin.

contains low organisms (micrococci) similar to, if not identical with, those in lymph from smallpox vesicles. Whether these organisms represent the contagium of the lymph or not, is a question still undecided. The experiments of Chauveau have rendered it probable that the contagium is a molecular substance, and is not dissolved in the lymph.

Other questions, the importance of which is obvious, are, what degree of protection against smallpox is afforded by cowpox, and what are the causes of the protection not being universal and complete? In a large majority of cases, vaccination affords, for a time at least, absolute protection against smallpox. In these cases the situation of persons vaccinated, as regards susceptibility to the latter disease, is precisely as if natural or inoculated smallpox had been experienced. But in a minority of cases the protection is only partial; the susceptibility to smallpox is not destroyed, but the disease is materially modified, constituting what is called *varioloid*. At certain times and places, the causes which give rise to the epidemic prevalence of smallpox being unusually efficient, a considerable number of vaccinated persons become affected with varioloid. Owing, however, to the comparative mildness of varioloid, the rate of mortality is very small, and, therefore, fails to represent the relative number of vaccinated persons who become affected with modified smallpox. It is to be remarked that smallpox, in a certain proportion of cases, is experienced a second time. From the following statistics it would appear that not much more protection is offered by the occurrence of variola than by vaccination: Of 5774 boys admitted into the Royal Military Asylum at Chelsea (England) in 48 years, 1950 had, on admission, marks of smallpox, and 3824 either had marks of vaccination or they were at once vaccinated. Of the former, 6.15 per 1000, and of the latter, 7.06 per 1000, contracted smallpox subsequently during their residence in the asylum.[1]

The opinion is largely held, and appears to be well founded, that the extent of protection afforded by cowpox is less in the latter than in the former part of the period which has elapsed since the discovery of vaccination; that is, a larger proportion of vaccinated persons have had varioloid of late years than heretofore, and hence, many have been led to entertain the belief that the vaccine virus has deteriorated in consequence of its transmission from person to person.

Another reason for the increase of varioloid among those who have been vaccinated is, the protective influence of vaccination diminishes after the lapse of a certain number of years. Varioloid occurs much oftener among those more or less advanced in life than among the young. The length of time which has elapsed after a vaccination, may fairly be considered as entering into the etiology of varioloid. The importance of revaccination rests upon this fact. Revaccination, after the lapse of a greater or less number of years, is completely successful, as regards the production of the vaccine disease, in a considerable proportion of cases, and partial success, as shown by imperfect or vaccinoid vesicles, is still more common. The epidemic prevalence of smallpox, embracing numerous cases of varioloid among vaccinated persons, has been promptly and completely arrested by universal vaccination and revaccination.

The importance of revaccination being admitted, the inquiry arises, how often should it be resorted to? There is no known law governing the duration of the protective influence of a single vaccination. Probably the duration varies widely in different persons, and some persons are protected by one vaccination for life. Some have thought that revaccinations should be practised as often as every three years, and others that an interval of twenty

[1] *Vide* Reynolds's System of Medicine.

years or more is allowable. It is evidently better that the period should be needlessly short than too long. With our present knowledge, the propriety, if not importance, of revaccinating every five years is to be advocated. In case of known exposure, or when smallpox prevails as an epidemic, it is proper to revaccinate without regard to previous vaccinations. Revaccination, in fact, is always proper as the readiest and safest test of insusceptibility to smallpox.

There is ground for the belief that the frequent occurrence of varioloid, and also unmodified smallpox, among those who suppose themselves to be protected by having had cowpox, is due, in no small measure, to imperfect or spurious vaccinations. In this country, vaccinators are often unqualified persons. The operation is performed, not infrequently, by those who make no pretensions to medical knowledge, and to a great extent by irregular practitioners. In many cases, persons vaccinated are never seen after the operation, they or their friends undertaking to judge for themselves of its success. Hence many persons are either wholly unprotected, or but partially protected.

A cause of inadequate protection is an insufficient number of vaccine vesicles. Many have supposed that a single vesicle is all that is required, and that the only advantage of inserting the virus in more than one spot is to diminish the risk of failure to procure a single vesicle. In many parts of this country it is not customary to procure more than one or two vesicles. Facts show that the number of vaccine vesicles has a decided influence on the amount of protective influence of cowpox. The following results of the analysis, by Simon, of nearly 6000 cases of smallpox contracted after vaccination, with reference to the proportion of deaths to the number of cicatrices, is interesting as connected with the present topic: The ratio of deaths among those who stated that they had been vaccinated, but who presented *no* vaccine cicatrix, was $21\frac{3}{4}$ *per cent.;* among those who had *one* cicatrix, $7\frac{1}{2}$ *per cent.;* among those who had *two* cicatrices, $4\frac{1}{8}$ *per cent.;* among those who had *three* cicatrices, $1\frac{3}{4}$ *per cent.;* and among those who had *four or more* cicatrices, $\frac{3}{4}$ *per cent.*[1] In a primary vaccination it is desirable that from four to six vesicles should be produced on each arm. The number should not be less, after known exposure to smallpox, in secondary vaccinations. A less number, however, may suffice when it is only desired to test the fact of protection by previous vaccinations.

Within the past few years an important practical question, relating to vaccination, has arisen in this country. In 1866, a case of spontaneous cowpox was discovered at Beaugency, in France. The virus obtained from this animal was perpetuated, through successive inoculations in heifers, conducted by Depaul, under the sanction of the French Academy of Medicine, and with the aid of the French government. The virus from this stock having been imported into this country by Dr. Henry A. Martin, of Boston, in 1870, he has kept up the supply through a continued series of heifer vaccinations; and, since that date, the supply has been kept up from virus derived from this stock, in New York and some other cities. The terms animal and bovine virus are used to distinguish that derived immediately from the heifer; that derived from the human subject being called humanized virus. The important practical question is whether the animal virus affords greater protection against smallpox than the humanized virus? That the latter has deteriorated in consequence of removes from the cow, seems certain. Vaccination with the long humanized virus is less constantly successful in producing vaccinia than formerly; the revaccination of persons who have been

[1] Aitken, *op. cit.*

vaccinated with this virus is oftener successful, and a diminished protection is shown by the greater number of vaccinated persons who become affected with varioloid. The opinion that vaccination with the animal virus secures a more complete and a longer exemption from the danger of contracting smallpox, is shared by many, and this virus is now extensively used in this country, instead of the humanized virus. It remains to be determined by the results of a long experience whether, assuming that, at the present time, the animal virus has a greater protective power, this power may not become deteriorated by distant removes from Beaugency stock, in heifers, as there is reason to believe has been the case in the human race. This, however, is a consideration which concerns the future; and a deterioration, if it occur, would only render it important to take advantage, at different periods, of other instances of vaccinia, in the cow, of spontaneous origin,[1] and in this way to renew the stock.

Vaccinia in man produced by the animal virus, differs, in certain respects, from the disease as produced by the long humanized virus. The full development of the vaccine pock requires a longer period; the pock continues to increase for several days after the eighth day, this being the period required for the full development of the pock after vaccination with the long humanized virus. The pock is of larger size. The crusts are not formed until the eighteenth or nineteenth day, and they remain adherent from the twenty-fifth to the thirty-fifth day. The vesicle does not spontaneously rupture, and the crust preserves the form of the vesicle, with the umbilicated centre. The constitutional symptoms are more marked. In a small proportion of cases (one in fifty) a vesicular eruption occurs over the body, and the vesicles, on close inspection, are found to be umbilicated. With respect to these points of difference, the disease, as now produced by the animal virus, corresponds with the disease as described and delineated by the earliest vaccinographers—a fact which, in itself, renders probable the deterioration of the humanized, and the superiority of the animal, virus.[2]

Assuming that the animal or bovine virus is equal to the humanized in its protective power (and at least this must be conceded), there are certain advantages which the former has over the latter. There is far less liability to local accidents, namely, ulcerations and erysipelas. Dr. Martin states that, in April, 1872, there had been, at least, 400,000 revaccinations made, in this country, with the Beaugency virus, and no case of death, of erysipelas, or of post-vaccine variola had been reported among them. Another advantage is a more uniform success in both primary vaccinations and revaccinations. Another is, the supply of virus can always be made to meet the demand. Again, an advantage which has only to be named for its importance to be apparent, is the fact that the virus from the heifer is incapable of communicating syphilis. Granting that the risk of syphilis is small when humanized virus is used, there is, nevertheless, a risk; syphilis has been repeatedly communicated. It is an immense advantage to eliminate all danger in this direction.

Deterioration of the humanized virus is to be added to the causes, previously enumerated, of the apparent inadequateness of vaccination to afford complete protection against smallpox. Assuming that this obstacle may be

[1] The term *spontaneous* is here used to distinguish from the disease produced by retrovaccination. Whether cowpox is ever in a broader sense spontaneous, is an open question.

[2] *Vide* Discourse by Dr. Martin in Journal of the Gynæcological Society of Boston. Also, Practical Remarks on Vaccination by Dr. Frank P. Foster, in Neumann's Handbook of Skin Diseases, translated by Bulkley. Also, Sur le Cowpox découvert a Passy, par Bousquet, Paris.

overcome by the use of animal virus, the other causes are removable; and, were they to be entirely removed, it is not improbable that the expectation which Jenner cherished of exterminating smallpox might be realized. Certain it is, that, were all the requisites for the most perfect vaccination to be invariably observed, and if all persons living were vaccinated and revaccinated, smallpox, if not exterminated, would be insignificant as regards its prevalence and severity. The difficulty of securing for all mankind a protection against the disease almost complete, is not so much in the insufficiency of the means, as in enforcing their adoption to the fullest possible extent. Vaccination and revaccination, in order to be universal, must be compulsory, and authoritative measures to secure the proper and successful performance of the operation are essential. To consider the most efficient legal provisions to accomplish these desirable ends would be to open up a wide field for discussion, which would be inconsistent with the objects of this work. Strange as it may seem, there are persons, not without intelligence, at this day, who entertain toward vaccination the prejudices which Jenner had to encounter.

It remains to notice some practical points relating to the operation for vaccination. The situation for the introduction of the vaccine virus should always be that usually selected, namely, on the arms near the insertion of the deltoid muscle. Uniformity of practice in this respect enables physicians and others to ascertain, without delay or doubt, the fact of a previous vaccination, and to judge of its success by an examination of the cicatrices. The vaccine lymph is to be preferred to the crust. The lymph is usually taken on ivory points or pointed quills, but the virus taken in this way to be effective must be recent. With a view to preservation, the lymph may be withdrawn from the vesicles in glass capillary tubes which are at once sealed by means of a spirit-lamp. A crust inclosed in wax and covered with tin-foil retains its activity for a considerable period.

As regards the mode of vaccinating, if dried lymph be used, or lymph contained in capillary tubes, it may be inserted by means of slight punctures, or by scraping away the epidermis, or by minute scarifications; the latter method is preferable. Having made, with a common lancet, numerous linear and transverse scratches, not deep enough to cause the escape of more than a drop or two of blood the lymph is to be applied over the scarified spots which should be from four to six in number and not larger than half a dime. If the incisions be sufficiently delicate, the operation gives no pain, and allowing the spots to dry before being covered by the clothing is all that is required. If the crust be used, a small portion should be dissolved, always at the time of the operation, in a drop or two of water, and applied by means of the lancet over the scarified spots. This is preferable to making punctures and introducing small pieces of the undissolved crust. The latter mode is apt to cause sores which, aside from the annoyance they occasion, may interfere with the specific action of the virus.

The age for the performance of a primary vaccination is a point of importance. There has been some discussion recently as to whether vaccination of the mother during the last months of pregnancy removes the susceptibility to the vaccine virus in the infant after birth. The experiments of Gast,[1] however, have shown that no reliance is to be placed upon this method of so-called intrauterine vaccination. Between the second and the third month of infancy is the period to be preferred for vaccination. A liability to exposure to smallpox, however, renders the operation advisable at an earlier period. It is desirable that the child when vaccinated should be in good health, but the operation should not be delayed on account of illness, if there be a liability

[1] Gast, Schmidt's Jahrbücher, Bd. 183, p. 201, 1879.

to exposure to smallpox. If the operation prove unsuccessful, another trial should be made, and, if this fail, the virus may be introduced a third time. Some persons are insusceptible to cowpox; an insusceptibility is to be inferred from two or three successive failures with virus which has proved successful in others. The attempt to vaccinate, however, should be repeated from time to time, for susceptibility may afterward exist. So long as there is insusceptibility to cowpox, there is little danger of smallpox being contracted. Aside from want of susceptibility, and exclusive of inertness of the lymph or crust used, the common cause of failure is undue bleeding from the scarifications, the flow of blood preventing the absorption of the virus.

Troublesome ulcerations occasionally follow vaccination, arising from irritation by the friction of clothing, or from an unhealthy condition of the system. These are to be treated like ordinary sores. Erysipelatous inflammation and abscesses may occur. These concomitants or sequels are not always evidence of any fault in the operation or impurity of the matter used. Dr. Henry G. Piffard, however, has reported cases in which the disease of the skin known as impetigo contagiosa has occurred as a sequel of vaccination with the virus in crusts both animal and humanized; and on the examination of a considerable number of crusts he has found in them not infrequently vegetable organisms which, as he has demonstrated, constitute the contagium of the cutaneous affection just named. The liability to the communication of this affection is a reason for preferring lymph to crusts for vaccination.[1] Ignorant persons are sometimes prone to attribute to vaccination diseases of any kind which may occur within a few weeks or months afterwards, and to charge the physician with having used impure vaccine matter. This impression may be so rooted as not to be removed, and, hence, a vaccination may very unjustly prove the occasion for a withdrawal of the confidence which the physician had previously possessed. So far as the imputation of communicating human diseases is concerned, it is avoided by using the animal virus, and this is a recommendation of the latter to be added to the advantages already mentioned.

After a known exposure to smallpox, if the person exposed have not been recently vaccinated, or if there be any reason to distrust a previous vaccination, revaccination should, of course, be promptly performed. It is proper to perform it without reference to previous vaccinations, with a view to test the susceptibility and render the security as complete as possible. It has occurred to me repeatedly to vaccinate, under circumstances involving the utmost possible exposure, persons who had never been vaccinated, and thereby to prevent the occurrence of smallpox. In one instance an unvaccinated child lived in the same room and slept with a person who had contracted smallpox. The first operation proving unsuccessful, it was repeated three days afterwards with success, and the child escaped. In another instance a patient with measles was supposed to have smallpox and sent to a smallpox hospital. He had never been vaccinated, and vaccination was at once performed; the vaccine disease was deferred until the measles had run its course, it then became developed, and smallpox did not occur. Owing to the relatively short duration of the period of incubation in cowpox, it anticipates the development of smallpox. I have not observed the co-existence of the two affections under these circumstances.

Varicella. Chicken-Pox.

Varicella, or, as it is commonly called, *chicken-pox*, is an affection quite insignificant as regards danger or distressing symptoms. It is important

[1] *Vide* articles by Dr. Piffard in the New York Med. Journal, Nos. for June and July, 1872.

with reference, *first*, to the question as to its having pathological relations with smallpox, and, *second*, to its discrimination from modified variola or varioloid.

It is an eruptive disease affecting, for the most part, children, but occasionally adults. The eruption is preceded generally by slight constitutional symptoms for about twenty-four hours. The eruption appears first on the body, and afterwards on the head. It is usually more abundant on the neck, body, and scalp, than on the face. The eruption is frequently quite small, and very rarely abundant. It is almost invariably discrete. It is a vesicular eruption from the first. The vesicles contain, at first, a transparent liquid which afterward becomes opaline, but not purulent except when they are irritated by scratching. Desiccation occurs from the fifth to the seventh day. The crusts are granular, and are rarely followed by cicatrices or pitting. Sometimes bullæ of greater or less size form instead of vesicles. New vesicles frequently continue to appear during the first three days of the stage of the eruption, and even after the desiccation of those which first appeared has commenced. During the eruptive stage constitutional symptoms are slight or wanting. The disease is contagious as regards children but very rarely as regards adults. Experiments made to determine its communicability by inoculation have so generally failed, that it is a question whether, in the few instances in which it was apparently successful, the contagium may not have been otherwise received. The period of incubation varies from twelve to seventeen days. Writers have instituted several varieties based upon differences as regards the size and shape of the vesicles. The ordinary variety, in which the vesicles are about the size of split peas and flattened at the top, has been distinguished as *varicella lentiformis*, *vel lenticularis*, or lenticular chicken-pox. The variety called *varicella coniformis*, *vel conoides*, or *swine-pox*, is characterized by the conoidal form of the vesicles. *Varicella globularis*, *vel globata*, is the name of a variety in which the vesicles are unusually large and globular in form. The different vesicles in the same case not infrequently present the characters of these three varieties. The division into varieties is of not the least practical consequence.

The name varicella, which is a diminutive of variola, meaning *little smallpox*, implies that the disease is essentially variolous. It has been considered as a modified form of variola, and is so considered by some eminent teachers and writers at the present time. The non-identity of the two affections is established by the following facts: The miasm of varicella is never known to give rise to ordinary variola, whereas the severest form of the latter disease may be derived from cases of varioloid. Varioloid prevails only during the prevalence of ordinary smallpox, but varicella not infrequently prevails when there are no cases of smallpox. Varicella is very rarely communicated to adults. This is not true of varioloid. Varicella affords no protection against variola, and, conversely, persons who have had smallpox contract varicella. Vaccination does not protect against varicella, and the latter does not interfere with the success of vaccination. It is not settled that varicella is ever communicable by inoculation. Other points of difference, showing the non-identity of varicella and varioloid, relate to the clinical history, and upon these points the differential diagnosis is to be based.

Although pathologically distinct, it must be confessed that the discrimination of varicella from varioloid is not always easy. The two affections are liable to be confounded. Cases of varioloid are not infrequently, at first, considered as cases of varicella, and *vice versâ*. In view of the great importance of making this differential diagnosis promptly and positively, the following diagnostic points claim the careful attention of the student and practitioner:—

The stage of invasion in varioloid is as long as, or longer than, in cases of ordinary smallpox, namely from two to three days. The short duration of this stage in varicella is a distinctive feature. The constitutional symptoms, in this stage, are often as marked in varioloid as in cases of ordinary smallpox. The mildness of these symptoms in varicella is a diagnostic point. The vesicular character of the eruption from the start is characteristic of varicella. In varioloid the vesicles are preceded by papules. In varioloid, as in ordinary smallpox, the eruption appears at first and especially on the face; in varicella, it appears first on the body, and is apt to be more abundant elsewhere than on the face. A capital diagnostic point relates to the central depression or the umbilicated appearance; this is generally discoverable in more or less of the vesicles in varioloid, and it is generally, if not invariably, wanting in varicella. The duration of the eruptive stage is less in varicella than in the great majority of cases of varioloid. Finally, traces of vesicles in varicella are rarely found on the mucous membrane of the mouth, fauces, and genitalia.

During the prevalence of smallpox, cases of varioloid in which the eruption is small, are often considered as cases of varicella. The cases of so-called varicella in adults when smallpox prevails, are generally cases of varioloid—hence, one source of the diffusion of smallpox.

Varicella claims no treatment. It is important to recognize it only in order to relieve apprehensions by the assurance that the disease is not varioloid.

CHAPTER VII.

ERUPTIVE FEVERS—(Continued.)

Scarlatina, or Scarlet Fever—Anatomical Characters—Clinical History—Causation—Diagnosis—Prognosis—Treatment.

THE exanthematous fever called, from the color of the eruption, *scarlatina*, or *scarlet fever*, is remarkable for the wide diversity which it presents, in different cases, as regards symptoms and fatality. In its mildest form it is a trivial affection; in its severest form there are few diseases more appropriately styled malignant. The disease has been divided into several varieties based on differences in symptomatic characters and intensity. Three varieties are generally recognized by writers, namely, *scarlatina simplex*, *scarlatina anginosa*, and *scarlatina maligna*. Widely different as are these varieties in respect of gravity and distinctive characters, they are not distinct diseases; essentially they are identical. A simpler division is into mild and severe scarlatina, but it will suffice to consider incidentally the events which belong to the latter, without treating of it separately.

Anatomical Characters.—The eruption on the surface and the morbid appearances in the throat constitute the leading anatomical characters in this affection. There is usually little or no trace of the eruption to be observed after death. The eruption is caused by hyperæmia, combined with more or less œdematous swelling, of the cutis. In a case in which death took place

at the height of an intense scarlatinal eruption, Birch-Hirschfeld observed many lymphoid cells between the epithelial cells of the rete Malpighii, as well as in the superficial and deeper layers of the corium. He also saw small extravasations of blood. Fenwick has called attention to blood extravasations in the lumen of the sweat-glands. The cutaneous affection of scarlatina is to be regarded as a superficial dermatitis of mild degree.

In the mildest form of scarlatinal sore throat, the mucous membrane covering the tonsils, soft palate, and pharynx, is reddened and slightly swollen. The tonsils are frequently enlarged. A phlegmonous inflammation of the parts named may occur in severe cases of the variety of the disease designated scarlatina anginosa. The swelling is then extreme. The submucous and the mucous layers become infiltrated with pus-cells. Abscesses form, especially in the tonsils. The phlegmonous inflammation may terminate in destructive ulceration or in gangrene. The phlegmonous inflammation may be propagated to the connective tissue in the submaxillary region, and give rise to extensive purulent collections in this situation. Erosion of the large vessels has been caused by this suppurative process in the neck. In some epidemics, diphtheritic inflammation of the throat has been a frequent attendant upon scarlet fever. The fibrinous exudation begins on the tonsils and extends to the soft palate and to the pharynx. It has less tendency than primary diphtheria to extend into the larynx. There is much controversy as to the relation which this diphtheritic affection of the throat bears to scarlatina. There are three prominent views as to this relation. According to one view the diphtheritic affection is anatomically the same disease as primary diphtheria, but it is produced by the scarlatinal poison; according to a second view, the disease, both anatomically and etiologically, is identical with primary diphtheria, and it is to be regarded as a complication of scarlet fever; according to the third view, scarlatinal diphtheria differs in its anatomical characters from primary diphtheria. Heubner has attempted to prove, from an anatomical point of view, the non-identity of scarlatinal diphtheria and primary diphtheria, but the differential criteria to which he calls attention are not sufficient to distinguish anatomically one disease from the other.[1] The inflammatory process may be propagated from the pharynx along the Eustachian tubes to the mucous membrane lining the cavity of the middle ear. Suppurative median otitis, with perforation of the tympanum, and sometimes with consecutive caries of bone, may thus be produced. Swelling and inflammation of the lymphatic glands of the neck not infrequently accompany scarlatinal angina. The glands may suppurate. The mucous membrane of the larynx, trachea, and bronchi, is sometimes inflamed. The inflammation in this situation is rarely accompanied by a fibrinous exudation. Lobular pneumonia is an occasional complication of scarlatina. Lobar pneumonia is less frequent. Fenwick has observed parenchymatous degeneration of the gastric tubules in this disease. Peyer's patches and the solitary follicles of the intestine are often moderately swollen. There may be found ecchymoses in the gastric and intestinal mucous membrane, but they are rarely abundant. Dysentery is a rare complication of scarlet fever. The spleen has often been found enlarged. Swelling of the mesenteric glands, as well as of other lymphatic glands of the body, has been observed in a number of cases. Parenchymatous degenera-

[1] The points to which Heubner calls attention are: 1. The pseudo-membranous deposits are much thinner in scarlatinal than in primary diphtheria, so that in the former disease membranes are not expectorated. 2. The fibrin in scarlatinal diphtheria is found between the epithelial cells and in the connective tissue of the mucosa and submucosa. He could detect no differences between the micrococci present in scarlatinal diphtheria and those of primary diphtheria. Beobachtungen über Scharlach-Diphtherie. Jahrbuch der Kinderheilkunde, xiv. p. 1, 1879.

tions of the liver, kidneys, and heart occur in scarlet fever. In some cases in which the immediate cause of death has been failure of the heart-power, fatty degeneration of the muscular substance of the heart has been present.

The most important sequel of scarlet fever is acute Bright's disease. Some regard this occurrence as a part of the scarlatinal process; others as a complication. The kidneys in cases of scarlatinal nephritis present appearances which have been described in the article on acute Bright's disease (page 863). The kidney is enlarged and generally pale. When death occurs some days after the onset of the nephritis, the accumulation of lymphoid cells in the intertubular tissue, and especially about the glomeruli, is well marked. Sometimes small abscesses form in the kidneys in this disease.

Clinical History.—The symptomatic events of the several stages separately will be first noticed, and, afterward, anomalous events and complications liable to occur in either of the three stages.

Stage of Invasion.—The attack may commence with a chill more or less pronounced, but not infrequently it is wanting. Vomiting is generally an early symptom, especially in children, with, in a certain proportion of cases, diarrhœa. The pyrexia, as a rule, is notably greater than in the other eruptive fevers. Epistaxis is not uncommon. Redness of the fauces, more or less vivid, may generally be observed in this stage, either with or without a sense of soreness, and pain in swallowing. The affection of the throat is due to the efflorescence which appears in this situation before its appearance on the skin. As regards the intensity of the pyrexia, pain in the head, prostration, and general malaise, different cases differ widely, not including cases of unusual severity. In very mild cases the symptoms are so slight that the patient does not take to the bed.

The average duration of this stage is about twenty-four hours; the eruption usually appears on the second day. Exceptionally it appears, on the one hand, a few hours after the attack, and, on the other hand, it may be delayed one, two, three, or more days after the time when it usually appears. A considerable delay in the appearance of the eruption is generally attributable to some complication.

Stage of Eruption.—This stage, in children, is sometimes ushered in by a transient convulsion which, at this period, is not a uræmic symptom. In its development and diffusion over the body, the eruption does not observe the same regularity as in smallpox and measles. It oftener appears on the body and limbs before making its appearance on the face and neck, but in a certain proportion of cases it appears first on the latter situations. It is rapidly diffused, extending more or less over the whole cutaneous surface in twenty-four hours. As regards the degree and extent of the efflorescence, different cases differ much. The first appearance is in the form of minute dots or specks. These coalesce, forming irregularly distributed patches which vary much in size and shape, having irregular or serrated margins. Exceptionally, the eruption remains punctiform, that is, in the form of distinct maculæ or spots. The redness is most vivid and remains longest in situations where the skin is delicate, as the inner surfaces of the arms and thighs and the flexures of the joints. The redness is vermilion or scarlet; it is not uniform, like erysipelatous redness, but, on close inspection, the patches are seen to be studded with points which are distinguished by a more deeply red color. The redness momentarily disappears on pressure, and white lines are produced by drawing a pointed hard substance—for example, a pencil—over the reddened surface. In some cases the whole cutaneous surface is covered with the efflorescence, presenting an appearance which has been compared to that of a boiled lobster. Generally, on passing the fingers

over the reddened surface, it is felt to be smooth, but in some cases there is a sensation of minute elevations or papules; these are the papillæ abnormally developed, as in the condition commonly known as goose-skin. Occasionally miliary vesicles are scattered, more or less abundantly, over the surface. The integument is slightly swollen; this is evident on the face, and is apparent to the patient when the hands are closed. The feet are also evidently somewhat swollen. The eruption is sometimes accompanied by more or less burning and pruritus. The eruption attains to its maximum of intensity and diffusion on the third day after its first appearance.

There is much variation in different cases in the amount of cutaneous eruption. It is sometimes slight. This is apt to be the case when the throat affection is unusually severe; the eruption then seems to be concentrated within the throat. Occasionally the efflorescence on the skin disappears shortly after its appearance, and afterward returns. It fluctuates as regards vividness, being especially marked in febrile exacerbations, and it is generally more vivid toward evening than in the early part of the day. In anomalous cases, which will presently be referred to, the eruption is wanting.

The throat is more or less affected in the vast majority of cases; but in some very mild cases there is no throat affection. If the throat be but slightly affected, there is simply redness over the tonsils, the posterior part of the pharynx, and extending more or less over the soft palate, with little or no swelling. The affection is then only an efflorescence. In most cases, however, there is more or less swelling of the tonsils, together with a white or ash-colored exudation in greater or less abundance. This exudation is generally not like that which characterizes diphtheritic inflammation. It adheres less closely; it is pultaceous, and cannot be detached in strips. It may receive a dark color from matters vomited and from the oozing of blood. In proportion to the amount of throat affection there is pain in deglutition, and the voice becomes nasal. The submaxillary and lymphatic glands at the angle of the jaw are frequently swollen and tender. A still greater degree of throat affection belongs among the anomalous events of the disease, and characterizes the variety distinguished as scarlatina anginosa.

The tongue early in the disease is generally coated. While the coating remains, frequently the papillæ projecting through it have the appearance of numerous red points; the surface of the tongue looks as if cayenne pepper or red sand had been sprinkled over it. This is seen in other affections. Another appearance is quite distinctive of scarlet fever. In the progress of the disease, the coating exfoliates, leaving the surface of the tongue clean and reddened; and, the papillæ being enlarged, the appearance is strikingly like that of a ripe strawberry. The strawberry-like tongue is a pathognomonic symptom; it is peculiar to this disease. It is often but not uniformly present. It is due to a condition of the mucous membrane analogous to that of the skin in the cases of so-called *rough*, as distinctive from *smooth*, scarlatina.

The pyrexia is not diminished, but, as a rule, increased after the appearance of the eruption. The frequency of the pulse and increased heat of the skin are more marked than in any other of the essential fevers. The pulse varies in different cases which, although more or less severe, pursue a favorable course, from 100 to 130 or 140 per minute. In extremely severe cases, especially in children, it rises still higher. Aside from frequency, the pulse is quick, often vibratory or thrilling, but always compressible, these characters showing excited action without augmented power of the ventricular contractions. The sphygmograph, as in all the eruptive fevers, shows absence of dicrotism. The skin is usually dry, and the heat, as felt by the hand, is often pungent. The thermometer in the axilla shows an increase of tempera-

ture to 105° Fahr., and in severe cases a still greater increase; it has been known to reach 112° Fahr.

During the stage of the eruption, anorexia continues, vomiting is not uncommon, constipation exists in some cases, and in some cases diarrhœa. Thirst is usually urgent. Delirium, manifested by incoherency, generally exists, save in very mild cases. I have known a patient, not considered ill enough to require a watcher during the night, get up and wander out of doors in a state of delirium. A melancholy instance, illustrative of the importance of watchfulness in the care of patients in the delirium of fever, occurred, many years ago, at the Louisville Marine Hospital during my term of service. A female adult patient affected with scarlatina, but not considered as seriously ill, had been removed to a room, by herself, in the uppermost story of the hospital building, with a view to isolation. During the absence of her attendant for a few moments, she precipitated herself from the window, and, falling upon the pavement, was instantly killed. Restlessness, jactitation, and insomnia are apt to be more or less marked. Albuminuria occurs in a certain proportion (about one-seventh) of cases during the eruptive stage. Transient, slight albuminuria occurs in scarlatina, as in various other affections, without denoting renal disease; but disease of the kidneys forms an important complication in certain cases of scarlatina, and will presently be noticed. The duration of the stage of eruption, in the majority of cases, is from 4 to 6 days. It is sometimes shorter; oftener it is prolonged to 8 or 10 days, and occasionally it continues for a longer period.

Stage of Desquamation.—The commencement of desquamation marks the beginning of this stage. Desquamation frequently commences with the decline of the eruption, and prior to its disappearance. The degree and extent of the desquamation is, in general, proportionate to the intensity and diffusion of the efflorescence. Desquamation is rarely wanting, save in the cases in which the efflorescence fails to appear. The cuticle is exfoliated either in the form of minute branny scales, called furfuraceous desquamation, or in pieces of epidermis of greater or less size. Occasionally the epidermis of the hands is detached entire, and may be stripped off like a glove. This is true also of the epidermis of the feet. Sometimes several successive exfoliations occur.

In cases which pursue a favorable course, the febrile movement diminishes with the commencement of exfoliation and gradually ceases, corresponding improvement taking place in other symptoms. The defervescence is sometimes rapid, but in most cases gradual. If the disease be uncomplicated, and there be no untoward events, convalescence is declared during the stage of desquamation. The desquamative process is frequently accompanied with pruritus which, in some cases, is excessive. Albuminuria occurs in this stage more frequently than in the stage of eruption, namely, in the proportion of one-fourth. As in the stage of eruption, so in the desquamative stage, the presence of albumen in the urine may, or may not, be indicative of an important renal complication. A recurrence of the eruption may take place during the stage of desquamation.

The duration of this stage is indefinite. It may end in five or six days. The desquamation is generally completed in from ten to twelve days, but, exceptionally, it continues for several weeks.

The foregoing sketch of the clinical history of scarlet fever applies to cases which are either mild or not extremely severe, and in which the course of the disease is regular, that is, without anomalous events or complications. Certain cases are characterized by extreme gravity of the symptoms at the outset of the disease. The pulse becomes very frequent, numbering 140, 150, 160, or more per minute. The thermometer shows notable hyper-

pyrexia. Great restlessness, delirium, coma and occasionally convulsions, are other symptoms denoting severity of the disease. Death may take place in one or two days, or sometimes even within a few hours from the attack. A fatal result may take place before the eruption appears on the skin or any pharyngeal redness is apparent. The disease, in such cases, is truly malignant. Cases of this description are liable to occur in certain epidemics. The gravity in these cases is not due to any complication, but to an unusual intensity of the essential morbid conditions which constitute the disease. Ataxic or nervous symptoms, in like manner dependent on the intensity of the disease, are liable to be developed at a later period, namely, active delirium, typhomania, carphologia, and subsultus tendinum. These symptoms characterize certain cases of severe scarlet fever.

Convulsions, coma, and delirium may be developed as effects of uræmia. Disease of the kidneys is an important complication in a certain proportion of cases. Generally, but not always, in these cases the urine is highly albuminous. Albuminuria, as already stated, may not indicate any important affection of the kidneys, if the quantity of albumen be small; and, on the other hand, grave disease of the kidneys may exist without albuminuria. The presence of casts, with white or red corpuscles in the urine, is more significant of renal disease than the presence of albumen. The danger of uræmia is proportionate to the scanty excretion of urine. Clinical facts show that scarlatina involves a special tendency to renal disease, not only as a sequel but as a concomitant. It is a rational supposition that the lining membrane of the secretory tubes of the kidneys takes on a morbid condition analogous to that of the mucous membrane of the pharynx, constituting a local affection serious in proportion as the excretion of urea is interfered with. General dropsy sometimes occurs during the progress of the disease, as well as afterward. Symptoms pointing to uræmia, in addition to the events already stated, namely, convulsions, coma, and delirium, are, cephalalgia, disturbance of respiration occurring without either bronchitis, pneumonia, œdema of the lungs or any appreciable pulmonary affection, defective vision, vomiting, and occasionally diarrhœa. These symptoms should direct attention to the urine as regards albuminuria, the presence of casts, and, more especially, the deficiency of urea. Uræmia, taking place either as a concomitant or a sequel of scarlet fever, may occur without albuminuria, and without dropsy. Hence the importance of examinations of the urine in all cases, with reference, not alone to the presence of albumen, but of casts and the quantity of urea.

Certain cases of severe scarlatina are characterized by a great amount of throat affection. The name *scarlatina anginosa* is applied to these cases. The tonsils are greatly swollen, and covered with a muco-purulent pultaceous deposit. Deglutition is difficult, and liquids taken into the mouth are returned through the nostrils. The inflammation may extend to the posterior and anterior nares, and acrid pus flows from the nose, excoriating the face. The breath emits an intolerable fetor in some cases. Sometimes, but rarely, the inflammation extends into the larynx and bronchial tubes. Œdema of the glottis is an occasional accident in adults. The structures of the eye may become involved, and destruction of both eyes has been known to follow. An extension of the inflammation through the Eustachian tube into the middle ear is liable to occur. I have met with a case in which the tympanum in each ear was perforated, and the ossicles were discharged through the external meatus. Permanent deafness, facial paralysis, and, in some cases, caries of the temporal bone followed by circumscribed meningitis and abscess of the brain, are effects of an extension of the local affection to the middle ear. The submaxillary and lymphatic glands of the neck become more or less enlarged, and sometimes suppuration takes place, constituting what have

been called *scarlatinous buboes*. I have met with a case of extensive sphacelation of the lips and cheeks, the patient being a child well nourished and healthy up to the date of the attack. Gangrene and ulceration within the throat are very rare events. The local events belonging to scarlatina anginosa, inclusive of inflammation and suppuration of the glands of the neck, may occur rarely in the disease, or, on the other hand, they may be developed during the stage of desquamation, the symptoms having previously denoted a mild form of the disease. A true diphtheritic exudation in the fauces characterizes certain cases.

In cases of so-called *scarlatina anginosa*, the cutaneous eruption is apt to be slight and sometimes wanting. Albuminuria is more apt to exist in these cases. Uræmic phenomena are liable to occur, but, exclusive of these, and of laryngitis or œdema of the glottis, the severity of the throat affection may be sufficient to lead to a fatal result.

Hemorrhages in various situations, together with petechiæ and vibices on the skin, characterize certain cases. The name *hemorrhagic scarlatina* has been applied to these cases. They are almost invariably fatal. Hæmaturia occurs in connection with renal disease, and, if not accompanied by hemorrhage elsewhere, is not necessarily of grave omen.

Complications other than those which have been noticed, and of rare occurrence, are articular rheumatism, usually confined to a few joints, vaginitis, pleuritis or pyo-thorax, pericarditis, and endocarditis (sometimes of the acute ulcerative form), the two latter affections being often associated with either rheumatism or renal disease.

In irregular cases of scarlatina the disease is often, but by no means always, severe. The only local manifestation of the disease may be a slight soreness of the throat, no cutaneous eruption taking place. In these cases the disease has been distinguished as *scarlatina faucium* and *scarlatina sine eruptione*. Cases of the throat affection, more or less severe, without any eruption on the skin, not infrequently occur during the prevalence of epidemics of scarlatina. An attack of this kind appears, in some cases at least, to render the patient thereafter insusceptible to the disease, but it is not uncommon for persons who have once had scarlatina in its regular form to suffer from the throat affection when exposed to the contagium. In cases of *scarlatina sine eruptione* the nature of the disease is not infrequently overlooked. Another irregularity in very mild cases consists in the absence of any affection of the throat, the cutaneous affection being more or less marked. In these cases, doubtless, the disease sometimes exists without being recognized, or it is confounded with roseola. It has been supposed that the disease may exist without either an affection of the throat, a cutaneous efflorescence, or febrile movement. The name *scarlatina latens* has been applied to such cases. The evidence of the existence of the disease in this latent form is the occurrence of characteristic sequels, namely, albuminuria and anasarca, in persons who had been exposed to the contagium without presenting any of the usual phenomena of scarlatina. The local manifestation of the disease, in these cases, is supposed to be exclusively in the kidneys. Assuming that such cases occur, and that this explanation be true, it is more correct to say that the scarlatinous contagium sometimes gives rise to acute Bright's disease without causing scarlet fever. I have referred to cases exemplifying this fact in treating of acute diffuse nephritis.

Scarlatina has various sequels. The one which occurs most frequently has just been alluded to, namely, albuminuria with general dropsy. This follows the disease in a considerable proportion of cases, the proportion being found to vary at different times and places. The time of its occurrence is from ten to twenty days after the date of desquamation. The symptoms are those

of acute diffuse nephritis, an affection which has been considered in connection with the diseases of the urinary system.[1] Œdema of the face and lower extremities is first observed, and anasarca frequently follows. Effusion takes place into the serous cavities if the anasarca be considerable. Hydrothorax sometimes exists to such an extent as to embarrass seriously respiration. The urine is scanty, sometimes it has a smoky appearance, and it may be distinctly bloody. It may, however, contain few or no red blood-corpuscles. It is usually loaded with albumen, but cases have been reported by Rayer and others of dropsy after scarlatina without albuminuria. Epithelial, granular, and hyaline casts are generally found in the urinary sediment. Some red, but more white, blood-corpuscles are usually present. Blood-casts are not frequent. There is notable anæmia, the appetite is deficient, the temper is irritable, and muscular debility is more or less marked. Pyrexia, varying in degree in different cases, accompanies these symptoms. Uræmic coma and convulsions, pulmonary œdema and œdema of the glottis are grave accidents incident to the renal affection. They occur happily in but a small proportion of cases, and, under judicious management, this affection is rarely fatal. Temporary blindness is a rare event occurring in connection with uræmic convulsions following this disease. Acute nephritis after scarlet fever rarely ends in chronic renal disease. It is more rational to consider the renal affection which follows scarlatina as a special effect of the latter, than to attribute its production to cold or other causes acting after the scarlatinous poison has ceased to act.

The opinion was held by Graves and others that the kidneys are oftener affected after mild than severe cases of scarlatina. This sequel certainly occurs after mild cases, and sometimes when, from the absence of either the throat affection or of the cutaneous eruption, scarlet fever had not been supposed to exist. A probable explanation, however, of its occurrence in a larger proportion of mild cases, is afforded by the fact that, of severe cases, a considerable number end fatally during the progress of the fever. It is to be borne in mind that coma and convulsions may occur as sequels of scarlatina, due to uræmia not accompanied by either albuminuria or dropsy. That the renal affection has no necessary connection with the eruption on the skin, is shown by its occurrence in cases in which the scarlatinous rash was wanting.

Pleuritis, pericarditis, and acute articular rheumatism are occasional sequels, as well as concomitants, of scarlet fever. Chorea is also to be reckoned among the occasional sequels. External otitis is not uncommon. A purulent discharge takes place from the ears, and sometimes there is considerable deafness. If the inflammation be wholly without the tympanum, the deafness will be temporary, and, under judicious management, the affection may generally be removed. It is apt to return, from time to time, for a considerable period after recovery.

Causation.—The communicability of scarlet fever is established by irrefragable proof, and it is probable that its causation always involves a contagium. The contagium from mild is as efficient as that from severe cases. It is important that this fact be popularly known. Many persons, in this country, think that the disease in very mild cases differs essentially from that in severe cases, and it is a common impression that the name scarlatina applies only to the former. Physicians should take pains to correct the error of supposing that the names scarlatina and scarlet fever indicate different diseases. The contagium is contained in emanations from the body, probably in both the expired breath and the cutaneous exhalations; hence, the atmo-

[1] *Vide* page 863.

sphere surrounding patients is infected. It appears to be certain that the disease has been communicated by inoculating with the serum contained in the vesicles which sometimes appear in conjunction with the cutaneous efflorescence, but that inoculation does not materially affect the duration or the severity of the disease. That the disease may be communicated by means of fomites is unquestionable. The contagium may be carried in the clothes of physicians, nurses, and others. The disease is probably in this way often diffused. Facts show that the contagium adheres to material substances and preserves its morbific power for a long period. Persons have been attacked on returning to houses in which cases have occurred weeks or months previously, and even when elaborate efforts had been made to remove the contagium. Scarlatina sometimes follows with notable frequency surgical operations.

The period of incubation is undoubtedly, as a rule, much shorter in scarlatina than in the other eruptive fevers. Its duration, however, varies in different cases. Trousseau cites a case in which the attack took place within twenty-four hours after exposure. In a case under my observation, the patient, an infant of nineteen months, was attacked twenty-four hours after the first symptom of illness in a young girl who assisted in taking care of the infant. In another case the duration was forty-eight hours. It is probable that the period rarely exceeds six days.

Statistics show that the disease occurs most frequently in the third and fourth years of life; that the liability to it diminishes progressively after the fifth year, and becomes very small after forty. Children under two years of age and infants at the breast are not, as has been incorrectly stated, insusceptible to it. Several instances of its occurrence under two years of age have come under my observation. In one of these, a child only three weeks old contracted the disease from her mother who was attacked a few days after confinement. Cases have been reported in which the disease was contracted *in utero*.

As a rule, this disease is experienced only once; but, making due allowance for cases in which roseola may have been confounded with scarlatina, the exceptions to this rule are not extremely rare. Secondary or tertiary attacks are rarely fatal.

Diagnosis.—Attention to the following diagnostic points renders the discrimination of the disease, in the great majority of cases, easy: The short duration of the stage of invasion, the intensity of the pyrexia, the appearance of the efflorescence in the throat prior to the cutaneous eruption, the appearance of the efflorescence on the body and upper extremities often before, or simultaneously with, its appearance on the neck and face, the rapid extension of the efflorescence over the cutaneous surface, the scarlet color of the efflorescence, the irregular and serrated margins of patches of efflorescence, the persistence or increase of the pyrexia after the appearance of the efflorescence on the skin. These are positive diagnostic features belonging to the clinical history of scarlet fever as contrasted with smallpox and measles. On the other hand, the two latter eruptive fevers are excluded by the shorter period of invasion than in both, pain in the loins not marked in this period, absence of the characteristic eruption of variola in the mouth and fauces, the non-occurrence of variolous papules and vesicles with depression in the centre, and of the remission of fever when the eruption appears; absence of coryza and bronchitis which belong to the history of rubeola, and of certain distinctive characters pertaining to the eruption of measles, which will be stated in treating of the latter.

The difficulties in the way of diagnosis relate, in the first place, to extremely mild cases, with a slight eruption, and without any affection of the throat.

In these cases the disease is liable to be confounded with roseola. The differential points will be noticed in treating of the latter in the next chapter. In the second place, the diagnosis may be difficult in cases in which the local manifestation is confined to the throat; that is, cases in which the cutaneous efflorescence is wanting. It must be confessed that the diagnosis in some of these cases must be, in a measure, based on their occurrence during the prevalence of scarlatina, and sometimes on the occurrence of well-marked cases in members of the same family. In some cases of doubt or error, the sequels of scarlatina, more especially renal disease, serve either to correct or establish the diagnosis.

A highly probable diagnosis, before the efflorescence appears on the skin, may be based on a sudden attack of vomiting, with high febrile movement, and redness of the fauces, in a subject between three and five years of age, especially during the prevalence of scarlatina.

Prognosis.—There is, perhaps, no disease in the nosology which presents, in different cases, wider extremes, as regards gravity, than scarlatina. In malignant cases the disease is rapidly fatal. The proportion of these cases varies much at different times and places. The prevailing type of the disease, in some seasons, is mild, and in other seasons, severe. Whether this variation be due to a difference in the contagium, or to adjunctive influences, we are unable to say. Aside from the intensity of the disease, the danger depends on complications liable to occur in cases which, as regards the general symptoms, may appear to be mild. The symptoms which denote imminent danger from the intensity of the disease, are, excessive frequency of the pulse, hyperpyrexia, jactitation, active delirium and prostration, the mode of dying, in these cases, being by asthenia.

The prognosis is unfavorable in cases in which the throat affection is unusually severe. It is extremely unfavorable if diphtheria become devoloped, either during the progress of the disease, or as a sequel. If laryngitis ensue, a fatal result is to be expected. Great enlargement and suppuration of the glands of the neck, irrespective of diphtheritic inflammation of the fauces, denote great danger. If gangrene of the throat or mouth occur, recovery is the exception rather than the rule. Cases characterized by hemorrhage from mucous membrane and petechiæ or vibices are generally fatal. Uræmic coma and convulsions involve imminent danger, and uræmia may occur in cases which, as regards the general symptoms, appear to be mild. These symptoms may be developed, and sudden death take place unexpectedly if examinations of the urine have been omitted. Daily examinations of urine are highly important. The presence of albumen or casts should always excite apprehension, but the immediate danger is proportionate to the deficiency of urea. The patient is by no means safe after albumen has disappeared from the urine, if casts continue to be found in the sediment, more especially if the quantity of urine be small and the specific gravity low. The prognosis is extremely unfavorable in cases of scarlet fever occurring in the puerperal state. I have known of a case in which the patient contracted the disease in the seventh month of pregnancy. She miscarried in the period of incubation; parenchymatous nephritis occurred as a complication, and the symptoms denoted great danger. She, however, recovered, and the child was living.

Richardson and others have reported cases of scarlet fever in which a fatal result was due to the formation of a heart-clot in the right cardiac cavities. This accident occurred in a case under my observation, proving fatal after the termination of the fever. The formation of an ante-mortem clot in this case was evident from the symptoms, and demonstrated by an examination after death.

TREATMENT.—Cases of mild scarlatina do not call for active measures of treatment. The often-quoted saying of the English Hippocrates, that scarlatina is only dangerous through the officiousness of the physician, is, however, hardly true even of these cases, for, be the disease never so mild, there is a liability to grave complications and sequels. On the other hand, in certain cases of severe scarlatina, the malignancy of the disease renders any treatment unavailing. With respect to this disease, as well as the other eruptive fevers, it is to be premised that there are no known specific remedies by means of which it may be arrested or controlled; but the inference by no means follows that judicious measures of treatment may not do much toward affording relief and diminishing the fatality from it. It is to be added that a comparison of different collections of cases with reference to the rate of mortality under different methods of treatment, is of little value on account of the wide diversity as regards severity of the disease.

Certain measures heretofore employed in the treatment of scarlatina are now regarded as opposed by sound reasoning and experience. This statement applies to bloodletting, active purgatives, mercurialization, blisters, and emetics. These are never indicated, and must of necessity prove hurtful. The discovery of a remedy which will arrest the disease by destroying within the body the special cause, in other words, an effectual parasiticide for the specific organisms and germs on which the disease is supposed to depend, belongs to the future. This statement applies to all the eruptive fevers. Carbolic acid, sodium sulpho-carbolate, and the sulphites have been tried with an apparently beneficial effect. I have heard testimony from physicians of experience in behalf of the usefulness of each of these remedies. It has not, however, been proved that they have a special curative efficacy. At the present time, therefore, the indications are to be drawn from particular symptoms, events, and complications in individual cases.

In the majority of mild cases, hygienic treatment is alone required. In addition to free ventilation, cooling drinks, and light nourishment, the hygienic treatment should embrace measures to maintain the functions of the skin. In view of the fact that renal disease, as a complication or sequel, is a source of danger in these cases, attention to the skin is important, however mild may be the disease. The tepid bath once or twice daily is to be recommended. If the bath be not practicable, the application of a sheet wet with tepid water, or repeated sponging of the body, may be employed in its stead. There is reason to believe that the more the functions of the skin are maintained by these measures, the less is the liability to an affection of the kidneys either during or after the disease. Exposure to cold is to be avoided both while the disease is in progress and in convalescence, but care in this respect should not lead to error in the way of free ventilation, or of oppressing the patient with an overplus of clothing. Vigilance or restlessness, if not relieved by the use of the bath, the wet sheet, or sponging, may indicate anodyne remedies. Constipation is to be relieved by simple enemas. Other symptoms may indicate appropriate palliative remedies.

In some cases, the leading indication is derived from the intensity of the fever as denoted by hyperpyrexia and the frequency of the pulse. To diminish the heat and the frequency of the heart's action is an important object of treatment. This object may be most effectually accomplished by the use of water. It was in this disease that Currie was led, nearly a century ago, to employ cold affusions with a happy effect. This mode of applying water was strongly advocated by Trousseau, who stated that he employed it with highly satisfactory results in a large number of cases in private and hospital practice. It is, perhaps, the most efficient measure to be employed for the relief of the active delirium which sometimes occurs

in this disease. The apparent boldness of the practice renders it frequently objectionable on the score of popular prejudice. Frequent sponging of the body secures, to a considerable extent, the same results; but the use of the wet sheet is hardly less efficacious than the cold affusion as practised by Currie. Employed as an efficient antipyretic measure, the wet sheet is applied over the whole body, without any other covering, and the surface is sprinkled with cool or cold water at short intervals, in the manner described in connection with the treatment of typhoid fever and insolation. The temperature is always reduced, one, two, or more degrees, by this measure, and it may be repeated as often as the thermometer shows a return to great intensity of heat. There is no occasion for fear on the ground of danger of repelling the eruption. The wet pack acts efficiently as a sedative and diaphoretic measure, and it has considerable potency as an antipyretic. The patient, stripped of all clothing, is enveloped in a sheet saturated with water at about the temperature of 70° Fahr., and closely covered with several blankets. Usually, after remaining in the pack for about an hour, free perspiration is induced. The pack is to be removed when this effect occurs, the body wiped dry, and the patient placed in bed. The frequency of the pulse is often notably lessened by this measure; the patient is tranquillized, and obtains refreshing sleep. The measure may be repeated once or twice daily. Its effect is so agreeable that patients often desire a repetition. In this disease, as in other fevers, full doses of quinia sometimes have a notable antipyretic effect.

In malignant cases, and whenever the intensity of the disease involves a tendency to death by asthenia, the chief reliance must be on sustaining measures. Alcohol is indicated in proportion to the frequency and feebleness of the pulse, together with general prostration. I have witnessed the same striking benefit from the free use of wine or spirits in certain cases of scarlatina as of typhus or typhoid fever. Alcoholics, however, are not to be given without discrimination, and the physician is to be guided in their use by watching their immediate apparent effects, precisely as in other essential fevers. In children, wine-whey, milk-punch, and egg-nog are eligible forms for the administration of stimulants and nourishment.

Cases of so-called scarlatina anginosa, in addition to sustaining treatment, call for measures addressed to the affection of the throat. The chlorate of potassa is generally considered, and probably with justice, an important remedy in these cases. From one to two drachms may be given daily. The chlorine mixture is highly recommended by Watson and others. Stimulating or caustic applications to the pharynx are of doubtful utility. The difficulty of making them in children, and the perturbation occasioned by making them forcibly, in spite of their resistance, are not small objections; but, aside from these objections, it may be doubted if they produce a beneficial effect. Antiseptic applications by gargling, if the patient be not too young, by means of a sponge if the resistance be not too violent, or, in the form of a powder, by insufflation, contribute at least to comfort. The solution of chlorinated soda may be used for this purpose, diluted with eight or ten parts of water. The permanganate of potash may also be used in the proportion of half a grain of the salt to five ounces of water. Other topical remedies are alum, tannic acid, the borate of soda, carbolic and the salicylic acid. The free use of iced drinks is useful as regards the condition of the throat. The patient may be allowed to take into the mouth small pieces of ice almost *ad libitum;* and for young children a convenient plan is to confine pieces of ice in a gauze bag which may be held in the mouth. Externally, compresses kept wet with cold water may be applied. It has been recommended to apply ice to the sides of the neck. It is customary to paint with iodine the neck

over glandular swellings. If suppurative inflammation ensue, poultices or the water dressing should be applied.

Extreme pruritus of the skin is, in some cases, a source of much annoyance, preventing sleep and increasing the constitutional disturbance. With reference especially to this symptom, some years ago a plan of treatment proposed by a German physician, Schneemann, consisted in the application of lard to the surface of the body, the rind of bacon being used for this purpose. This plan was adopted to some extent in this country. It relieves, in some cases at least, the pruritus, and diminishes the febrile excitement. Other applications, however, less disagreeable, are equally efficacious. Glycerine and the rose-water ointment, glycerine and cologne-water, in the proportion of one part of the former to four or five parts of the latter, or, what is still better, vaseline, may be substituted.

Convulsions are generally due to uræmia, but, occurring early in young children, they may be incident to the development of the disease without denoting a renal complication. Whether uræmic or otherwise, if they continue, the inhalation of chloroform is indicated. I have notes of cases in which this measure was employed with immediate relief, and recovery followed.

Uræmic phenomena in addition to convulsions, namely, cephalalgia, disturbance of vision, and coma, render prompt measures of treatment vastly important. Saline purgatives or elaterium are to be employed at once to eliminate urea, and diaphoresis should, if possible, be procured by the use of the warm or hot air bath, the wet sheet, or by the hypodermic administration of the muriate of pilocarpin. Vomiting and purging should always suggest the inquiry whether they be not due to uræmia, and, if so, they are not to be arrested. Albuminuria, and especially a deficiency of urea in the urine, should lead to measures with a view of forestalling the effects of uræmia. Fomentations are to be applied over the loins, the bowels are to be kept loose with saline laxatives, and, with reference to this object, it is important to produce diaphoresis by means of the warm bath or the wet sheet.

Restlessness and vigilance, if not relieved by measures of treatment already noticed, may require anodyne remedies. The succedanea of opium are to be preferred, namely, belladonna, hyoscyamus, etc. If, however, these be not efficacious, opiates are to be given, but cautiously in young children. With reference to the liability to heart-clot, Richardson advises the carbonate of ammonia, given in small doses frequently repeated. Several writers have advocated this remedy as having a special salutary influence in scarlatina.

The treatment of the sequels of scarlatina need not be here considered. The most frequent of the important sequels, namely, acute diffuse nephritis, has been considered in a former part of this work, to which the reader is referred. In the treatment of pleuritis, pericarditis, rheumatism, and chorea, are involved essentially the same principles as when these affections occur in other pathological connections. External otitis is often neglected, and is apt, therefore, to continue, and, in the end, lead to impairment of hearing. Daily cleansing the ear by the injection of tepid water and soap will usually prove sufficient to effect a cure; but if the affection continue in spite of this simple measure, which from its very simplicity it is often difficult to enforce, mild astringent injections should be employed.

I will add a remark with reference to the prevention of renal disease as a sequel of scarlatina. The occurrence of this sequel being generally attributed to cold, it is common to confine patients within doors, and sometimes even to the bed, for two or three weeks after convalescence. Regarding, however, the sequel as a remnant of scarlatina, this extreme care is unnecessary. It is sufficient to observe the same precautions with regard to exposure to cold or other morbid agencies as during convalescence from any

acute affection. Gestation, out of doors, has seemed to me to be useful even when patients are suffering from albuminuria and general dropsy following scarlet fever.

It remains to notice the protective influence against scarlatina, which has been imputed to belladonna. For the conflicting statistical data bearing on the question whether minute doses of this remedy tend to render the system, for the time, insusceptible to the disease, the reader is referred to works treating of materia medica and therapeutics. In estimating the force of evidence for, and against, the assumed prophylactic efficacy of this drug, it is to be considered that the failures to afford protection are the positive facts. A certain proportion of persons do not contract scarlet fever, however great the exposure. We have no data for determining the proportion of persons among those exposed at any particular time or place, who are thus naturally insusceptible. Of those who, under the use of belladonna, fail to contract the disease, it may be said that they might have been naturally insusceptible, whereas, all the instances in which the disease is contracted notwithstanding the use of belladonna, militate against its protective power. Giving due weight to this consideration, satisfactory proof of its prophylactic power requires that the number of failures shall not be large; and, judged by this rule of evidence, it is extremely doubtful if there be any ground for imputing to this remedy a prophylactic power. It is, however, to be considered that to prescribe belladonna as a prophylactic is always a harmless experiment, and is, therefore, only objectionable on the score of supererogation. Moreover, as the popular mind has been directed to this question, the wishes of friends are often better satisfied if the drug be prescribed. These considerations may properly influence the physician. The following are the directions for the use of the remedy: "Dissolve from one to three grains of fresh and well-prepared extract of belladonna in an ounce of cinnamon water, adding a few drops of alcohol to prevent fermentation. Of this solution may be given, two or three times a day, one drop for each year of the child's age, to be so administered for two weeks, or longer, if the danger should continue."[1] The only reliable way of protection against the disease is to avoid the contagium. To do this effectually, it is necessary, not only that persons do not come within an infecting range of patients, but that they avoid those who have been within this range, the houses in which there have been cases, and everything that may prove to be fomites. Cases occurring in hospitals and private houses should be at once isolated, and all articles in the apartment occupied by patients should be properly disinfected. Removal without the limits of the prevalence of the disease is advisable when it is found that cases are apt to prove malignant or severe. On the other hand, if cases be pretty uniformly mild, it is to be considered that the period is favorable for having the disease. Voluntary exposure, with the intention that the disease shall be contracted, is, however, under no circumstances to be recommended.

CHAPTER VIII.

ERUPTIVE FEVERS—(Continued.)

Rubeola, or Measles—Clinical History—Causation—Diagnosis—Prognosis—Treatment. Roseola. Rötheln. Dengue.

RUBEOLA, so called from the red color of the eruption, called also *morbilli*, and commonly known as the *measles*, is a disease of less importance than the eruptive fevers which have been considered. It is generally a mild and often a trivial disease; but it is desirable as early as possible to discriminate it from other eruptive fevers; it is of frequent occurrence; it is sometimes accompanied by grave complications; it is occasionally followed by serious sequels, and, in a certain proportion of cases, the disease is intrinsically severe, or even malignant. Hence, rubeola is by no means an unimportant disease. By German writers the term rubeola is used to denote an eruptive fever distinct from measles, called also Rötheln, and in this country distinguished as German measles.

Rubeola has no special anatomical characters exclusive of the internal and external efflorescence which is most conveniently considered as belonging among the symptoms of the disease. I shall pass, therefore, at once to the clinical history.

Clinical History.—The career of this disease is subdivided, like the other eruptive fevers, into the stages of invasion, eruption, and desquamation, each stage claiming separate consideration.

Stage of Invasion.—The distinctive local symptoms in this stage resemble those of a common cold, or rather an attack of influenza. There is coryza, with frequent sneezing, and an acrid muco-serous discharge from the nostrils. The eyes are irritable, reddened, and watery. Epiphora is sometimes marked, the tears excoriating the face, and there is more or less intolerance of light. Subacute laryngitis, denoted by hoarseness, frequently occurs, and the symptoms of bronchitis are generally present, the cough being dry, sonorous, and painful. Occasionally the pharynx is the seat of subacute inflammation. The bronchitis, laryngitis, and coryza are due to the efflorescence which takes place on the mucous membrane of the air-passages prior to its appearance on the skin. With these local affections, which vary much in intensity in different cases, there is associated moderate pyrexia, the axillary temperature rarely exceeding 102° Fahr., accompanied by irregular chilly sensations and shivering, but rarely by a distinct chill; the appetite is impaired or lost, and in some cases nausea and vomiting occur; pain in the head and limbs, with debility and lassitude, are, in general, proportionate to the pyrexia. The general are often out of proportion to the local symptoms, as in cases of influenza; they are less intense than in the stage of invasion in variola and scarlatina, and in certain cases they are slight. Constipation exists in some cases, and in other cases there is diarrhœa. Convulsions sometimes occur in this stage, chiefly in children. In general they are not indicative of danger. Epistaxis is, in some cases, a prominent symptom. Spasm of the glottis, or false croup, is an occasional symptom in young chil-

dren. An erythematous eruption sometimes precedes that which is proper to the disease.

The average duration of this stage is from three to four days. The duration is, therefore, twenty-four hours longer than in variola, and forty-eight, or more, hours longer than in scarlatina. Cases are not very infrequent in which the duration is five, six, or seven days, and even longer, and, on the other hand, it may be but three or two days, and even a single day.

Stage of Eruption.—A transient convulsion may usher in this stage in children, but it is of much rarer occurrence than in scarlet fever. The efflorescence first appears on the temples and forehead. In a few hours it extends over the head and neck. It is gradually diffused over the body and extremities, its full development occupying from thirty-six to forty-eight hours. In the slowness of the extension of the rash over the cutaneous surface, this fever differs from variola and scarlatina.

The eruption has at first an appearance of minute red dots or specks which soon enlarge, become slightly elevated, and tend to arrange themselves in circular or crescentic forms. The papules resemble those in smallpox prior to the appearance of vesicles; but they are larger and softer. They bear a resemblance to flea-bites. The redness momentarily disappears on pressure. Increasing in number and size, they coalesce to a greater or less extent, and form blotches of variable dimensions, with curvilinear or semilunar borders, contrasting, in the latter respect, with the irregular or serrated patches of efflorescence in scarlatina. Aside from cases in which a petechial eruption occurs, the eruption proper to the disease sometimes shows, not only hyperæmia, but infiltrated hematin, the redness being with difficulty removed by pressure, and a brownish color remaining after the eruption has disppeared. The eruption in some cases is everywhere confluent, being uniformly diffused over the whole or the greater part of the cutaneous surface. The color of the eruption is dull or deep red, offering a contrast to the crimson or scarlet redness of the scarlatinous efflorescence. The portions of skin not occupied by the eruption retain the normal appearance. In proportion to the abundance of the eruption, there is swelling which is most marked on the face. The eruption is sometimes attended with considerable pruritus. Occasionally vesicles are intermingled with the rubeolous papules (morbilli vesiculosi vel miliares). On the fourth day of the eruption it begins to fade successively on the face, trunk and extremities, and the stage of desquamation commences.

During the stage of the eruption, the symptoms denoting coryza, laryngitis, and bronchitis continue. The bronchitis, in this stage, gives rise to a more or less abundant expectoration, consisting of greenish or yellowish sputa which are frequently nummular. Dry and moist bronchial râles are often heard on auscultating the chest. The irritability of the eyes continues, and not infrequently there is conjunctivitis. Pharyngitis, in some cases, continues, and sometimes the inflammation extends into the Eustachian tube, occasioning partial deafness. The pyrexia does not disappear nor diminish with the development of the eruption. On the first and second day of the eruption, the temperature of the axilla may rise to 104° Fahr. and even higher. From this date, in the natural course of the disease, the temperature rapidly diminishes. Other symptoms denoting constitutional disturbance are proportionate to the pyrexia. The latter, save in exceptional cases, is much less in degree than in scarlatina. The tongue is generally coated, and not infrequently, the elongated papillæ, projecting through the coating, present the appearance of red points.

Stage of Desquamation.—This stage may be considered as having commenced when the eruption begins to fade. The duration of the stage is from four to eight days. In uncomplicated cases pursuing a favorable course, this

stage is the stage of convalescence. Actual desquamation occurs in only a certain proportion of cases. It may be more or less marked. It is always furfuraceous, the epidermis being exfoliated in branny scales, not in patches or flakes. Coincident with the decline and disappearance of the eruption, the pyrexia diminishes and ceases. More or less cough and expectoration are apt to continue after the cutaneous eruption has disappeared, and persisting conjunctivitis is not uncommon. Occasionally the eruption on the skin reappears after having existed for the usual period and disappeared. Diarrhœa, usually mild, is apt to occur in this stage.

The career of the disease thus extends from twelve to sixteen days.

The foregoing sketch of the clinical history relates to cases in which the disease pursues a typical course. Anomalous cases occur, the disease in some being very severe, or malignant, and in others unusually mild. The affections of the Schneiderian membrane, larynx, and bronchial tubes are sometimes wanting. Writers have considered these cases as constituting a variety of the disease called *rubeola sine catarrho*. To a certain extent, doubtless, cases which have been considered as of this variety have been cases of roseola. On the other hand, it is supposed that cases occur in which the local manifestations are limited to the mucous membrane; hence, another variety called *rubeola sine eruptione*. It must be difficult to decide positively that rubeola exists when the cutaneous efflorescence is wanting. In the cases belonging to the two varieties just named, the disease is unusually mild. A severe form of the disease is characterized by the occurrence of petechiæ and hemorrhage in various situations. The phenomena of purpura are associated with measles in these cases. Of this rare form of the disease the following case is an example: The patient was a man aged about 25 years. The rubeolous eruption was abundant, presenting the characteristic appearances, but was somewhat darker than usual. Scattered among the patches of efflorescence, over the whole surface of the body, were petechiæ varying from the size of a pin's head to a split pea. There was hemorrhage from the nose and mouth; blood also was discharged from the bowels and was contained in the urine. The tongue and gums were pallid except at certain points which were stained with exuding blood. Blood was effused beneath the conjunctiva, infiltrating the whole surface of the eyeball except the cornea. The case terminated fatally. The form of the disease is distinguished as *hemorrhagic rubeola*. It has been called also *rubeola nigra*, or black measles.

Gangrene attacking the mouth and occasionally the anus, vulva, nose, lungs, and larynx, sometimes occurs in connection with rubeola Other morbid conditions than those belonging to the latter, it is to be presumed, must concur in giving rise to this event. It has been observed chiefly in young children in eleemosynary institutions. Aside from any such local events, or important complications, this disease sometimes assumes a severe form, presenting the ataxic and adynamic symptoms of typhus or typhoid fever, and ending fatally from an intrinsic tendency to death. Such cases, however, are extremely rare.

In the great majority of the cases in which the disease is grave, the gravity is dependent on complications. The important complications most likely to occur are seated in the respiratory system. Diphtheritic laryngitis or true croup is sometimes developed. Capillary bronchitis is another fatal complication liable to occur in children; and occurring in children under three years of age, it generally destroys life. It is more liable to occur in hospital than in private practice. Broncho-pneumonia and lobar pneumonia are the most frequent of serious complications. The latter, in young children, is likely to prove fatal, and is by no means devoid of danger to adults. Pleuritis is an occasional complication, but it is far more infrequent than pneumonitis. Croup,

capillary bronchitis, and more especially pneumonitis, are not less likely to occur as sequels than as concomitants of rubeola.

A delay in the appearance of the eruption is generally an effect of some important complication. The occurrence of an important complication is apt to lead to a notable diminution and sometimes retrocession of the eruption. It is a popular error to attribute the complications to the retrocession of the eruption; the latter is a consequence, not a cause, of the former. Irregularity as regards the situation in which the eruption first appears is sometimes observed. In rare instances the efflorescence first makes its appearance on the lower extremities, and extends thence over the body, upper extremities, and head.

After recovery from rubeola, pulmonary phthisis, acute tuberculosis, and tuberculous meningitis are observed in a proportion of cases, not large, but sufficient to show that the system is left in a condition favorable for the development of these affections. Affections distinguished as scrofulous are apt to follow as sequels, namely, scrofulous ophthalmia, coryza, and otorrhœa, enlargement of lymphatic glands, etc. After an extensive prevalence of measles in any place, it is observed for some years that the mortality among children exceeds the average mortality at other times. The practical importance of these facts is obvious.

Causation.—Rubeola, like scarlatina and variola, is a contagious disease. The contagium is not only received by those brought into close proximity to persons affected with the disease, but it may be transported to a distance by means of fomites. Persons contract the disease from the contagium adherent to the clothes of those who may have recently visited rubeolous patients. Physicians may in this way diffuse the disease.

The disease may be communicated by inoculation either with blood from an exanthematous patch, or with the secretion from the eyes and nostrils. The activity of the rubeolous contagium, however, is much less persistent than that of the contagium of smallpox and scarlet fever. The communicability, not alone by inoculation, but by means of an infected atmosphere or by fomites, belongs to the stage of invasion, as well as to the eruptive and desquamative stages.

The duration of the period of incubation varies within widely separated limits, namely, between one day and thirty days. Probably in the majority of cases the attack occurs from six to ten days after exposure. The duration was within these limits in a dozen cases under my observation in which the time of exposure could be definitely fixed, with a single exception in which the duration was fourteen days. When produced by inoculation, the period of incubation is somewhat shorter than it is usually when the disease occurs naturally.

The susceptibility to the disease exists at all ages. Cases are much more frequent in children than in adults, but this is owing to the fact that the majority of persons have the disease in childhood, and are generally thereby made insusceptible. They who escape the disease in early life on account of not being exposed to the contagium, are liable to contract it at any subsequent age. The susceptibility is very slight during the first six months of infantile life. As a rule, this disease, like scarlatina and variola, renders the system ever afterward insusceptible to it, but exceptions to this rule are not very rare. Well-authenticated cases in which the disease has occurred three and even four times have been reported. Prevailing in camps, schools, hospitals, and communities, as an epidemic, this disease presents at different times a great diversity as regards mildness or severity, and the tendency to

particular complications; in other words, the character of different epidemics of rubeola, as of other epidemics, is by no means uniform, but varies much in different seasons and places.

Diagnosis.—The diagnosis of rubeola, after the appearance of the efflorescence on the skin, is generally unattended with difficulty. The diagnostic characters which have been embraced in the clinical history are sufficiently distinctive. The more important of these are: the long duration of the stage of invasion, the affection of the air-passages, the appearance of the eruption almost invariably first on the face, and its gradual diffusion over the body; the color of the eruption, its papular character, the softness of the papules, and the tendency to assume a crescentic arrangement. So far as the eruption is concerned, early in the eruptive stage there is some resemblance to the papules of smallpox; but the differential points which have been presented in treating of the latter disease should enable the practitioner to make the discrimination. In a case of rubeola in which the cutaneous efflorescence is not abundant, and the air-passages are unaffected, the disease is liable to be confounded with roseola; but the eruption in these two affections differs, and, moreover, such cases are extremely rare. Cases in which the air-passages are alone affected, that is, in which there is no cutaneous efflorescence, hardly admit of a positive diagnosis, but such cases are extremely rare. Their occurrence during the prevalence of rubeola in persons known to have been exposed, is chiefly the ground on which the diagnosis is to be based.

The diagnosis cannot be made with positiveness prior to the appearance of the efflorescence on the skin. The occurrence, however, of coryza, irritability of the eyes, and bronchitis, with pyrexia, in persons who have never had measles, at a time when the disease is prevailing, renders a diagnosis during the period of invasion highly probable. The diagnosis is sometimes delayed by the early occurrence of complications which interfere with the regular course of the disease, especially as regards the eruption. The appearance of the latter, however, sooner or later in the great majority of cases, removes the difficulty which may previously have existed.

Of this fever, as of all the eruptive fevers, the diagnosis in the negro must, of course, be based on other points than those relating to the color of the eruption. "In the pure negro, the eruption appears as yellowish spots slightly elevated, and giving a sensation of roughness; in the mulatto, as a dusky-brown, ill-defined; and in the lighter shades, more distinct, reddish-brown spots, approaching the characteristics of the eruption in the white."

Prognosis.—In the majority of cases, as this disease is ordinarily presented in civil practice, it is either mild or unattended with danger. But in a certain proportion of cases the disease is severe and dangerous. The severity and danger are due to the anomalous events and complications which have been noticed in connection with the clinical history. The number of cases rendered fatal by co-existence of capillary bronchitis, diphtheritic laryngitis, pneumonitis, etc., is not inconsiderable. The rate of mortality differs greatly at different times and places, so that the statistics of any particular epidemic would not furnish results applicable generally to the disease. It is apt to prove a serious disease in camps. Woodward states that, of the 38,021 cases contained in the official returns from the armies of the United States in the first two years of the late civil war, there were 1864 deaths. Bartholow is of the opinion that these figures do not express the actual fatality due directly or indirectly, that is, by complications and

sequels, to this disease during the war; he estimates the ratio of deaths to cases as 1 to 5.[1]

During the war, the prevalence of the disease was great among recruits, especially those from the country; and the sequels, or the effect upon the general health, incapacitated a considerable proportion for remaining in the service. Taking into view the mortality and the enfeebled condition remaining for a long time in many of the cases which did not end fatally, measles proved to be one of the most formidable of camp-diseases. With reference to the efficiency of troops in active service, it would seem to be desirable either to expose new recruits to the disease when they can pass through it under the most favorable hygienic conditions, or to isolate cases at once wherever they occur in camp. Doubtless the rate of mortality and the disqualifying effects of the disease were often due to the co-existence either of scorbutus or malarial poisoning.

Treatment.—In ordinary cases, the disease calls for nothing but palliative measures and attention to hygiene. The cough may be palliated by anodynes, and these may also be indicated by restlessness or vigilance; and for the pyrexia, if considerable, gentle diaphoretic and refrigerant remedies may be prescribed. The object of treatment in these cases is simply to render the patient as comfortable as possible; the disease pursues a favorable course without any therapeutical interference. It is a widely diffused popular notion that saffron (*crocus sativus*) is a valuable remedy in measles, as well as in the other eruptive fevers, given for the purpose of promoting the eruption. There is little ground for this notion, but the remedy is harmless. Cathartics in this, as in the other eruptive fevers, are not indicated, and are likely to do harm. Emetics are rarely, if ever, indicated. The patient should be confined to a room in which the temperature is agreeable, but free ventilation should be secured. The air of the room, in the treatment of cases of this fever, as of the other essential fevers, and, indeed, of all acute diseases, should be effectually changed after short intervals by opening the windows, protecting the patient against drafts by covering the face as well as the body. The body may be sponged, in portions at a time, with tepid or cool water. This may be done without any fear of causing the eruption to disappear prematurely. If the degree of pyrexia call for antipyretic treatment, the wet sheet may be resorted to. Refrigeration will not render the patient more liable to pneumonia or other pulmonary complications. Quinia or salicin may also be given for an antipyretic effect. As a protection for the eyes, the room should be moderately darkened.

In cases in which the disease is rendered severe by complications, the treatment will have reference to the latter. The general principles of treatment, in these cases, are the same as when the complicating affections occur in other pathological connections. It would, therefore, be a repetition to consider the indications derived from the different complications. A practical question relates to the retardation, diminution, or retrocession of the eruption in some complicated cases. Is it important to resort to active measures designed to promote the appearance of the eruption? The importance of this object of treatment has doubtless been much exaggerated. Certain measures employed for this object, such as emetics, active stimulants, the hot or vapor bath, and overloading the body with clothing, are not to be employed. This general rule may be adopted, namely, measures should not be employed for this object if, aside from the object, they are likely to be hurtful. The tepid bath, stimulating pediluvia, and sinapisms, or other

[1] Sanitary Memoirs of the War.

rubefacient applications to the skin, are not excluded by this rule. It is to be considered that the complications do not occur in consequence of the eruption being delayed or insufficient, or "striking in;" it is more probable that the latter are effects of the former.

Cases presenting ataxic or adynamic symptoms, either with or without complications, claim the tranquillizing and supporting measures indicated in other diseases with the same symptoms.

It is important to bear in mind the liability to scrofulous and tuberculous affections after recovery from this disease. Patients should be placed under hygienic influences which will tend to invigorate the system, with a view to obviate a tendency to the development of these affections.

Protection against this disease, and the prevention of its diffusion, can be secured only by means of the isolation of cases and measures of disinfection. Children should be kept from school and other places in which they are brought into contact with other children, whenever, from the symptoms of the stage of invasion, the nature of the disease is to be suspected. There is ground for the opinion that the communicability is greater in this stage. The clothes worn by patients, the bedding, and the apartments should be disinfected. These protective and preventive measures are especially important during the prevalence of an epidemic in which there is a tendency to grave complications. They are of less importance in mild epidemics, inasmuch as the subsequent insusceptibility which, as a rule, the disease confers, is obviously desirable.

Roseola.

The eruptive fever called *roseola* or *rose rash*, sometimes called *false measles*, is an affection of very little importance, exclusive of the liability to confound it with rubeola and scarlatina.

The eruption is preceded by symptoms of constitutional disturbance for one or two days. These symptoms are, cephalalgia, loss of appetite, with sometimes nausea and vomiting, and occasionally diarrhœa, chilly sensations, febrile movement, and general malaise. In young children, convulsions may occur. The constitutional disturbance is more or less marked, but it is frequently slight. The affection of the throat and that of the air-passages, which belong to the history of scarlatina and rubeola in the stage of invasion, are slight or wanting in roseola.

The eruption appears in the form of rose-colored spots or patches which are not elevated, the redness disappearing momentarily on pressure. It appears on different parts of the body, not commencing on the head and extending over the body as in rubeola. Frequently it appears on the body and extremeties and not on the face. It continues for twenty-four or forty-eight hours only, in a majority of cases. It disappears without desquamation, and is liable to return. It is sometimes accompanied with considerable pruritus. The affection has neither sequels nor complications. It may, however, occur in the course of other affections, especially in the stage of invasion in varioloid, in articular rheumatism, and in epidemic cholera after reaction. It has no gravity. One attack affords no protection against recurrences. It is oftener presented in females than in males. It prevails not infrequently as an epidemic, and chiefly during the summer season. Some authors consider it to be contagious.

Attention to the foregoing points will suffice for the discrimination of the affection from scarlatina and rubeola. It does not call for treatment.

The use of the balsam of copaiba by some persons induces an efflorescence analogous to that of roseola, and more rarely the use of cubebs, the iodide of

potassium, turpentine, and the sulphate of quinia. A variety of the affection belongs to the history of syphilis.

Rötheln.

The affection called by German writers *rötheln*, and rubeola (*German measles*), is probably not a new disease in this country, but it has not been heretofore recognized as distinct from roseola. Prof. J. Lewis Smith studied an epidemic occurring in New York, in 1874, and found the characters which distinguish this affection. It occurs as an epidemic, and is, probably, contagious. It affects all ages, but especially children. It differs from measles in having a period of invasion, rarely longer than a day; in a much less degree of pyrexia; in the appearance of the eruption first on the body and neck, and in the rapid diffusion of the eruption. The eruption, moreover, is not papular; the spots are round, not oval, and there is no tendency to a concentric arrangement. There is slight coryza, but the larynx and bronchial tubes are rarely affected. These points are sufficient for the discrimination from measles.

The color of the eruption sometimes resembles that of scarlet fever rather than measles. The affection bears a close resemblance to extremely mild cases of the former of these diseases. In making the discrimination, reliance is to be placed on the occurrence of other cases having the diagnostic characters of rötheln, and the non-prevalence of scarlet fever. If circumstances render the diagnosis doubtful, it is advisable to consider the disease as probably scarlet fever.

It is probable that cases of rötheln and of roseola have been not infrequently supposed to be cases of measles and scarlatina, and in this way is perhaps to be explained some of the reported instances of the latter diseases occurring in the same person more than once.

That this disease is essentially distinct from measles and scarlet fever, is proven by its epidemic occurrence, by its affording no protection against these diseases, and by the fact that the latter afford no protection against it. These are sufficient grounds for recognizing a separate special cause. Rötheln, like roseola, is devoid of danger, and rarely calls for more than hygienic treatment.

Dengue.

The following succinct account of the epidemic affection commonly called *dengue*, an unclassical name of uncertain derivation, supposed to be synonymous with "dandy fever," is based chiefly on communications by Dickson, Wragg, Campbell, and Fenner, describing the affection as it occurred in Charleston, S. C., Augusta, Ga., and New Orleans, and on the published clinical lectures of Charles of Calcutta. Dickson's name is especially identified with the affection from his having been the historian of its visitation in this country in 1828, and he contributed more largely to what is known respecting it than any other American writer.

The affection prevailed extensively in the West India Islands in 1827 and 1828, and about the same time in many parts of the Southern States of this country. An affection supposed to be the same prevailed in Philadelphia in 1780, and was described by Rush. It was then, as since, frequently known as the *breakbone fever*. Other epidemics supposed to be identical have occurred at various periods in Egypt, India, and other parts of the world. Cocke and Copland apply to an epidemic affection supposed to be the same the name *scarlatina rheumatica*.

The development of the affection is either abrupt or slow, more frequently the former. The symptoms attending its development are anorexia, chilly sensations, but rarely a pronounced chill, languor, lassitude, and general malaise. These symptoms exist in some cases for only twenty-four hours, but in other cases for several days before the affection is fully developed.

After the access or forming period follows a febrile stage or a paroxysm of fever. The duration of the pyrexia varies from nine hours to three or four days, the average duration being about thirty-six hours. During this stage, and sometimes during the access, acute, often excruciating, pains in the head, eyes, muscles of the neck, loins, and extremities are prominent traits of the affection; hence the name *breakbone fever*. The pains diminish or disappear with the cessation of the fever, and the patient, who had taken to the bed with the onset of fever, is now able to sit up, and complains only of debility; perhaps he returns to his accustomed vocation. But in four or five days the pain often returns, with frequently a recurrence of the pyrexia, debility, and malaise, compelling a return to the bed. During the febrile stage there are irregular remissions. The pyrexia is sometimes considerable, the axillary temperature rising to 105° Fahr., and even higher.

In the great majority of cases an eruption occurs at a variable period after the febrile paroxysm. The eruption presents in different cases a diversity of characters. It resembles in some cases very closely the efflorescence of scarlatina. In other cases it is not unlike the eruption of rubeola. It is sometimes papular, like either lichen or urticaria, and it is sometimes vesicular, like either sudamina or varicella. Erysipelas and purpura are occasionally observed. Hemorrhage from the nose, mouth, bowels, and uterus occurs in some cases. Coryza and pharyngitis are occasional complications, and the latter is sometimes associated with enlarged cervical glands.

The convalescence is often tedious; the recovery of strength, appetite, etc., is apt to be slow. The average duration of the disease is about eight days. Relapses are not infrequent. As regards incidental events and sequels, convulsions in children occasionally usher in the attack; delirium like that of delirium tremens has been observed to succeed protracted vigilance, and in pregnant women miscarriage is apt to take place. A rheumatic condition of the joints, abscesses, boils, and carbuncles are not infrequent sequels.

The extent of prevalence of this epidemic is remarkable. Wragg computes the number of cases at one time in Charleston at 10,000, and during the epidemic seven- or eight-tenths of the population were affected. All classes are attacked, persons of either sex, children and octogenarians.

The duration of epidemics is brief, ceasing usually in six or eight weeks. Of the special cause nothing is known. Dickson regarded the affection as contagious. This opinion is opposed by the rapid and almost simultaneous diffusion of the affection, by the limitation of its prevalence to towns or within a circumscribed area, and the short duration of epidemics. That author also was of the opinion that, as a rule, immunity from subsequent attacks is secured when the disease has been once experienced. In proof of this opinion, he stated that, at Charleston, where the disease prevailed in 1850, those only escaped who had experienced it during the epidemic of 1828. The occurrence of a few cases of the disease among those who had it in 1828, he accounts for by supposing that after an interval of 22 years, the susceptibility was renewed.[1] It is an affection chiefly occurring in warm climates, and prevails especially in cities and large towns. To the latter rule there are, however, striking exceptions.

This affection, although extremely distressing, and presenting not infre-

[1] Elements of Medicine, 2d edition, page 748.

quently severe symptoms, is very rarely, if ever, fatal. Its apparent intensity is in striking contrast to the absence of danger.

The affection is self-limited, and there are no known means of arresting or abridging it. The treatment, therefore, consists of palliative measures. Opiates to relieve the pains, restlessness, and vigilance, are indicated. Rubefacients to the spine and in other situations are useful. Alcoholic stimulants, given pretty freely, have been found beneficial. A high temperature is an indication for antipyretic treatment. Charles recommends moderate doses of belladonna. During convalescence, tonic remedies and hygienic measures to promote appetite and the recovery of strength are indicated.

CHAPTER IX.

DIPHTHERIA.

Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment.

OF the general diseases which remain to be considered, one of the most important is the affection now commonly known as *diphtheria*. This affection has prevailed at times as an epidemic in various parts of the world from a remote period. It has been described by writers in different countries and epochs, under a variety of names, such as, *ulcus Egyptiacum vel Syriacum*, *cynanche maligna*, *cynanche contagiosa*, *angina maligna*, *angina gangrænosa*, *morbus suffocans vel strangulatorius*, *Garrotillo*, *malignant sore-throat*, *epidemic croup*, etc. In this country, until within the last twenty-five years, it has occurred but rarely and to a limited extent during the present century. It was described by Bard, in 1789, under the name *angina suffocativa*. The distinctive characters of the affection were very clearly elucidated by Bretonneau, in 1821, 1825, and 1826, who applied to it the term *diphtherite*, whence originated the name *diphtheria*. This name, the significance of which relates to the most characteristic local event, namely, the formation of a false membrane, has, to say the least, the negative merit of not involving any hypothesis concerning the pathology of the affection.

Anatomical Characters.—Diphtheria is characterized anatomically by the presence upon certain mucous membranes of a fibrinous exudation in the form of a false membrane. There is much confusion as to the use of the terms croupous exudation and diphtheritic exudation. Some attach to these names a purely clinical significance, and speak of the fibrinous exudation in diphtheria always as diphtheritic, and of that in croup as croupous. But no anatomical differences have yet been established between the exudations in the two diseases.[1] Others call a fibrinous exudation in the fauces always diphtheritic, and one in the larynx, trachea, or bronchi, croupous. But a false membrane

[1] This statement is true at least for all those who are not convinced that the exudation in diphtheria contains specific organisms by which it can be distinguished from fibrinous exudations occurring upon mucous membranes in other diseases. Organisms which in their morphological characters can be considered distinctive of diphtheria have not been demonstrated to the satisfaction of most pathologists.

in the former situation may present the same characters as one in the latter, and *vice versa*. Again, others designate all fibrinous exudations in or upon mucous membranes as croupous, not distinguishing, as a separate variety, diphtheritic exudation. From an anatomical point of view it is, however, convenient to distinguish between fibrinous exudations which simply rest upon the surface of the mucous membrane and those which likewise infiltrate the substance of the mucous membrane. It is in this purely anatomical sense that the terms croupous exudation and diphtheritic exudation have been used in this work (pp. 38, 295, 410). The fibrinous exudation, when it simply lies upon the mucous membrane without infiltrating it, is called croupous; when it is present in the substance of the mucous membrane, as well as upon its surface, it is called diphtheritic. A croupous exudation is sometimes only loosely attached to the mucous membrane, so that it can be readily stripped off; at other times it is firmly adherent, so that it cannot easily be removed. The latter variety of croupous exudation simulates a diphtheritic exudation and has been called such by the majority of writers. According to Wagner, Rindfleisch, and Weigert, many, probably most, of the so-called diphtheritic pseudo-membranes of the mouth and fauces are in reality croupous; that is, while closely adherent to the mucous membrane, they do not infiltrate it. Weigert has given the name pseudo-diphtheritic to these closely adherent croupous exudations.

It is to be noted that the terms croupous exudation and diphtheritic exudation, as thus defined, are purely anatomical terms, and are not to be confounded with the terms croup and diphtheria used in a clinical sense. A false membrane, in the form of a croupous or of a diphtheritic exudation, may be produced upon mucous membranes by a variety of causes, only one of which is the special poison of the disease diphtheria. As has already been remarked in the article on membranous croup (page 295), the distinction between diphtheria and membranous croup is to be based chiefly on clinical and etiological grounds, and not upon the characters of the exudation in the two diseases.

The tonsils, the pillars of the fauces, the soft palate, and the pharynx are the parts primarily affected in the vast majority of cases of diphtheria, and the local affection may be limited to these situations. Often, however, the process extends to the mucous membrane of surrounding parts. The larynx is often involved, and thence the fibrinous exudation may extend to the trachea and to the large and medium-sized bronchi. The pseudo-membranous inflammation not infrequently invades the nasal cavity. The Eustachian tube may be involved; and even the mucous membrane lining the cavity of the middle ear exceptionally is covered by false membrane. The mucous membrane of the cheeks, gums, and base of tongue may present patches of false membrane. The diphtheritic inflammation may extend a variable distance down the œsophagus. Diphtheritic conjunctivitis occurs in some cases, and involves considerable danger of loss or impairment of vision, chiefly from destructive ulceration and from opacity of the cornea.

The parts communicating with the pharynx are not the only parts which may be involved in cases of diphtheria. The lips, the anus, the vulva, the vagina, and the prepuce are sometimes affected. The mucous membrane of the puerperal uterus is sometimes attacked. The affection also appears in some cases on excoriated or ulcerated parts of the skin, as on vesicated surfaces, wounds, ulcers, leech-bites, in short, wherever the skin is deprived of the epidermis. Exceptionally it may be seated in some one or more of the parts which have been named, exclusive of the fauces, the latter remaining unaffected. Parts other than those primarily affected are liable to be invaded at any time during the career of the disease.

In the majority of cases of diphtheria the false membrane appears first on the tonsils or the soft palate. The pseudo-membranous exudation is often, although not necessarily, preceded by a simple (catarrhal) inflammation. The false membrane is observed first as a grayish-white, slightly elevated patch, which cannot be detached from the mucous membrane without leaving a bleeding surface. The white patches may remain distinct, or they may coalesce and form one membrane which covers the greater part of the tonsils, the soft palate, and the pharynx. As the pellicular deposit increases in thickness it acquires a yellowish or dirty-gray color. Sometimes it has a reddish or brown hue from admixture with blood. The membranous exudation is sometimes soft and pulpy in consistence; often it is firm, almost leather-like, and elastic, and can be detached in a single layer. At autopsies the membrane is generally found to be softened. In the course of three or four days, sometimes longer and sometimes shorter, the false membrane becomes loosened from its attachment to the mucous membrane, so that it can be readily separated without injury to the subjacent tissue. The separation of the membranous exudation—either as a coherent layer or as a soft, disintegrated mass—leaves the subjacent mucous membrane either smooth and intact, or ulcerated. The mucous membrane is left in an ulcerated condition chiefly in those severe cases in which the fibrinous exudation extends into its substance. Ulcers may be produced also by a suppurative process in the mucous membrane. The disease may be attended by grave constitutional symptoms even when the false membrane is seated superficially.

Outside of the pseudo-membranous exudations the mucous membrane is reddened. It presents, usually, ecchymoses in greater or less number. It is swollen from œdematous infiltration and the presence of inflammatory products. The tonsils especially are often greatly enlarged. The uvula may be swollen to twice its normal size. The inflamed mucous membrane is usually coated with a muco-purulent secretion which may be present upon the false membranes.

The extension of the membranous exudation into the larynx is not uncommon, and is a serious event in the clinical history of the disease. The characters of the fibrinous exudation in the larynx, the trachea, and the bronchi, are the same in diphtheria as in membranous croup (*vide* page 295). The false membrane in the trachea and bronchi is of the typical croupous variety, that is, it lies loosely upon the mucous membrane. In most parts of the larynx it is also loosely attached, but on the epiglottis and the vocal cords it is usually more firmly adherent. As a rule, the pseudo-membrane is readily separated from mucous membranes covered with cylindrical epithelium and having a well-marked basement membrane, whereas it is more adherent to mucous membranes lined with flat epithelium.

Pathologists are not agreed as to the exact structure of the croupous and the diphtheritic exudations. Most regard the false membranes as composed of a network of fibrin inclosing epithelial and pus-cells, often much altered in their appearance, and more or less granular matter. Red blood-corpuscles are also frequently found in these exudations. In the loosely attached croupous exudations of the trachea and larynx, the fibrin generally presents the ordinary appearance of a reticulum of finely fibrillated fibrin. But much difference of opinion exists as to the network in the closely attached croupous (or pseudo-diphtheritic), and in the diphtheritic exudations in the mouth and pharynx. Some have failed to find any substance resembling fibrin in these exudations. There is, however, as a rule, a reticulum composed of fibres broader, more refractive, and more irregular in shape than those of ordinary fibrin. Some believe that this reticulum is produced by the coagulation of a fibrinous exudation from the blood. Others attribute its formation to the

coalescence of epithelial or of pus-cells which have been greatly altered in their composition and forms.[1] Distinctly fibrillated fibrin, like that in the fibrinous exudation of serous membranes, may be present in the false membranes of the pharynx as well as in those of the trachea. The false membrane, when of the croupous variety, generally occupies the position of the epithelium and rests upon the basement membrane of the mucosa. Sometimes intact epithelium is found beneath the croupous exudation.[2] Sometimes epithelial cells devoid of nuclei and more or less distorted, are found in this situation or within the false membrane. Pus-cells are generally present in large number in the pseudo-membranes. They are usually in greater abundance in false membranes from the fauces than in those from the larynx and trachea. These cells may, also, be without nuclei, and of a hyaline appearance, but, as a rule, they are nucleated and granular. Red blood-corpuscles are sometimes present in abundance. Rod-shaped bacteria and micrococci are usually found in the exudations. The micrococci may be in zoöglœa or colonies, in which case they can be readily recognized under the microscope. The view which attributes to these micrococci a special agency in the causation of the disease is far from proven. Organisms similar in appearance are found in decomposing substances.

The tissue of the mucous membrane beneath the croupous exudation sometimes presents little change. Usually, however, it is infiltrated with a greater or less number of pus-cells, and contains small hemorrhages. Colonies of micrococci are sometimes found in lymph-spaces of the mucous and submucous tissues. In the diphtheritic variety of exudation the fibrinous material is found in the stroma of the mucous membrane, together with red blood-corpuscles and pus-cells. In this variety, according to Weigert, many of the pus-cells and of the tissue-cells are without nuclei, and have undergone the metamorphosis called coagulation-necrosis.

In certain cases of great severity, portions of the mucous membrane of the mouth and pharynx are separated in the form of sloughs which undergo decomposition and emit a foul odor. The necrotic process may extend into the

[1] Wagner attributes the production of all croupous exudations to a so-called fibrinous degeneration or croupous metamorphosis of epithelial cells, in consequence of which the cells assume a homogeneous appearance and acquire antler-like processes which anastomose with each other. Rindfleisch likewise denies that the reticulum in the false membranes of the pharynx is formed of fibrin derived from the blood, but he was not able to confirm Wagner's observations. He thinks that the pseudo-membrane is composed wholly of cells, and that the network is produced by the coalescence of pus-cells which have acquired a homogeneous, glistening appearance, and in which the nuclei have become indistinct. Weigert, while he was able to discover epithelial cells which had undergone a metamorphosis similar to that described by Wagner, confirms, in the main, Rindfleisch's view, as far as the structure of the pseudo-diphtheritic and of the diphtheritic membranes is concerned. Weigert attributes to coagulation-necrosis the metamorphosis in the epithelial and the pus-cells. Leloir has recently described a vesicular transformation of cells (like that mentioned under smallpox) which, he thinks, leads to the formation of a network resembling fibrin. Nasiloff, Steudener, and many others, believe that the network is, in reality, composed of fibrin, and is formed by coagulation from exuded plasma in the same way as in the fibrinous exudations on serous membranes.

[2] There is also considerable discrepancy of statement as to the relation of the epithelium to the false membrane. Most observers have found the epithelium usually absent from its normal situation ; others have found it oftener present than absent. Weigert (whose views have been mentioned in Part First, page 38) is of the opinion that fibrinous exudation never occurs upon mucous membranes without antecedent destruction of the epithelium. More extended observations are needed before his views on this point can be accepted. The observations of Perls, reported by Posner, are opposed to Weigert's theory as to the cause of fibrinous inflammation of mucous membranes. (Virchow's Archiv, Bd. 79, p. 354, 1880.)

deeper tissues. This malignant form of the disease is called *gangrenous* diphtheria. Sometimes thick pseudo-membranous deposits are so disintegrated and decomposed as to give a false appearance of gangrenous diphtheria.

The lymphatic glands of the neck, especially those near the angle of the lower jaw, are more or less enlarged. As a rule, the amount of enlargement corresponds to the severity of the affection within the throat. The glandular affection rarely proceeds to suppuration.

The lungs may present a variety of appearances, none of which is characteristic of the disease. When death has resulted from suffocation in consequence of involvement of the air-passages, the anterior and upper parts of the lungs are found to be emphysematous. Bronchitis and broncho-pneumonia are not infrequent complications of diphtheria. Hemorrhagic infarctions have been found. The extension of the fibrinous exudation to the bronchi has already been mentioned. Œdema glottidis may develop in the course of diphtheria.

When the disease has been attended with symptoms of severe blood-poisoning, ecchymoses in the serous membranes, and parenchymatous degeneration of the heart, liver, kidneys, and muscles have been found after death. Acute fatty degeneration of the heart has been found in certain cases which terminated suddenly with signs of paralysis of the heart. The kidneys may be the seat, not only of parenchymatous degeneration, but also of an acute nephritis. Oertel has found colonies of micrococci in the kidney, but they do not seem to be frequently present. Acute ulcerative endocarditis is a rare complication of diphtheria. The spleen is not infrequently somewhat enlarged and softened. These changes in the internal organs are those which characterize acute infectious diseases in general.

Clinical History.—Diphtheria presents, in different cases, such differences as regards general and local symptoms, the latter incident especially to the localizations of the diphtheritic affection, that some writers have instituted several varieties of the disease. Without adopting formally any of these, it will suffice to indicate the important diversities in connection with the symptomatology.

A marked point of difference relates to the development of the disease. The attack is sometimes abrupt, commencing with a chill more or less pronounced, followed by considerable or marked pyrexia; or the disease may begin with symptoms denoting great prostration. But not infrequently the development is gradual and insidious, the patient complaining of indefinite ailments, and the characteristic affection of the throat being discovered on inspection when there were few or no local symptoms pointing to the existence of the disease. After the development of the disease, the symptoms are naturally divided into general and local, the latter being referable especially to the parts affected with the diphtheritic process.

The affection of the fauces is rarely accompanied by notable pain or soreness, and hence a liability to overlook its existence. The sensibility of the parts appears, in some cases, to be diminished. Deglutition is sometimes painful, but, in other cases, unattended with pain. Incomplete paralysis of the muscles concerned in deglutition, which will be noticed as a sequel, is sometimes a concomitant of the disease, giving rise to more or less difficulty of swallowing, especially liquids. These may regurgitate through the nose. If the exudation be abundant and loose, pharyngeal râles occur with respiration, especially during sleep. The breath in some cases is notably fetid, suggesting the idea of gangrene of the throat or lungs, events not frequent in the history of the disease. The extension of the false membrane over more or less of the buccal mucous surface, occasions more or less pain in connection

with the introduction into the mouth of food or drinks, together with ptyalism, and stiffness of the parts, involving difficulty of articulation and absence of taste. The affection of the anterior nares is preceded and accompanied by a discharge which produces irritation and swelling of the upper lip, limited to one side of the lip if one nostril only be affected. In other situations accessible to view, on a mucous surface or on the skin, the diphtheritic process gives rise to more or less pain or soreness, and is attended by a sero-purulent discharge variable in quantity, frequently ichorous and sometimes fetid. As a rule, the gravity of the disease is commensurate with the extent of the local affection and the abundance of the exudation. It does not follow from this fact that the gravity depends on the local affection—the latter may be a criterion, not the cause, of the former.

The symptoms denoting an invasion of the larynx are essentially those which belong to the history of fibrinous laryngitis or true croup. These have been already considered.[1] Cough, having more or less of the characters known as croupous, feebleness of the voice with elevation of pitch, or aphonia, and labored, stridulous respiration, point to this most serious localization of the affection. The embarrassment of respiration may be increased paroxysmally, as in simple laryngitis or in true croup, from the addition of spasm of the muscles of the glottis. Swelling of the tonsils and pharynx may be sufficient to occasion some obstruction to respiration without invasion of the larynx. It is to be borne in mind that laryngitis may be excluded so long as the voice remains unaffected. Diminished respiratory murmur and embarrassment of the respiratory function out of proportion to the amount of laryngeal obstruction, with the presence of moist bronchial râles, denote an extension of the affection to the bronchial tubes.

Passing to other symptoms than those directly referable to the parts affected with the diphtheritic process, cases differ widely as respects the amount of constitutional disturbance. Irrespective of an affection of the larynx, which of necessity involves great danger, cases are either mild or more or less severe. In some mild cases the disease is almost trivial, patients not taking to the bed, and perhaps not keeping within doors. But, however mild cases may be at the outset and during more or less of the career of the disease, there is always a liability to the occurrence of diphtheritic inflammation in new situations, to the development of grave symptoms, and to important sequels. In the cases in which the disease is mild throughout its career, the local affection is confined to the fauces, or, exceptionally, to a limited space in some other situation.

In cases of greater or less severity, the clinical history embraces symptoms referable to the different anatomical systems, namely, the circulatory, cutaneous, respiratory, digestive, nervous, and urinary.

The pulse in some cases becomes very frequent; in other cases the acceleration is moderate, and it is sometimes slight. In the course of the disease the pulse is sometimes at first more or less rapid, afterward suddenly falling below the average of health. Aside from frequency, the pulse is soft or compressible. It is sometimes irregular—a symptom of unfavorable omen, if it be independent of pre-existing organic disease of the heart. Hemorrhage from the nostrils is not an infrequent symptom; it occurs occasionally from the throat and mouth. Epistaxis is sometimes so profuse as to require mechanical means for its arrest. Under these circumstances it denotes great gravity and danger, and hemorrhage in other situations is to be regarded as ominous.

The skin rarely presents much increase of heat. In some cases there is no increase, and not infrequently in the course of the disease the surface becomes

[1] *Vide* p. 296.

cool or cold. The pyrexia, as a rule, is less than in most other acute diseases. The temperature may, however, be high. Petechial spots or ecchymoses are sometimes observed, occurring generally in connection with hemorrhage from mucous surfaces. In grave cases the skin presents an anæmic aspect, even when hemorrhage has not occurred. In the cases in which the air-passages become affected, there is more or less lividity of the surface, especially marked on the face and prolabia. The disease has no characteristic eruption; rose-spots are sometimes observed and other forms of eruption, namely, erythema nodosum, urticaria, and sudamina, but these are accidental.

The symptoms referable to the respiratory system are due to fibrinous inflammation of the larynx, trachea, and the bronchial tubes. These have been already referred to among the symptoms incident to the local affections characteristic of the disease. If life continue sufficiently, false membrane, in these cases, is expectorated, sometimes in the form of hollow tubes like macaroni, but generally in patches of irregular size and shape.

The desire for food is generally either notably diminished or lost. Aside from pain and difficulty in deglutition, or the suffering caused by food and drinks when the mouth is affected, there is often an invincible repugnance to nourishment, so that, in children, if given at all, it must be forcibly administered. Vomiting is a frequent, and in some cases, a prominent, symptom. This, as well as anorexia, is serious from the interference with alimentation. Diarrhœa is not uncommon, and is a symptom of bad omen. In the cases in which the diphtheritic affection extends into the œsophagus, false membrane is expelled by vomiting in the form of ribbons, provided death does not take place before the exfoliation is completed.

In the majority of cases the mind is unaffected. Slight passive delirium occasionally occurs, and sometimes the delirium is active. The latter denotes great gravity of the disease. Convulsions and coma are rare, but both are of occasional occurrence. Convulsions have been observed at all periods of the disease; coma is the forerunner of a fatal termination. It is probable that coma and convulsions, occurring in this disease, are generally due to uræmia.

Albuminuria is a frequent symptom. The proportion of cases in which it occurs is variable. It varies considerably at different times and places. Generally, the albumen contained in the urine is small, but it is sometimes abundant. In the cases in which it is abundant, the diphtheritic exudation is generally large and the swelling of the glands of the neck unusually great. General dropsy in connection with albuminuria is rare; it has, however, been observed in a small number of cases. There may be evidences of the development of acute Bright's disease, in which case casts and usually some red and white blood-corpuscles will be found in the urinary sediment. Hæmaturia has been observed in cases presenting the symptoms of purpura or the hemorrhagic diathesis. As in the other febrile diseases, the urine contains a larger amount of urea than in health, a fact showing an increased waste of the tissues.

The duration of the disease is from one to two weeks. In fatal cases the duration may fall short of a week, death sometimes taking place within forty-eight hours. On the other hand, the illness may continue for an indefinite period beyond the maximum duration of the career of the disease, owing to consecutive affections or sequels. Aside from the characteristic diphtheritic affections, which are properly components of the disease, complications are rare and accidental. Pneumonitis is occasionally developed; and the affection of the kidneys giving rise to an abundance of albumen in the urine and sometimes to general dropsy is perhaps to be regarded as a complication. The disease, however, may be associated with other diseases. Its concurrence with scarlatina, measles, and smallpox has been repeatedly observed.

The sequels of this disease form an important part of the clinical history. Anæmia and general debility are apt to persist for a considerable period. Feebleness of the action of the heart sometimes exists to such a degree as to lead to sudden death from syncope.

Paralysis affecting more or less of the voluntary and sometimes the involuntary muscles is a characteristic sequel. The muscles of the soft palate and pharynx are oftenest affected, and paralysis here generally precedes its occurrence elsewhere. The palatine muscles are sometimes affected during the course of the disease, but generally not until after a period varying from a week to four weeks from the date of convalescence. In a slight or moderate degree, the paralysis in this situation is denoted by a certain amount of difficulty in deglutition and the regurgitation of liquids through the nostrils. In a greater degree, which is happily rare, there is very great difficulty in swallowing, and it may be even necessary to introduce aliment by means of the stomach-tube. Under these circumstances, sudden death has been caused by the passage of aliment into the larynx. On inspection, the soft palate is seen to be relaxed and immovable. The paralysis affects the reflex action, so that the palate remains motionless when irritated with a pointed instrument. The existence of paralysis in this situation is indicated by a nasal intonation of the voice, and sometimes by a snoring sound in respiration. The paralysis in some cases affects the tongue and muscles of the face, so that articulation is difficult, and the patient may be unable to perform the acts of suction and whistling. The act of gargling is also difficult or impossible.

The paralysis is sometimes limited to the muscles of the palate, pharynx, and mouth, but not infrequently it extends to other muscles. Exceptionally, the paralysis is manifested primarily, or solely, elsewhere than in the throat and mouth. The lower limbs are most apt to be affected, and paralysis here generally takes precedence of its occurrence in the upper extremities. The paralysis of the limbs is developed gradually, and is preceded by tingling, numbness, and a sensation of coldness. The loss of power over the muscles may be complete, or there may be different degrees of paresis. The paralysis sometimes assumes the form of hemiplegia. One of the upper extremities may be paralyzed in connection with paraplegia. The upper limb on one side and the lower limb on the opposite side may be alone affected. Trousseau observed the paralysis to affect successively and recurrently the different extremities. Finally, the paralysis is sometimes general, that is, all the extremities are paralyzed, and, in addition, the paralysis may involve the face, the muscles of the throat and mouth, of the neck and trunk, and certain of the involuntary muscles. Cases in which the paralysis is so extensive are extremely rare.

In connection with the paralysis of motion, the sensibility in the affected parts is often notably diminished. The power of feeling pain is either lost or more or less impaired (analgesia), and also the tactile sense (anæsthesia). Exceptionally, the sensibility of the integument is morbidly increased (hyperæsthesia).

The special senses are liable to be affected, more especially the sense of sight. Vision may be affected by paralysis of the external rectus muscles, causing converging strabismus. Aside from this cause of disturbance, the most frequent form of disorder is presbyopia. The defect of sight is then obviated by the use of convex glasses. Occasionally the form of disorder is myopia. In these cases the disorder consists in defective power of adjustment in the eye for distant or near objects. But in some cases the impairment of vision is amaurotic. Complete amaurosis occasionally occurs. There is reason to believe that the amaurosis is sometimes attributable, in part at least, to uræmia. Disordered vision is in some cases the first of the paralytic

sequels, and the paralysis is sometimes limited to the organs of sight. The other special senses, namely, taste, smell, and hearing, are sometimes affected, but rarely as compared with the sense of sight.

The paralysis sometimes affects the intercostal muscles and diaphragm, giving rise to dyspnœa, and involving danger from inability to carry on the respiratory acts. The muscles concerned in defecation are sometimes paralyzed, causing retention of, or inability to retain, the feces. In like manner the paralysis may affect the bladder, causing retention of urine, or, on the other hand, the sphincter muscles may be affected, giving rise to incontinence. Notable impairment or loss of virile power may be here mentioned as one of the sequels of diphtheria.

The paralysis in the different situations in which it occurs after diphtheria, is functional, that is, it is not dependent on appreciable lesions as yet ascertained. In fatal cases lesions have not been discovered, and, if death do not take place, the paralysis is temporary; recovery may be expected after the lapse of a few weeks or months. As regards the frequency of the paralytic sequels, more or less impairment of deglutition is common, but paralysis elsewhere occurs in a minority of cases. These sequels take place in cases of mild as well as severe diphtheria.

Pathological Character.—Diphtheria is a general disease—an essential fever. The pyrexia and constitutional symptoms are not merely symptomatic of the inflammation involved in the local diphtheritic affections. With regard to these, the opinion held by many, perhaps by most, physicians, is that they are the manifestations of a special morbid condition of the system, that is, they are secondary to the general disease, having a relation to the latter like that of the intestinal lesions in typhoid fever, or that of the characteristic local affections of the skin and mucous membranes in the eruptive fevers. In a measure opposed to this is the view held by some, namely, that the affection of the throat is primary as regards the general disease. Many of the advocates of this view maintain that the micrococci found in the exudation within the throat constitute the special cause of the disease; that, entering from without, they find lodgment in the throat, and, finding here the favorable conditions, they multiply, wander into adjacent parts, enter the blood, and form colonies in situations more or less remote from the place of their entrance. For a further exposition and a discussion of the pathological points involved in this recent view, the reader is referred to other works.[1] Although it has much probability, it cannot, at the present time, be considered as established.

Irrespective of the supposed agency of micrococci, and without involving necessarily the germ-theory, the opinion is held by many that, in grave cases of diphtheria, the pyrexia and other general symptoms are due, in a greater or less degree, to the absorption of septic matter from the parts in which the diphtheritic affection is seated, in other words, that septicæmia is often an important secondary element of the disease.

A question which has occasioned much discussion, and concerning which opinions differ, is whether diphtheria and exudative laryngitis, or the so-called true laryngeal croup, are distinct diseases. Regarded from a clinical point of view, it seems to me clear that this question is to be answered in the affirmative. The latter affection is identical with diphtheria only in so far as that the laryngeal inflammation is characterized by an exudation or a false membrane. Now, diphtheria occurs and may end fatally without any affection of the larynx. Of course, the terms exudative laryngitis and laryngeal croup

[1] *Vide* Oertel in Ziemssen's Cyclopædia, Am. ed., vol. i.

are not applicable to these cases. If these terms be applied to laryngitis whenever the inflammation is pseudo-membranous, it may be proper to say that, in the cases of diphtheria in which the diphtheritic affection involves the larynx, the disease denoted by these terms exists as a complication. The laryngeal disease in these cases is secondary, not primary. In other respects diphtheria with an exudation in the larynx differs materially from a primary exudative laryngitis or laryngeal croup. In the former, the affection of the throat precedes the laryngeal affection, often for several days. In the primary so-called true croup, the exudation may appear in the fauces, but it does not extend to the nares, into the œsophagus, etc., nor does it occur in other situations. A considerable enlargement of the cervical glands does not occur. Albuminuria is not a symptom. The pyrexia and other general symptoms are purely symptomatic of the local inflammation. The disease is sporadic, never prevailing as an epidemic. It affects almost exclusively children. It is never followed by paralytic affections. There is no evidence of its contagiousness. The relative distinctive features of the two diseases are epitomized by saying that diphtheria is a general disease, or an essential fever, whereas the so-called true croup belongs among the local diseases.

A diphtheritic affection of the throat occurs as an element of scarlatina, and the two diseases may exist in combination. The combination of the two diseases is the probable explanation of reported instances in which patients with scarlet fever apparently communicated diphtheria, and *vice versâ*. The following instance came under my observation: The patient, a boy aged four years, had well-marked diphtheria, and no eruption. After convalescence he became affected with complete hemiplegia and general dropsy, the urine denoting acute diffuse nephritis. During his convalescence a sister was attacked with scarlet fever, the efflorescence being abundant. The boy had the sequels of both scarlatina and diphtheria, after what appeared to be purely an attack of the latter, and he communicated to his sister the former and not the latter disease.

CAUSATION.—Diphtheria rarely occurs sporadically. It is eminently an epidemic disease. That the diphtheritic exudation contains a contagium is a general belief. This belief is based on instances in which the disease has followed the accidental introduction of some of the diphtheritic exudation into the mouth or nostrils; on the production of the disease in animals by inoculation, and on the introduction of the disease into situations where it had not previously existed by patients coming from situations in which it was prevailing. It is true that experiments by Trousseau and Peter to produce the disease in themselves by voluntary inoculation failed. Peter went so far as to apply freely to the throat lint charged with diphtheritic matter. But positive outweigh any number of negative facts. Distrust has been thrown upon the experimental inoculation of animals. The results of the careful experiments of Curtis and Satterthwaite, as well as of the more recent experiments of H. C. Wood and Formad, are opposed to the doctrine that diphtheria can be produced in animals by inoculation. The importation of a disease may be due to the portability of the special cause which is not necessarily a contagium. As bearing upon the last-named point, the following instance coming under my observation possesses interest: Diphtheria occurred in a family residing on Staten Island, distant six or eight miles from New York. Two children of this family, perfectly well, were sent to the house of a friend in the latter city for security against the disease. There were no cases of diphtheria within, or in the neighborhood of, the house to which the children were sent. In a few days both children were attacked with diphtheria, and were at once sent back to their home. Two days afterward, two young girls in

the family into which the children had been received were attacked with diphtheria. The larynx was involved in both cases. One died after tracheotomy had been performed; the other recovered without the operation. A sister and a domestic nursed the girls, and were in the chamber with them night and day. Neither they nor any other member of this family had the disease. These facts seem to exemplify portability and not contagion.

Sporadic cases occur under circumstances which seem to render it impossible that a contagium was involved. The number of such instances justifies the opinion that, if the disease be contagious, it may be also produced without the agency of a contagium. Admitting that there is room for doubt as regards the contagiousness of the disease, the propriety of measures dictated by the general belief that it is contagious is not to be doubted.

Unsanitary conditions favor, in no small degree, the occurrence of the disease in both its sporadic and epidemic form. The particular conditions which have this effect are not known; nor is it known whether the effect be produced by an influence upon the multiplication of disease-germs outside of the body, or by increasing the susceptibility of the persons exposed thereto.

Epidemics of diphtheria are irregular in their occurrence. It is a remarkable fact that they were scarcely known in America from the epidemic in 1771, described by Bard, up to about 1856, and since the latter date they have occurred in all parts of the continent. The disease is often limited, in its prevalence in particular sections, to a circumscribed area. For example, it has been observed to be restricted to a narrow strip of land on the banks of a stream. The special cause seems to require auxiliary causes, at present unknown, which are peculiar to certain localities.

The susceptibility to the disease is not equal in all periods of life. In the great majority of cases patients are between three and twelve years of age. Persons of any age are, however, liable to be attacked. Circumstances pertaining to sex, social position, occupation, etc., do not appear to be connected with the causation. The period of incubation has not been ascertained. It is estimated to vary between two and eight days.

Epidemics differ as regards certain features of the disease and the rate of fatality. In some epidemics there is an unusual tendency to an invasion of the larynx, and the amount of exudation in other situations is unusually large in the majority of cases; in other epidemics the local affection is confined to the fauces, as the rule, and the disease is generally mild. In respect of variations at different times and places, diphtheria resembles other epidemic diseases.

Diagnosis.—It is important to define clearly the comprehensiveness of the term diphtheria in respect of diagnosis. Some physicians are accustomed, during an epidemic, to consider cases of simple or follicular pharyngitis as cases of diphtheria. This is sanctioned by writers who recognize as a variety of the disease "catarrhal diphtheria," that is, diphtheria without the local diphtheritic characteristics. Now, it is perhaps a rational supposition that the special cause may give rise to a pharyngeal inflammation and pyrexia without fibrinous exudation; but, however rational, it is only a supposition. On the other hand, it is well known that pharyngitis without diphtheritic characters is a common affection. False statistics in regard to death-rate, and erroneous conclusions respecting the effect of treatment, can only be avoided by recognizing, as an essential criterion, the local diphtheritic characteristics. Adopting this rule, the diagnosis cannot be positive prior to the membranous exudation which may be preceded for a variable period by pyrexia and other general symptoms. These, from their violence, may mislead without an examination of the throat. Thus, I have known an

attack, with high fever and delirium, shortly after confinement, to be mistaken for a time for puerperal fever. When it is an intercurrent disease in the course of another fever, it is apt for some time to be overlooked. In a case related to me by a medical friend, there being notable abdominal tenderness and great prostration, the disease for twenty-four hours was supposed to be acute peritonitis.

The diagnosis is easy when the local manifestations have taken place. The only liability to error is in confounding with the diphtheritic affection pharyngitis with a deposit of mucus or an abundant follicular secretion. The appearance in some cases resembles that of a true exudation. The distinctive points are these: A deposit of mucus or of follicular secretion is generally limited to, or especially marked over, the tonsils; it can be wiped off, but is not removable in strips; it may be seen to dip into the follicular depressions, and it is often thrown off in twenty-four or thirty-six hours. On the other hand, a diphtheritic exudation has the characters of a false membrane; it generally extends more or less over the soft palate and uvula; if removed, it comes away in strips, and it is never exfoliated in thirty-six hours.

Prognosis.—The proportions of deaths in collections of cases reported by different observers present much variation. This is measurably due to the fact that, irrespective of treatment, the fatality in different epidemics varies within widely separated limits. The variations in statistics are also due in a measure to the error of confounding with diphtheria pharyngitis with follicular secretion, and the error of applying the name diphtheria to all cases of sore throat occurring during an epidemic. Without attempting, therefore, to express the average death-rate in figures, it must suffice to say that it is sometimes very large and sometimes comparatively small.

The danger is, first, from an invasion of the larynx. Of the cases in which the air-passages become involved, the vast majority end fatally. The prognosis in these cases is always exceedingly unfavorable. Apnœa either causes or contributes largely to the fatal result whenever the larynx becomes involved. The patient cannot be considered as secure against diphtheritic laryngitis so long as the career of the disease continues, but the danger from this source progressively diminishes after the first week.

The danger is, second, from asthenia or exhaustion. The violence of the disease may destroy life within forty-eight hours from the date of the attack, or perhaps even at an earlier period. In these cases, the disease is truly called malignant. Using the language of metaphor, for the want of precise knowledge of the general conditions on which the fatality in these cases depends, the vital powers are said to be overwhelmed with the force of the disease. But in the larger proportion of the cases in which the disease proves fatal by asthenia, the powers of life are gradually exhausted, and death takes place in the second week. In the cases in which the larynx is unaffected, the prognosis is always unfavorable if the diphtheritic membrane extend from the fauces into the posterior and anterior nares, if it pervade extensively the buccal membrane, or if it exist abundantly in other situations. Other unfavorable prognostics are, frequent vomiting, diarrhœa, copious epistaxis or hemorrhage in other situations, great frequency, irregularity, or feebleness of the pulse, coldness of the surface, abundance of albumen in the urine, convulsions, delirium, and coma.

A fact important to be borne in mind is the liability to sudden, fatal syncope in this disease. It may occur in cases which, as regards the general symptoms, do not present an appearance of great gravity. It generally occurs on some unusual exertion, as in getting out of bed; it has been known

to occur even during convalescence. It is probable that, in some of the cases in which a fatal result occurs suddenly or unexpectedly, the death is occasioned by the formation of a thrombus in the right cavities of the heart. It may also be referable to parenchymatous degeneration of the heart.

The paralytic affections which are liable to supervene do not, in general, involve danger. The danger incident to these affections relates to innutrition in the cases in which deglutition is extremely difficult or impossible, and to apnœa when the respiratory muscles are involved in the paralysis.

Treatment.—With reference to therapeutical indications, it is convenient to divide cases into those with, and those without, a diphtheritic affection of the larynx. And, *first*, the treatment of cases in which the larynx does not become affected, will be considered. The indications in these cases relate to the general condition and to the local affection.

It is obvious that views which relate to the pathological connection between the pharyngeal affection and the general condition, must have great influence upon the rational indications as regards local treatment. If the disease be produced by bacterial germs or organisms which, received into the mouth or nostrils, find a habitat in the mucous membrane generally of the throat, and that generated here are broods of parasites which migrate into adjacent parts and into the blood, it is a reasonable supposition that local treatment is first in importance. According to this view, the object is to destroy the parasites as early, quickly, and effectually as possible. There is sufficient probability of the correctness of this view to dictate the propriety of making trial of different articles and methods with reference to a parasiticidal effect. Another view renders local treatment rationally important, namely, that which attributes the general symptoms, in a greater or less degree, to the absorption of septic matter, not accepting the theory that the morbific agency of this matter is due to organisms. According to this view, it is a reasonable supposition that to prevent septicæmia is an important object of local treatment. Rational considerations, however, no matter how strongly they may seem to be supported by morbid anatomy together with accepted doctrines of etiology and pathology, are never sufficient for the establishment of therapeutical rules without the results of clinical experience. Making proper allowance for the variableness of the disease in different epidemics, we have not, at present, sufficient clinical data for determining the relative value of the different kinds of either the local or the general treatment of diphtheria, and we lack the important standpoint for deciding upon the influence, collectively, of all kinds of treatment, namely, the mortality when the disease is allowed to pursue its course unaffected by any therapeutical measures.

Caustic and irritating applications to the throat, namely, the nitrate of silver, hydrochloric acid, the sulphate of copper, and the strong solutions of the pernitrate or persulphate of iron, have heretofore been in vogue. They are still employed by some practitioners, and their use is sanctioned by some standard authors. They are objected to on the following rational grounds: Impairing the continuity of tissue facilitates the entrance of organisms or septic matter into the system; and observation teaches that secondary diphtheritic exudation is apt to occur in any situation on the mucous surface or skin in which there is abrasion, as, for example, after the application of a blister. Many physicians have testified to the apparent hurtfulness of these applications. On the other hand, testimony is not wanting of their usefulness. A medical friend of much experience is convinced that, by the prompt and thorough application of nitric acid, if the part primarily affected can be seen and reached, the progress of the disease may with certainty be arrested. He claims that want of success can only be explained by lack of thoroughness in

the application. It should be made by bringing into contact over the whole of the affected part, either lint or several thicknesses of linen cloth holding the acid, and with sufficient pressure for the acid to penetrate the exudation and act upon the underlying tissue.

Cauterizing applications have of late years, to a great extent, given place to those supposed to be useful by means of a disinfectant or antiseptic effect. Remedies applied for this effect are carbolic acid, salicylic acid, permanganate of potassa, chloral hydrate, sulphite of soda, benzoate of soda, subsulphate of iron, and the chlorate of potassa. Two or more of these are sometimes combined. The applications in a liquid form may be made by means of a probang, a camel's-hair brush, or a spray producer. The latter is preferable, especially in children. The salicylic acid is conveniently applied in the form of a dry powder combined with bismuth. The chlorate of potassa may be taken dry into the mouth combined with pulverized sugar. The applications are to be made by means of injections into the nostrils if the exudation be seated in the Schneiderian membrane. Whatever be the disinfecting or antiseptic articles employed, they should not be concentrated sufficiently to cause local irritation, and they should be repeated at short intervals. Oertel advises a spray from a solution of the chlorate of potassa and salicylic acid, with, in severe cases, the addition of the permanganate of potassa, to be continued for a quarter of an hour, and repeated every hour or even every half hour. The thorough cleansing of the affected parts by gargling or injections with tepid water holding some disinfectant in solution, is an important part of the local treatment. Oertel attaches much importance to the promotion of suppuration, and advises for this end the frequent inhalation of hot steam.

The degree of efficacy to be attributed to local treatment, and the particular applications to be preferred, are to be settled by further clinical experience. Different physicians differ as to the importance of topical applications, and as regards preferences among those which are in use. In the deficiency of data for exact conclusions, the opinions of individual observers will have weight in proportion to their opportunities for observation, and the confidence placed in their opinions.

With reference to the general treatment, if the germ theory be adopted, it is a legitimate purpose of clinical observation to discover a remedy to be taken into the system for a parasiticidal effect. Several remedies are supposed to have this effect. Some physicians attribute to the sulphites efficacy in this way, given in full doses, after short intervals. From twenty to thirty grains of the sulphite of sodium may be repeated every two or three hours. The sulphocarbolate of sodium, in doses of a scruple, to an adult, every hour or two, in the practice of a medical friend of much experience, has seemed to him signally useful. This remedy improperly prepared is sometimes extremely offensive to the taste; properly prepared, and given with an agreeable syrup, it is not repulsive. The benzoate of sodium, given hourly in doses aggregating in twenty-four hours from fifteen to twenty-five grammes, has lately been used with apparently notable benefit in Germany.[1] It is claimed by Dr. E. W. Chapman, on the basis of clinical experience, that alcohol, given early and as largely as can be borne without symptoms of alcoholism, acts as an antidote, and that, conjoined with quinia, it is an effective curative agent. We may hope that for this disease, and for other infectious diseases, remedies may be discovered which will have a controlling influence like that of quinia in the malarial fevers.

Aside from remedies for a special controlling influence, in view of the fact that, if the larynx be not affected, the danger is chiefly from asthenia, the

[1] *Vide* Niemeyer's Lehrbuch, edited by Seitz, tenth edition, 1879.

great object of treatment is support. Much importance belongs to alcohol as the most efficient factor in the supporting treatment. The principles which should govern its employment are the same as in the essential fevers and other diseases tending to destroy life by asthenia. These principles need not here be repeated. In this disease, as in the essential fevers, there is sometimes a notably increased tolerance of alcoholics. Jenner cites a case in which two drachms of brandy were given hourly, with advantage, to a child three years of age. In a case of great severity which came under my observation, half an ounce of brandy was given hourly, the patient being thirteen years of age, without any excitant effect, the case ending in recovery. In the use of alcoholics the physician is to be guided by the indications and by carefully watching the immediate effects. Alimentation is an essential part of the treatment. The diet should be concentrated, highly nutritious, and embrace the necessary variety of alimentary principles. Milk meets pre-eminently these requirements. A serious difficulty in the treatment often arises from the invincible repugnance to nutriment, and sometimes from the persistence of vomiting. Owing to the difficulty of alimentation in some cases, and sometimes to a want of appreciation of its importance, death takes place from innutrition. Of tonic remedies, the sulphate of quinia and the tincture of the chloride of iron are generally regarded as eligible articles.

All the measures heretofore known as antiphlogistics, namely, bloodletting, general or local, purgation, mercurialization, emetics, and nauseants, are rationally contra-indicated by the simple fact that the danger is not from the inflammatory manifestations of the disease, but from the general condition which tends to destroy life by asthenia. Clinical experience has abundantly shown these measures to be injurious. Blisters and other counter-irritant measures are not to be employed, occasioning, as they are likely to do, new foci of diphtheritic inflammation.

Symptoms incidental to the disease claim palliative treatment. Vomiting is to be relieved by bismuth, creasote, hydrocyanic acid, etc. Diarrhœa calls for opium and astringents. Anodynes, that is, opium or its succedanea, the bromides, or the chloral hydrate, are often required by restlessness and vigilance. Hemorrhage indicates the use of hæmostatics topically and internally.

The treatment of cases in which diphtheritic laryngitis becomes developed, involves the same general principles as that of cases without the laryngeal affection. But, in addition, are indicated measures to hasten the separation of the false membrane within the larynx, precisely as in cases of laryngitis with false membrane disconnected from diphtheria, that is, in cases of sporadic or primary so-called true croup. The most efficient of the measures for this end is the inhalation of warm vapor or steam. With reference to this measure, and other points relating to the treatment directed to the laryngeal affection, the reader is referred to the chapter of this work devoted to pseudo-membranous laryngitis.[1]

The rules with respect to tracheotomy, when the danger from laryngeal obstruction is imminent, are the same as in cases of primary croup. There is undoubtedly less hope of success from surgical interference than in the latter affection. With reference to the propriety or importance of the operation, however, the simple question is, are lives ever saved by it? This question is undoubtedly to be answered in the affirmative. The question, how many lives are saved, is of less importance in its practical bearing. If lives are ever saved by tracheotomy in diphtheria, a practitioner is reprehensible if he allow a patient to die from laryngeal obstruction without opening the trachea. The patient is entitled to the chance of being saved by the operation, however small that chance may be.

[1] *Vide* page 299.

The propriety of precautions against contagion has been already referred to. Patients affected with the disease should be at once isolated. Whenever practicable, the removal, especially of children between three and twelve years of age, from an infected house or district, is advisable. Thorough disinfection of the dejections, of all articles which have been in contact with patients, and of the apartments which they have occupied, is to be enjoined. Auxiliary causes are to be sought after in defective sewerage, drainage, overcrowding, want of ventilation, etc., and removed if discovered.

CHAPTER X.

ACUTE, SUBACUTE, AND CHRONIC ARTICULAR RHEUMATISM.

Acute Articular Rheumatism—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Subacute and Chronic Articular Rheumatism.

THE term *rheumatism* is used to denote a constitutional disease characterized by certain local manifestations seated in the articulations and the fibrous tissues in other parts; the term has also been applied to neuralgic and other affections supposed to arise from the constitutional morbid condition existing in the ordinary form of the disease. I shall consider, *first*, *acute articular rheumatism* or *rheumatic fever*, and *second*, *subacute* and *chronic rheumatism*. The affection known as *muscular rheumatism* has been considered in connection with diseases of the nervous system, under the name myalgia. The disease called *gout* is in certain respects analogous to rheumatism, although presenting essential points of difference. After having considered the forms of rheumatism just named, I shall consider, in the next chapter, gout and rheumatoid or deforming arthritis, often called rheumatic gout.

Acute Articular Rheumatism. Rheumatic Fever.

Acute articular rheumatism, as the name imports, involves an affection of the articulations or joints. The affected joints present the phenomena of inflammation, and the affection is also called acute rheumatic arthritis. Opportunity is rarely offered to study the morbid appearances within the joints in cases of acute articular rheumatism. Often when symptoms referable to the joints have been well marked during life, little change is to be found in these structures after death. It may be supposed that in these cases the condition is one chiefly of hyperæmia and œdema. In many cases, however, the articular cavity contains an increased amount of fluid which is more or less turbid from admixture with pus-cells. The synovial membrane may be reddened from hyperæmia, and thickened from serous infiltration. In rare cases, flocculi of fibrin have been found within the articular cavity. Much of the swelling about the joints during life is due to inflammatory œdema of the tissues surrounding the affected joints. The quantity of fibrin in the blood is notably increased in acute articular rheumatism. In the course of the disease certain internal organs are liable to become inflamed. The inflammation is generally seated in the fibro-serous tissues, and especially in the

endocardium and pericardium. In a pathological view, the endocarditis, pericarditis, and other internal inflammations which occur in cases of acute articular rheumatism, are local manifestations of the disease, like the arthritic affections, but it is most convenient to consider them in the light of complications.

Clinical History.—Acute articular rheumatism, in the majority of cases, commences with a sudden attack, and in nearly one-half of the cases in which the attack is sudden it takes place at night. In a small proportion of cases, pyrexia precedes the local manifestations for a period varying from a few hours to one or two days; hence one reason for the name *rheumatic fever*, instead of acute rheumatism. In most cases, however, the fever and the local manifestations are simultaneous in their occurrence. Sometimes pain and soreness of the joints, together with indefinite ailments, precede the development of the disease for a variable period.

The development of the disease is denoted by an affection of one or more of the articulations. The local phenomena are pain, tenderness, increased heat, swelling, and redness of the skin. The pain differs in intensity in different cases, but, as a rule, it is not intense so long as the parts are perfectly quiet. Pain is especially excited by movements of the affected joints. In severe cases the slightest motion is insupportable; even jarring the bed or room occasions suffering. Pressure over the joints is painful. Owing to the pain occasioned by movements, the patient maintains, as long as possible, a fixed position; changes of the decubitus cause often extreme suffering. Swelling is most apparent in joints not covered with muscle, namely, the knee, wrist, elbow, ankle, and the smaller joints of the hands and feet. It is less apparent in the hip and shoulder. The swelling is due, in part, to a morbid increase of liquid within the synovial cavity, and in part to effusion into the surrounding structures. The redness is due to an erythema in the form of patches or zones which do not present well-defined borders. The redness, like the swelling, is not apparent over the hip and shoulder, but only over joints comparatively superficial. The swelling and the redness are, in general, proportionate to the acuteness of the rheumatism.

In some cases several joints are affected either simultaneously or in quick succession (polyarthritis); in other cases the affection is limited to a single joint for a greater or less period (monarthritis). In the course of the disease, in most cases, various joints are successively affected, and frequently a greater or less number of joints are affected at the same time. It is a peculiarity of the rheumatic inflammation to leave one or more joints abruptly, the local phenomena sometimes disappearing within a few hours, and to attack as abruptly other joints. Cases differ as regards the number of joints affected in the course of the disease; in some cases few or no joints escape, and in other cases the rheumatic inflammation remains limited to a few joints or even to a single joint. The fibrous tissues elsewhere than within and around the joints, and exclusive of the visceral organs, are liable to be attacked. Thus, those of the dorsum of the hand and of the instep, the ligaments of the neck and back, and the sclerotic tunic of the eye are sometimes involved.

The disease is extremely variable as regards the number of joints affected, either simultaneously, or successively, the order in which they are attacked, etc.; yet the local manifestations are governed by an important pathological law, namely, the law of parallelism. Corresponding joints are often affected together, and, when this is not the case, the different affected joints are either on one side of the body, or joints on the two sides which are analogous, namely, the knee and elbow, wrist and ankle, hip and shoulder, are affected

in combination. In an analysis of 21 cases with reference to this point, out of 88 instances in which either a joint was affected singly or more or less joints affected in combination, there was but a single violation of the law of parallelism.[1] This disease, therefore, is eminently one of the bilateral or symmetrical diseases. As respects the relative liability of the different joints to become affected, the analysis just referred to showed the order to be as follows: The knee, ankle, and wrist, shoulder, hip, elbow, phalangeal joints, first of the hands, and second of the feet, and the maxillary joint.

Acute articular rheumatism is always accompanied by more or less pyrexia. In addition to the fact that the pyrexia sometimes precedes the local manifestation, a reason for the propriety of regarding the disease as an essential fever is to be found in the fact that the pyrexia is not always in proportion to the number of joints affected or the intensity of the rheumatic inflammation, as denoted by pain, soreness, heat, etc. The pulse rarely exceeds 90 per minute. The axillary temperature in different cases varies from 102° to 110° Fahr. Sweating is generally a symptom more or less prominent, occurring especially at night. The sweat emits a notably sour odor. In connection with profuse sweating, sudamina or miliary vesicles not infrequently appear on the neck and trunk. The appetite is either lost or greatly impaired. Thirst is more or less urgent. The tongue is frosted or coated. The saliva becomes acid. Generally the bowels are constipated, but exceptionally there is diarrhœa. The urine is diminished in quantity; its specific gravity is high, owing chiefly to a decrease of water; the coloring matter is increased, and, on cooling, the urates are deposited in abundance. Owing to the increase of the pigment of the urine, the sedimentary deposit is usually of a reddish color. The deposit of this lateritious sediment does not show an increase of the amount of uric acid in the urine, but only the diminution of water. Quantitative analyses of the urine have shown the quantity of uric acid not to be greater than in health. The chlorides are sometimes deficient, and occasionally the urine is slightly albuminous. Pain in the head is not common. The intellect, as a rule, is not disturbed unless a cerebral complication occur, which is rare; but mild delirium is sometimes observed. In general, the strength is well preserved. Sleeplessness is usually a source of discomfort and more or less prostration, sleep being prevented by pain on change of position and the perspirations.

An important feature of the acute articular rheumatism is its tendency to invade certain of the structures of the heart. Endocarditis occurs in a considerable proportion of cases. It is, however, less frequent than has heretofore been supposed, as already explained in treating of that affection. The inflammation, as a rule, is limited to the membrane lining the left cavities of the heart, and it affects especially the portion of this membrane situated upon the mitral valve. In a large proportion of the cases of valvular lesions of the heart, more especially mitral lesions, their point of departure is rheumatic endocarditis. Pericarditis occurs less frequently. As a rule, when pericarditis becomes developed, endocarditis co-exists. For a consideration of these affections, as developed in rheumatism, the reader is referred to the section devoted to diseases affecting the circulatory system. It may be repeated here that pericarditis and probably endocarditis sometimes precede the local manifestations elsewhere. It is convenient to speak of these affections as complications, but, properly speaking, they are to be reckoned among the local manifestations of the disease; that is, they are dependent on the same internal determining cause to which the affection of the joints is to be

[1] Analysis of twenty-one cases of articular rheumatism, by the author. Buffalo Medical Journal, March, 1854.

referred. But it is to be noted that rheumatic endocarditis and pericarditis differ from rheumatic arthritis in presenting, as a rule, the ordinary results of inflammation, namely, exudation of fibrin, formation of false membrane, and sometimes suppuration, results which are rare in the articular manifestations. The structures of the heart are liable to become involved in proportion to the acuteness of the rheumatism. They may become involved at any period in the course of the disease, but the liability is greatest in the early and middle period. They are more likely to occur the younger the patient. They occur rarely in patients over forty years of age.

Bronchitis, pleuritis, and pneumonitis are occasionally developed. They are, however, so rare that it may be a question whether they are not accidental complications. The meninges of the brain are sometimes affected. Examples, however, are infrequent. Active delirium, convulsions, and coma are observed in a small number of cases. In some of these cases the appearances denoting meningitis have been found after death, but in other cases the cerebral structures are devoid of the evidences of inflammation. The events just named are sometimes associated with pericarditis, and are probably connected pathologically with the latter affection. It is possible that rheumatic inflammation may attack the meninges of the brain, leaving no traces after death, as has been observed with respect to the joints. In a fatal case under my observation, in which the symptoms pointed to meningeal inflammation, the autopsy showed only a certain amount of hyperæmia. There is also room for the supposition that, in some cases, delirium, convulsions, and coma may be due to uræmia, disease of the kidneys being accidentally associated with rheumatism. Meningitis, distinguished as rheumatic, has some distinctive features which have been mentioned in a previous section (*vide* page 698). Cerebral embolism from masses of fibrin detached from within the left cavities of the heart is an event of rare occurrence. I have met with two cases of peritonitis developed in the course of the affection, the peritoneal inflammation ending in recovery. Acute rheumatism occurs either before or after an attack of chorea sufficiently often to denote some pathological connection between these diseases. It is developed occasionally in connection with scarlet fever.

The duration of acute articular rheumatism varies greatly. The disease ends from self-limitation, but the minimum and maximum of duration are widely apart. These statements have reference to the course of the disease when left to itself, that is, no active measures of treatment being employed. In 1862, I observed, at Bellevue Hospital, 13 cases which were allowed to pursue their course uninfluenced by therapeutical interference, some palliative measures being alone employed. I am not aware that, prior to this date, any one had undertaken to study, in this way, the natural history of the disease. I reported the 13 cases in the American Journal of the Medical Sciences, No. for July, 1863, entitling my article "A Contribution toward the Natural History of Articular Rheumatism." In making an analysis, in 1854, of 24 cases which I had recorded, I was impressed with the importance of obtaining knowledge of the natural history of the disease, as the point of departure for the study of therapeutical measures. With reference to this point, in my report of the analysis, I used the following words: "At the present moment we cannot answer the question, 'what are the intrinsic tendencies of articular rheumatism as respects its continuance, its complications, and its remote consequences in the organism?' Were we able to answer this question by an appeal to facts, we should then have a criterion by which to estimate the favorable or unfavorable influences of different methods of treatment pursued in a series of cases; as it is, in bringing statistical information to bear on the therapeutics of the disease, we can only study the

immmediate effects of different remedies, and institute comparisons, in this point of view, and also with reference to the duration of the disease, etc., in different series of cases treated by different methods."[1] In my "Contribution to the Natural History of Articular Rheumatism," published in 1863, I premised a report, in full, of all the cases (13) by the following account of my plan of study: "On entering on duty at Bellevue Hospital in August, 1862, I resolved to treat with only palliative measures the cases of articular rheumatism which should be received into my wards, so long as circumstances might lead me to conclude that, by continuing this plan, no injustice was done to the patients whose relief was, of course, paramount to any other object. The cases thus treated progressed so satisfactorily, that I found no ground for a discontinuance of the plan. The last of the cases, in fact, was the only one in which any important complication occurred. Some of the cases were recorded by myself, and the remainder by my clinical assistant, Dr. Shiverick." . . . . "The reported cases were treated, throughout the whole course of the disease, with only palliative measures. These measures consisted of opium in some form given in small or moderate doses, the application, generally, of dry flannel to the affected joints, and the external use of either the soap and opium liniment, or the tincture of aconite. But to secure the moral effect of a remedy given specially for the disease, a 'placebo' was given consisting, in nearly all the cases, of the tincture of quassia very largely diluted. This was given regularly, and became well known in my wards as the 'placeboic remedy' for rheumatism. The favorable progress of the cases was such as to secure for the remedy generally the entire confidence of the patients. I may add, that all the cases were brought before the medical class in attendance during the winter."

Of these 13 cases, an endocardial murmur existed in 11; but the murmur was limited to the base of the heart in all but 3 cases. Moreover, all the patients but two were women; and, in women affected with articular rheumatism, a systolic basic murmur is the rule, with few exceptions, the murmur being generally of hæmic origin. In only one case was pericarditis developed. In this case, the pericarditis occurred directly after the patient's admission. Pneumonia occurred subsequently. The patient, however, recovered.[2]

The duration in these cases, respectively, from the date of attack to convalescence, excluding the case in which pericarditis and pneumonitis occurred, was as follows: In three cases under 15 days, in one case between 15 and 20 days, in three cases between 20 and 25 days, in three cases between 25 and 30 days, and in the remaining two cases 45 and 56 days. The mean duration was a fraction under 26 days.

These cases established the fact that acute articular rheumatism belongs among the self-limited diseases. Two years after the publication of my report in 1863, namely, in 1865, a communication by Dr. Henry G. Sutton, embracing a tabulated report of 41 cases treated chiefly with mint water, appeared in the Guy's Hospital Reports. Twenty-two were males, and nineteen females. The average duration from admission to the cessation of pain, the skin being cool, and no relapse taking place, was, in the male cases, 13.5 days, and in the female cases, 15.5 days. The average number of days in hospital was, for males, 27.6 days, and for females, 26.3 days. The duration prior to admission into hospital, in many of the cases, was considerable, the longest being six weeks. Pericarditis became developed in four cases,

[1] *Vide* Buffalo Medical Journal, March, 1854, vol. ix. p. 557.

[2] *Vide* A Contribution toward the Natural History of Articular Rheumatism by the Author. American Journal of the Medical Sciences, July, 1863.

and pleurisy in five cases. In a second report by Dr. Sutton of cases treated, in the same manner, in a subsequent volume of Guy's Hospital Reports, the average duration to convalescence was 9 days; and, in a third report of 25 cases in the Trans. Royal Med. Chirurg. Society, 1869, the average duration was 10 days.[1]

The illness of patients affected with rheumatism may be indefinitely prolonged by pericarditis and pleuritis. But of the cases which I analyzed in 1854, embracing five cases of endocarditis and one case of endo-pericarditis, different methods of treatment being employed, the minimum duration was 7 days, the maximum 26 days, and the average duration was a little less than of all the cases, namely, a fraction over 16 days.

A peculiarity of rheumatism is that it does not pursue a steady continuous march from the beginning to the end, but its course is often marked by notable fluctuations as regards the general and local symptoms. Not infrequently, after a few days, the affected joints are nearly free from pain, soreness, etc., the febrile movement subsides, and convalescence appears to be near at hand, when suddenly, the local manifestations and the pyrexia are renewed with perhaps as much or even more intensity than before. This may occur repeatedly during the career of the disease.

Pathological Character.—In view of the number of parts in which the local manifestations are often seated, the apparent migration of the inflammation from part to part, and more especially the law of parallelism as regards the arthritic affections, it is a reasonable supposition that the pathology of the disease involves a morbid principle in the blood. This principle is not, as has been supposed, uric acid; an analysis of the blood in forty typical cases of rheumatism, by Garrod, failed to show its presence in larger quantity than exists in health, whereas in gout a morbid quantity is demonstrable.[2] A more probable supposition is that which originated with Prout, namely, that the morbid principle is lactic acid, and that this *materies morbi*, circulating with the blood, acts upon certain parts and gives rise to the local manifestations of the disease. The lactic acid theory receives support from the occurrence, in repeated instances, of articular rheumatism in cases of diabetes treated with this acid. Efforts to demonstrate the correctness of this theory have thus far failed. Assuming the correctness of the theory, it remains to ascertain on what depends the abnormal accumulation of lactic acid in the blood. The latter is an effect of conditions or processes of which we have no positive knowledge.

Causation.—Rheumatism is one of the diseases supposed to be frequently, if not generally, caused by suppression of the functions of the skin, and attributed especially to the action of cold upon the surface of the body. This view of the causation has but little foundation. It is true that patients are apt to refer the disease to cold, but they often fix upon some particular exposure under the belief that this agency is of course involved, for it is a popular notion that rheumatism generally proceeds from cold. A careful interrogation will show in many, if not most, cases, that the statement has little to support it. And how often is exposure to cold not followed by rheumatism! That the causation may involve the agency of cold is not to be denied *in toto*, but the considerations which are to follow render it probable that cold acts only as an exciting cause.

[1] In Dr. Sutton's communications there is no reference to my report in the Amer. Journ. of the Med. Sciences, 1863.

[2] On Gout and Rheumatic Gout. London, 1877.

A special predisposition is requisite; in other words, the disease involves a rheumatic diathesis. This predisposition or diathesis may be congenital and inherited, or it may be acquired. There are persons congenitally prone to the disease. This is shown by the occurrence of the disease in early life, and by its recurrence more or less frequently in the majority of the persons who are once attacked by it. Statistics establish conclusively the hereditary transmission of the disease. It is a matter of common observation that the disease prevails among the different members of certain families. Age has a decided influence in the causation. It occurs very rarely under the age of five years. It may, however, occur in infancy. I have met with a case in which it occurred at one year of age, aortic lesions and hypertrophy of the heart existing at the age of two years. In the majority of the cases of a primary attack, patients are between fifteen and thirty years of age. If a person have not experienced one or more attacks before the age last named, the liability to the disease diminishes afterward, and becomes quite small after fifty. The number of males attacked by this disease exceeds the number of females, but the difference is not great. External influences pertaining to season play a small part in the causation. The disease prevails most in humid, changeable climates. It is a disease of frequent occurrence in all climates within the temperate zone, but is comparatively rare in tropical and frigid latitudes.

These statements express briefly the sum of what is actually known with respect to the causation. In the existing state of knowledge we are alike ignorant of the special perversion in which consists the essential pathology of the disease, and of the special agencies upon which these perversions depend.

Diagnosis.—The disease is to be discriminated from gout. For the differential points the reader is referred to the chapter treating of the latter disease. In general, the diagnostic features of acute articular rheumatism are so obvious that the disease is at once recognized. The chief difficulty in diagnosis, exclusive of the discrimination from gout, relates to cases in which the rheumatic affection is confined to a single joint. The problem, in these cases, is to distinguish rheumatism from a purely local affection of the joint, that is, *synovitis*, or *simple acute arthritis*. The following are the points in this differential diagnosis: The fixedness of the inflammation in a single joint, from the first, in the latter, whereas in articular rheumatism it is rare that the mobility of the disease is not to some extent manifested. The existence of pyrexia in some cases of articular rheumatism prior to the affection of the joint. The want of correspondence between the degree of pyrexia and the local phenomena in rheumatic cases. The longer duration of the local affection in cases not rheumatic, and, in certain cases, the swelling and redness being greater than in rheumatic cases. The rapid disappearance of the local affection, often, in cases of rheumatism, and the speedy recovery of the use of the affected joint, the disappearance and recovery being more slow in cases not rheumatic. The occurrence of endocarditis or pericarditis in a certain proportion of rheumatic cases. The age of the patient and the previous occurrence of rheumatism are points to be taken into account.

Cases of pyæmia in which a purulent effusion takes place into certain joints, are sometimes mistaken for cases of rheumatism. Attention to the antecedent and concomitant circumstances should prevent this error. Purulent collections within the joints in cases of puerperal fever are embraced in this category. The so-called gonorrhœal rheumatism is generally monarthritic, and the association with gonorrhœa or gleet points to the character of the affection.

Prognosis.—This disease is very rarely fatal; the immediate danger to life is small. When death takes place during the career of the disease, it is due to complications, including under this head pericarditis. But the majority of cases in which pericarditis occurs do not end fatally. Active delirium, convulsions, and coma denote imminent danger, but it has been seen that these are extremely infrequent events. Pulmonary complications may prove serious. A source of danger, in some instances, is intense hyperpyrexia.

The disease, aside from the complications just referred to, and the suffering attending it, is serious in view of the liability to endocarditis which may lay the foundation for incurable and grave lesions of the heart. The immediate danger from rheumatic endocarditis is slight; the lesions resulting from this affection rarely occasion inconvenience until after the lapse of several years. Grave cardiac lesions do not invariably follow rheumatic endocarditis, and in some cases there remains no evidence of any permanent injury from that disease. An endocardial murmur sometimes disappears. Ulcerative endocarditis is an occasional event, giving rise to pyæmia.

The liability to embolism is to be mentioned. Emboli may be derived from the left side of the heart, consisting of fibrinous masses formed in connection with endocarditis; or a clot may form in the right side of the heart, and cause plugging of the pulmonary artery. Sudden death during the course of acute rheumatism is sometimes caused by pulmonary embolism. An example has fallen under my observation. The patient, a robust man, aged about 50, was apparently convalescing from a mild attack of rheumatism. He had been treated with alkalies and opium. There was no evidence of endocarditis. Suddenly, in the evening, he was seized with acute pain in the chest, followed by febrile movement. The pain was relieved by an opiate. On the following morning he suddenly complained of a sense of suffocation and said he was dying. Death took place in a few minutes after this sudden change. On examination after death, the pulmonary artery was found to be plugged with a firm black clot. The heart was free from disease. The lower lobe of one of the lungs was in the first stage of pneumonitis. Nothing was found to account for the sudden death except the pulmonary embolism. Other instances of this accident have been reported.

Acute articular rheumatism seldom ends in the chronic affection.

Treatment.—There are few diseases in the nosology, the treatment of which, during the last half century, has undergone such mutations as that of acute articular rheumatism. Among the measures more or less in vogue during the period just named are the following: Bleeding, general and local, mercurialization, colchicum carried to the extent of producing vomiting and purging, nitrate of potassa, an ounce or more given daily, opium in large doses, large doses of quinia, and the use of the veratrum viride. Cases in which reliance has been chiefly placed on each of these measures, have pursued a favorable course, and the treatment has seemed to be successful. Want of knowledge of the natural history of the disease, that is, the history based on the observation of cases in which the disease has been allowed to pursue its course under favorable hygienic circumstances, uninfluenced by therapeutical interference, has heretofore rendered it difficult to judge of the effect of different methods of treatment. My report of 13 cases, and the report by Dr. Sutton of a larger number, treated with only palliative remedies, show an intrinsic tendency in the disease to end within a shorter period, and a less degree of liability to complications than have been hitherto generally supposed. Hence, it may be reasonably concluded that the influence of different methods of treatment over the duration of the disease and the occur-

rence of complications, has been much over-estimated. Each of the measures above enumerated probably is, to a certain extent, useful in certain cases, but a special controlling influence over the disease is exerted by none, and clinical observation has shown the development of endocarditis, pericarditis, and other complications, under treatment by each of them. It is not worth while, therefore, to discuss their merits and demerits severally, inasmuch as few, if any, practitioners now rely upon any one of them.

Of late years the practitioners of this country have generally adopted the alkaline treatment, first systematically employed by Wright in 1847, and afterward, on a larger scale, by Garrod and Fuller. The bicarbonate of potassa, the bicarbonate of soda, and the tartrate of potassa and soda, are the remedies usually employed. Garrod's report of fifty cases treated with alkalies largely given, showed an average duration of six or seven days; and in no case, after the patient had been under the influence of this treatment for forty-eight hours, was any affection of the heart developed. It would, however, be an erroneous inference that cardiac complications never occur after the patient is fairly under the influence of this treatment. I have notes of several cases in which pericarditis was developed when alkalies had been freely given, the urine having been rendered alkaline. But that the liability to these complications is lessened by this treatment must be admitted. Moreover, this treatment seems to exert some influence in abridging the duration of the disease. Fuller claimed for the alkaline treatment, efficiently pursued, the power of lessening the febrile movement, relieving the arthritic inflammation, abridging the duration of the disease, and preventing endocarditis and pericarditis. With reference to the latter, which is manifestly the great object of treatment, he stated in 1862, that his experience embraced, up to that time, one hundred and ninety-four cases, and that "in no single instance has any heart affection occurred after the patient has been under treatment for twenty-four hours." The analysis by Dickinson of cases treated with alkalies and of cases treated by different remedies, affords conclusive evidence of the usefulness of the alkaline treatment as regards diminishing the liability to cardiac complications. His statistics show that a "partial alkaline treatment" is useless. To be effectual the alkalies must be given sufficiently to render the urine alkaline.[1]

To secure as quickly as possible protection against cardiac affections, the alkali selected should be given at once in large doses and repeated at short intervals until the urine gives an alkaline reaction. From one to two drachms of the bicarbonate of either potassa or soda may be given every three or four hours. To render it more grateful to the palate and stomach, citric acid or lemon-juice may be added to each dose which is to be taken during effervescence. This quantity is generally well borne, and the urine, as a rule, is rendered alkaline in twenty-four hours. I have given, without inconvenience to the patient, the dose just stated, every two hours, and produced alkalinity of the urine in twelve hours. The quantity of the alkaline remedy should be much diminished as soon as the urine is alkaline, the doses afterward being repeated once or twice only in the twenty-four hours. To secure more diuretic effect than is produced by the alkaline remedy alone, the acetate, nitrate, or bitartrate of potassa, the acetate of ammonia, or small doses of colchicum, may be added. The tartrate of potassa and soda, which is much used as an alkaline remedy in this disease, is inferior to the bicarbonate of potassa or soda, because it must be given for a longer period before alkalinity of the urine is produced. It is well adapted to maintain an alkaline condi-

[1] *Vide* article by Dr. Wm. H. Dickinson in Trans. Med. and Chirurg. Society, 1862.

tion of the urine, after this condition has been produced by the bicarbonate of potassa or soda.

An important late discovery is that acute rheumatism may be controlled by salicin and by salicylic acid. Dr. Maclagan communicated the discovery as regards salicin in 1876. The salicylic acid was subsequently found to have a similar controlling influence over the disease, and it is now generally used in this country. Either remedy, to prove effective, must be given in large doses, the quantity required, as a rule, being proportionate to the intensity of the symptoms. A medium dose of salicin is fifteen grains repeated every three or four hours. Success, however, is more sure with doses of from twenty to thirty grains, repeated every two hours, and, in very severe cases, even hourly. The remedy is to be given in these doses until the pain is relieved and the pyrexia diminished. This result generally follows in from twenty-four to forty-eight hours. Twenty grains every two hours may be continued until there is complete apyrexia, and afterward smaller doses for a week or longer. The treatment with large doses is to be resumed whenever the pyrexia and acute arthritic symptoms return. The salicylic acid is usually given in the form of the salicylate of soda, the dose being a scruple or more, repeated every two, three, or four hours, according to the severity of the disease.

The salicylic acid in these doses is apt to irritate the throat and stomach. It has, in some instances, produced alarming toxical effects and even death.[1] These facts render salicin preferable. No such effects have been observed to follow the latter remedy, and its controlling influence over the disease is probably not less than that of the salicylic acid.

These remedies should not supersede the full alkaline treatment. My own observations have led to the conclusion that the treatment with salicin or salicylic acid is not protective against the cardiac complications, except by arresting or shortening the duration of the disease; hence, in order to prevent these complications, alkalies should be given not less promptly and freely, together with these remedies, than before the introduction of the latter.

Intense hyperpyrexia claims more prompt and efficient treatment than that by salicin or salicylic acid. The antipyretic measures employed in other fevers are indicated, namely, large doses of quinia and cold sponging or the wet sheet. The arthritic affections do not contra-indicate these measures. The following case is cited in illustration of their efficacy: A young woman was attacked with acute rheumatism in the seventh month of pregnancy. A mitral systolic murmur denoted endocarditis. The axillary temperature rose to 109° Fahr. She miscarried, the labor being brief and easy. She was treated with quinia in large doses, alkalies, and sponging the whole body with cold water. The latter was employed constantly during the hyperpyrexia. These measures proved efficient, and the patient recovered.

The palliative treatment embraces opiates or other anodynes for the relief of pain, restlessness, and inability to sleep. Thirst may be relieved by the free use of water or lemonade. Lemon-juice given in large quantity is one of the remedies for this disease in vogue within late years. It is, in fact, an alkaline remedy, but, taken in sufficient quantity to render the urine alkaline, the stomach often rebels against it, and the alkaline carbonates are to be preferred.

The affected joints claim local measures of treatment. The application of cloths saturated with an alkaline and opiate solution, as recommended by Fuller, is useful. Fuller's solution consists of from four to six drachms of

[1] *Vide* American Journal of the Medical Sciences, July, 1880, p. 296.

the carbonate of soda or potassa, dissolved in a mixture of an ounce of Battley's solution (for which laudanum may be substituted), two ounces of glycerine, and nine ounces of rose-water. The soap and opium liniment is a good local application. A liniment containing chloroform has been found useful. I have found the tincture of aconite applied to the parts to afford marked relief. Some practitioners prefer to envelop the joints with dry flannel or cotton. In the choice of local applications, the sensations of the patient may serve as a guide. Extension of the limbs by means of an apparatus for that purpose, or simply a cord, pulley, and weight, in order to diminish the pressure of the articulated surfaces upon each other, affords marked relief. The application of pasteboard splints, lined with cotton, and confined by a firm bandage, has been found not only to relieve pain, but to promote the disappearance of the inflammation. Any measure which has the latter effect lessens the pyrexia, for, assuming the disease to be an essential fever, the pyrexia is, in part, symptomatic of the arthritis. Cold applications to the affected joints, and even the ice-bag, are recommended by German authors. Kunze recommends the subcutaneous injection of a two per cent. carbolic acid solution as highly effective in diminishing pain and the other inflammatory symptoms. He injects a quantity contained in a hypodermic syringe twice or thrice in the neighborhood of two or three of the affected joints. He states that often after the relief procured by this measure the local symptoms do not return. He considers this measure as a useful auxiliary to the treatment with salicin or salicylic acid.[1] Much relief is afforded, in some cases, by what may be termed methodic friction. Using some lubricating embrocation, the friction at first over the affected joints, if they be extremely tender, must be as light as possible to avoid giving pain. The force of the friction, however, may be gradually increased, until, at length, the patient is sometimes able to bear without suffering as much pressure as can conveniently be made. Methodic friction, gradually increased up to as much pressure with the hands as can be borne without pain, leaves the affected joints more comfortable for several hours, and the operation may be repeated once or twice daily.

The treatment of rheumatic endocarditis and pericarditis has been already considered. Pleuritis and pneumonitis are to be treated according to the indications in individual cases, as when they occur in other pathological connections. The indications pertaining to active delirium, convulsions, and coma are derived from the pathological conditions with which these events may be associated, namely, either cerebral meningitis or uræmia.

A plan of treatment advocated by a French physician, Dechilly, and revived by Davies, of London, consists in the application of several large blisters near the affected joints. The flow of serum is to be promoted after the removal of the blisters, by linseed-meal poultices. In one of the cases reported by Davies, it was calculated that the amount of surface blistered was 296½ square inches. Davies claims that this local treatment should supersede other measures. The cases reported by him, however, do not show that this treatment has any controlling influence over the disease, and it is not to be recommended.

Da Costa has reported 30 cases treated with the bromide of ammonium in doses of from fifteen to twenty grains every three hours. Of these cases, in 23 there was no cardiac complication when this treatment was commenced, and in none of the 23 cases was any cardiac complication subsequently developed. The mean duration of the disease was 22.5 days.[2] Senator has

[1] Lehrbuch der practischen Medicin, 1878.
[2] *Vide* Penn. Hospital Reports, vol. ii., 1869.

made some observations on the treatment with benzoic acid. Giving from two and a half to three drachms of the acid, or from three to nearly four drachms of the benzoate of soda, during the twenty-four hours, the disease was apparently shortened. This result I have observed in a few cases. Its efficacy is vastly inferior to salicin and salicylic acid. Trimethylamine, employed largely in this disease by Arvenarius, of St. Petersburg, a quarter of a century ago, has more recently been employed with success by Lagrange and Dujardin-Beaumetz, in France.[1]

Subacute and Chronic Articular Rheumatism.

The terms subacute and chronic rheumatism are applied, not alone to cases having the distinctive features of the disease just considered, save acuteness, but to affections resembling articular rheumatism only in their situations, and also to persistent pains in different parts of the body, supposed to involve a rheumatic diathesis. I shall notice, under this heading, true articular rheumatism in so mild a form as to be distinguished as subacute and chronic, involving, as there is reason to suppose, a constitutional condition, if not identical with, allied to, that in the acute disease. The affection called rheumatoid arthritis will be noticed after gout has been considered.

Subacute rheumatism may have all the characters of the acute disease, minus intensity. It is, then, the same disease in a mild form. There is a liability to the cardiac complications, although it is much less than when the disease is acute. The treatment is the same, with modifications which are suggested by the want of acuteness of the symptoms. The alkaline remedies are indicated as protective against cardiac complications.

Both acute and subacute articular rheumatism may end in a chronic arthritic disease. The essential constitutional affection, in these cases, may not continue, but there remains an affection of one or more of the joints previously affected. The arthritic affection is perhaps a sequel of the rheumatic disease, rather than the latter persisting in a chronic form.

In most cases of chronic rheumatism the disease is from the first subacute. It depends doubtless upon an internal determining cause. If it cannot be affirmed that this cause is identical with that in acute articular rheumatism, a relationship between the two diseases may fairly be inferred.

Cases of chronic rheumatism are frequently met with in medical practice. The patients are generally in middle or advanced life. A greater or less number of joints may be affected. The affection remains fixed in certain joints, that is, it does not shift from joint to joint, as in cases of acute rheumatism. The affected joints are tender, painful to the touch, sometimes swollen from intra-articular effusion, their temperature is more or less raised, and the surface may be reddened. Motion is painful, especially at first after periods of rest. A grating sensation and sound often accompany the first movements after these periods. The local symptoms vary much in degree at different times, and patients often observe a connection between an increase of these symptoms and certain atmospherical conditions. They often say that their sensations enable them, not only to judge of existing conditions, especially as regards moisture, but to foretell changes which are soon to take place.

Pyrexia is wanting except when there is an exacerbation as regards the local symptoms. The digestive and nutritive functions may be but little, or not at all, affected. There is no liability to cardiac complications, nor to disease of internal organs other than the heart.

The diagnosis involves discrimination from rheumatoid arthritis which will

[1] *Vide* National Dispensatory, 1879.

be considered in the next chapter. In the latter occur anatomical changes, dislocations, and distortions which do not belong to the history of chronic rheumatism. Subacute or chronic synovitis, not rheumatic, is to be excluded. The points to be considered in differentiating the latter from rheumatic arthritis are those which have been stated in connection with the diagnosis of acute articular rheumatism. Whenever chronic rheumatism has been preceded by the acute disease, this fact has, of course, an important bearing on the diagnosis.

Chronic rheumatism is devoid of immediate danger, but it persists, in many cases, indefinitely, and, in not a few instances, during life. Anchylosis of the affected joints sometimes takes place. Notable atrophy of muscles may be a result of their inaction when the disease interferes greatly with muscular movements.

In cases of chronic rheumatism, the treatment so important in the acute disease is less effective. Alkalies are comparatively of little service, and, if their use be much prolonged, they do harm. Salicin, or salicylic acid, has little controlling influence. A great variety of remedies, with reference to a constitutional effect, have had advocates. Observing proper care not to do harm by medication, trial should be made of different remedies. Of these may be mentioned the preparations of guaiacum, namely, the simple tincture, the ammoniated tincture, the mixture or the compound decoction of sarsaparilla into which guaiacum enters, the bichloride of mercury, iodide of potassium in large doses, colchicum in small or moderate doses, the hydrochlorate of ammonia, sulphur, and arsenic.

The local treatment is important. Benefit may be obtained from flying blisters or the application of the tincture of iodine. Methodic friction or shampooing, as described in connection with the acute form of the disease, and stimulating embrocations, are often of much utility. Counter-irritation by "firing" has been recommended. Palliation of pain may frequently be procured by the application of the tincture of aconite or the veratria ointment. The treatment has reference to two objects, namely, the removal of, *first*, the inflammatory condition, and, *second*, the effects of the inflammation. In order to prevent stiffness and anchylosis, passive motion is advisable as soon as the inflammatory condition subsides.

Rendering the affected joints immovable by means of pasteboard splints and bandaging should be tried. The immobility, however, should be continued for a few days only at a time, and, in the intervals, passive movements may be important to prevent anchylosis. Local douches with either cold or warm water, or with each in alternation, may prove of service. Electricity, epecially with the constant current, has been found serviceable.

External measures acting upon the entire surface are, perhaps, in certain cases, not less useful than internal remedies. Reference is had to the simple tepid bath, the alkaline bath, the Turkish bath, the sulphur vapor bath, and hydropathic packing. The resources of treatment should not be considered as exhausted without a fair trial of these measures.

Measures having reference to improvement of the general health and the invigoration of the system, form an essential part of the treatment, embracing tonic remedies, with attention to diet, clothing, exercise, etc. It is unnecessary to go into details which are essentially the same in the treatment of most chronic affections. Change from a cold, changeable, and humid climate to one mild, uniform, and dry, often proves the most effective measure which can be adopted. The mineral springs are frequently resorted to with advantage by persons suffering from chronic rheumatism. Of the different waters, the alkaline, sulphurous, saline, and chalybeate are each useful in certain cases. Doubtless, however, much of the benefit derived from watering-places is due to the various incidental hygienic influences.

CHAPTER XI.

GOUT, RHEUMATOID ARTHRITIS.

Gout—Anatomical Characters—Clinical History—Pathological Character—Causation—Diagnosis—Prognosis—Treatment. Rheumatoid Arthritis.

THE disease called gout is allied to articular rheumatism, and the two affections have been considered to be identical. As will be seen, however, they are shown to be essentially distinct forms of disease by points of contrast pertaining to morbid anatomy, clinical history, pathological character, and causation. They are kindred diseases in the same sense as the different eruptive fevers, or typhus and typhoid fever, are related to each other; gout and rheumatism may be said to belong to the same family, but each has a separate individuality. The name gout, or its synonym in different languages, is universally applied to the disease to be now considered. In its etymology the name relates to a characteristic feature of the disease, namely, a morbid deposit within and around the joints.

Gout occurs as an acute, a subacute, and a chronic affection. Writers have made other varieties, such as irregular and misplaced gout. As the subacute form is not always chronic, it is convenient to consider this form when of brief duration and the acute form under one head. The term *transient gout* will embrace the acute and subacute form, the latter ending too soon to be considered as chronic. *Persistent* or *chronic gout* will embrace all cases in which the disease is protracted.

Anatomical Characters.—The anatomical characters distinctive of this disease consist in the presence within and around certain joints, as well as sometimes in other situations, of a chalk-like deposit composed chiefly of urate of soda. Mingled with the urate of soda have been found in small quantity other salts, as urate of lime and of magnesia, and carbonate and phosphate of lime. The urate of soda is present in the form of acicular crystals, with which may be mingled amorphous, granular matter. In the majority of cases the morbid deposit occurs first in the metatarso-phalangeal articulation of one of the great toes. In the course of the disease, other joints become affected. At first the disease manifests a preference for the small joints of the foot and hand, but subsequently (and in rare cases primarily) larger joints, as the knee and elbow, become involved. The shoulder and the hip are not often affected. The urate deposit seems to form a white, chalk-like incrustation upon the free surfaces of the articular cartilages. Careful examination, however, reveals that the deposit is in the substance of the cartilage and not upon its free surface. Usually only the superficial layers of the cartilage contain the deposit, so that the part of the cartilage nearest to the bone appears normal. Upon microscopical examination are found acicular crystals arranged in little clusters which radiate from a centre. The centre of a cluster is often a cartilage-cell. The interspaces between the clusters may be free, or may contain crystals scattered irregularly. The crystals are deposited both within the spaces occupied by the cartilage-cells and in the basement substance, sometimes more in the former and sometimes more in the

latter situation. If the crystals be dissolved by the action of warm water or of weak alkaline solutions, the cartilage is often found to present an entirely normal appearance. The cartilage may be somewhat eroded. The urate deposit does not often induce destructive inflammatory changes in the cartilage. Cornil and Ranvier describe proliferation of the cartilage-cells as a frequent result of the deposit of the urate of soda. Garrod has shown that a single paroxysm of gout suffices to cause a certain amount of the urate deposit in the affected joint.

Concretions of urate of soda are often found in the synovial membranes and the ligaments of joints. These gouty concretions are called *tophi* or *chalk-stones*. The tophi consist of needle-shaped crystals of urate of soda, mingled with granular matter and animal substance. Their consistence is usually compared to that of mortar. The stiffness of the joints observed during life is due more to the affection of the ligaments than to the alterations of the cartilage. Fibrous anchylosis of the joints may occur. Deformities of the joints resembling those of rheumatoid arthritis may be produced by chronic gout. Tophaceous matter may be found also in the perichondrium, the periosteum, the periarticular connective tissue, the tendons and their sheaths, the spongy texture of bone, and in bursal sacs. The deposit in masses, varying in size from that of a pin's head to a split pea, not infrequently occurs in the helix of the ear. Among the rare situations for gouty deposits may be mentioned the perichondrial tissue of the larynx, the sclerotic coat of the eye and the tarsal cartilage, the outer sheaths of vessels and of nerves, the anterior surface of the dura mater of the spinal cord (Ollivier). In general those tissues are most liable to be affected which are possessed of little vascularity, but the gouty deposit has been found in such vascular structures as the skin and the muscles. Tophi, especially those seated subcutaneously, may lead to the formation of abscesses which burst and discharge pus mingled with chalky material.

Todd and Garrod have established the fact that gout is one of the causes of that form of chronic Bright's disease represented by the small granular kidney. The diseased kidney presents the gross and the microscopical changes which, in a previous part of the work, have been described as characteristic of this form of renal disease (page 877). When the small granular kidneys are the result of gout, deposits of urate of soda are always found in the renal tissue. The deposit is found chiefly in the pyramids where it appears in the form of whitish lines and points. A similar accumulation of the urate of soda may also take place in the cortical substance. The morbid deposit is found both within the tubes, and in the interstitial tissue. It may occur in the small kidneys developed independently of gout. The form of diseased kidney developed in the course of gout has been called by Todd the *gouty kidney*. Litten and Cohnheim have observed the presence of waxy degeneration in gouty kidneys. Concretions of urate of soda have been found in the renal calices and pelvis.

It has been shown by Garrod, that the blood in gout contains an excess of uric acid, which is present in the form of urate of soda. According to this author, no appreciable amount of uric acid is present in the intervals between the early attacks of gout, but in chronic gout the blood is rich in uric acid, even during the intervals between the paroxysms. The accumulation of uric acid in the blood constitutes the condition called *uricæmia* or *lithæmia*, which has been considered in Part First of this work (page 79).

A great variety of morbid conditions, besides those mentioned, have been attributed by some writers to the influence of gout. Thus it has been thought that gout predisposes to atheroma of the arteries, to aneurism, to the formation of renal calculus, to cystitis, to bronchitis, to gastritis, to diabetes mellitus,

and to various cutaneous diseases, especially psoriasis and eczema. It is doubtful to what extent the gouty diathesis is causative of these and other affections which may occur in gouty individuals.

Clinical History.—Transient gout and persistent gout require separate consideration as regards their clinical history. Having considered these forms of the disease, I shall notice irregular and misplaced gout.

Transient Gout.—Under this head are to be embraced all cases in which the disease is of short duration, that is, the duration not sufficiently prolonged for the disease to be regarded as chronic. In this form of the disease the patient is said to have an attack or fit of gout. The disease is generally acute, but sometimes subacute.

The seizure is generally sudden, occurring, as a rule, during the night, and, in the majority of cases, after midnight. In a certain proportion of cases the seizure occurs without premonitions; the patient may have retired to bed feeling as well as usual. But in some cases there are prodromic phenomena, consisting of cardialgia, gastric flatulency, eructations and other dyspeptic ailments, together with inability to exert the mental faculties, irritability of mind, and depression of spirits. These phenomena are not sufficiently significant to lead to the expectation of an attack of gout if one or more attacks have not been already experienced; but in persons who are subjects of the disease they may denote an impending seizure. Observations have shown that for several days preceding a gouty paroxysm there is a notable diminution of uric acid in the urine.

The seizure is marked by pain which, in the great majority of cases, is seated in the metatarso-phalangeal joint of one of the great toes. The pain soon becomes more or less intense; frequently it is excruciating, being compared by patients to pain caused by the gnawing of an animal, a dislocation of the bone, a nail driven into the joint, tearing of the parts with pincers, etc. Such comparisons only express intensity of suffering, for it is not to be supposed that patients have actually experienced the pain produced by the various causes mentioned. A sense of throbbing in the part accompanies the pain. More or less pyrexia is developed, preceded by shivering. These symptoms continue for several hours, and then the pain and fever subside, the patient is comparatively comfortable and obtains some sleep. The relief is usually accompanied by slight perspiration. In the mean time the affected joint becomes swollen, the skin is reddened and shining, the subcutaneous veins are distended, the heat is raised, and there is exquisite tenderness to the touch. These appearances are observed after the severe pain has abated.

In some cases a single paroxysm of severe pain only is experienced, but much oftener the seizure is renewed on the following night, and on successive nights, for a variable period. The local affection may remain in the joint affected at the first seizure, or the affection may be transferred from this joint to the corresponding joint of the opposite foot. In some cases the inner side of the foot, the instep, or the heel becomes affected, and the affection may extend to the larger joints and to the small joints of the upper extremities. This extension of the local manifestations of the disease rarely occurs until after several attacks, and it occurs more especially in cases of chronic gout. After recovery from transient gout, there is often a feeling of better general health than before its occurrence; the patient is relieved of indefinite ailments which previously existed.

During the continuance of transient gout the symptoms referable elsewhere than to the part or parts affected vary considerably in different cases. Pyrexia is more or less marked in proportion to the acuteness of the local manifestations. The fever appears to be symptomatic, and, as a rule, is less

than in cases of acute articular rheumatism. The appetite is frequently impaired or lost, but in some cases is preserved. Dyspeptic ailments are sometimes present and sometimes absent. The urine is generally scanty, high-colored, and deposits a lateritious sediment on cooling. The excretion of uric acid is lessened. The bowels are generally constipated.

Cases also differ much as regards the local symptoms. The affection may be called acute when the pain is severe, the swelling, redness, etc., marked, these local symptoms being accompanied by a corresponding amount of fever. On the other hand, the affection is subacute when the pain is notably less severe, the other local symptoms less marked, and fever either slight or wanting. In respect of the seizures of pain, occurring usually in the night-time, they are in some cases paroxysmal, the pain passing off in the day, but in other cases more or less severity of pain continues during the day as well as night; in other words, remissions occur instead of intermissions. The local symptoms gradually decline as the fit or attack passes off. Œdema of the part or parts is more or less marked at the decline of the local affection, with frequently pruritus, and, in the majority of cases, furfuraceous desquamation of the epidermis. The local symptoms just named are diagnostic of gout as contrasted with rheumatism. Cramp affecting the muscles of the leg, the thigh, and in other parts of the body, is a symptom more or less marked in a considerable number of cases.

The duration of transient gout varies from a few days to several weeks. In the majority of cases the paroxysms recur nightly for at least a week. Generally the paroxysms or exacerbations are less and less severe in proportion to the duration. If the disease continue beyond three or four weeks, it is to be considered as persistent or chronic. An attack of acute or subacute gout, more especially the latter, may eventuate in the persistent or chronic form of the disease, or, having continued for a variable period, the disease for the time ceases, recurring at longer or shorter intervals in the vast majority of cases.

Persistent or Chronic Gout.—Gout, commencing as either an acute or subacute affection, in a certain proportion of cases continues as a chronic affection for many weeks, months, and even years. Generally this persisting or chronic form of the disease is preceded by the occurrence of many transient attacks recurring after intervals which become shorter and shorter, until, at length, as it were, they run together. When the disease is persistent, it has not continuously a uniform severity, but remissions occur from time to time, and, not infrequently, intercurrent acute attacks take place.

In the persistent or chronic form, the local symptoms which characterize the acute affection, namely, intense pain, heat, and redness, are either slight or wanting. There is little or no fever. Disorders of the digestive system are often present, and the general health is more or less impaired. In this form the joints are liable to become stiffened, anchylosed, and deformed, from the abundance of the gouty deposit. Chalk-like concretions are apt to occur within and around the small joints of the hands. In some cases collections of semi-solid matter are felt near the surface, and if they be opened, the matter may be pressed out. Sometimes collections of considerable size open spontaneously. The solid concretions, or chalk-stones, sometimes make their appearance through the skin. The gouty matter may be deposited in the bursæ-mucosæ in the neighborhood of joints. In a certain proportion of cases, the number happily not large, the hands and feet become permanently distorted and crippled, the fingers sometimes presenting an appearance compared by Sydenham to a bunch of parsnips. Nodules of the deposit are frequently seen on the helix of the ear, sometimes also on the eyelids, and occasionally on the face.

In chronic, as in acute, gout, the predilection of the disease, as regards the seat of the local manifestation, is for the joints of the great toe. An affection of other joints primarily occurs in a small proportion of cases. After the great toes, the order in which parts are liable to become implicated, according to Garrod, is as follows: The heels and ankles, the knees, the smaller articulations of the hands, the elbows, and lastly the shoulders and hips. There are, however, numerous exceptions to this order of sequence. A blow, sprain, or other injury may determine the seat of the local affection. A point of difference in different cases pertains to the number of joints which become affected. In some cases the local manifestations of the disease, however long it may persist or frequently recur, remain concentrated on a few joints; in other cases a large number of joints are implicated, and, again, in some cases different joints are affected in successive attacks. If the same and a few joints be always affected, and the disease either persist or recur frequently, permanent changes in the affected joints are more likely to occur. Another point of difference, in different cases, relates to the palpable changes in the affected joints. Some gouty patients escape anchylosis and nodosities, although they suffer from the disease more or less throughout their lives, whereas, in other cases, the hands and feet become deformed and crippled after a comparatively short duration of the disease.

Irregular and Misplaced Gout.—It is an old doctrine that local manifestations of gout are liable to be seated in the different visceral organs, namely, the stomach, intestines, lungs, heart, and brain. Disorders referable to these viscera, preceding the ordinary manifestations of gout, have been considered as gouty, and it has been supposed that gouty disorders of viscera may occur without any affections of the joints either accompanying or ensuing. In such cases gout is said to be *irregular* and *misplaced. Anomalous* and *latent gout* are other terms applied to these cases. Sometimes during an attack of gout the affection of the joint or joints suddenly disappears, and symptoms denoting an affection of some internal organ supervene. In these cases a transference or metastasis of the gouty manifestations is supposed to take place, and the name *retrocedent gout* is employed to express such an occurrence. These notions are probably, in a measure, well founded, but it is difficult, with our present knowledge, to say how far they are to be accepted as correct. The difficulty consist in the inability to determine whether antecedent, co-existent, or consecutive affections, in certain cases of gout, are not associated merely by coincidence. It has doubtless been too much the custom to consider all affections occurring in persons subject to gout, as of a gouty character, and the gouty diathesis is often considered to exist on insufficient data. Making, however, due allowance for error, it can scarcely be doubted that the constitutional morbid condition which constitutes the disease in cases of gout, may determinine disorders, sometimes of a grave character, in organs more important to life than those in which the local manifestations are usually seated. Evidence of a pathological connection of these disorders with gout is afforded by complete relief following the development of a gouty affection of the joints, by their occurrence directly after a gouty affection of the joints has been apparently suppressed, by the absence of any other appreciable causes explaining their occurrence, and by the indefinite or anomalous character of the disorders.

Disorders of the stomach and intestine attributed to gout, are neuralgic pain or spasm and persistent vomiting, accompanied with more or less prostration, diarrhœa, and, in some cases, symptoms denoting enteritis. It is doubtful if inflammation of the stomach or intestinal canal be ever due exclusively to gout.

Disturbed action of the heart is not uncommon in gouty patients. It

sometimes occurs in an alarming degree, but it may be doubted if a purely functional disturbance occurring in this connection ever prove fatal. Valvular lesions and enlargement of the heart may exist in persons affected with gout, but clinical observation furnishes little or no evidence of the cardiac affections in these cases being dependent on gout. The want of a tendency to endocarditis and pericarditis is one of the points distinguishing gout from rheumatism.

Cough, asthmatic dyspnœa, and bronchitis are attributed to gout. Spasmodic affections of muscles, or cramp, in various situations, neuralgia affecting the branches of the fifth pair, the sciatic nerve and other nervous trunks, paroxysmal headache and hysteria, are to be added to the list.

Delirium and fatal coma are among the disorders imputed to gout. These symptoms may be due to uræmia, or to meningitis, which may, or may not, be dependent on gout.

The deposit of the urate of soda in the uriniferous tubes, in cases of gout, has been stated under the head of the morbid anatomy. It is not difficult to understand that this deposit may accumulate and form renal calculi. Clinical observation shows that gouty persons are prone to the formation of renal calculi and to paroxysms of pain caused by the passage of the stones along the ureter, or renal colic. The opinion of Todd and others, that the contracted kidney may be due to gout, has been referred to. The co-existence of renal disease, in certain cases, may account for the occurrence of some events which have been heretofore considered as being specially connected with gout, namely, vomiting and purging, headache, neuralgia in different situations, delirium, convulsions, and coma. The existence of renal disease is to be ascertained by means of the urinary changes which have been already considered. The urine presents the characters distinctive of the small granular kidneys. It is usually clear, abundant, and deposits but little sediment. The amount of albumen in the urine may be slight, but in some cases it is considerable. Casts are not usually abundant, and they may be absent. Slight albuminuria in the course of gout is not necessarily indicative of Bright's disease.

Cystitis and urethritis have been attributed to gout, but the existence of any special pathological connection may be doubted. This statement is also applicable to certain affections of the skin and to various affections which occur in persons subject to gout. This is not saying that the existence of the gouty diathesis is not to be taken into account in the management of all associated affections. Graves called attention to the habit of grinding the teeth as peculiar to cases of gout. The habit proceeds from an uneasy sensation in the teeth, which is in this way momentarily relieved.

Pathological Character.—The researches of Garrod show that the pathology of this disease involves a particular morbid condition of the blood, namely, an abnormal accumulation of uric acid, *uricæmia* (*lithæmia*).[1] The blood in health contains only a trace of uric acid. In 47 cases of gout, an analysis of the blood-serum by Garrod showed a notable increase of this constituent. Garrod has also shown that, during an attack of acute gout, the uric acid in the urine is notably diminished. It is apparently increased, since a deposit of the urates in more or less abundance, when the urine cools, is common; but the increase is only apparent, the deposit being due to the scanty quantity of urine. In chronic gout the quantity of uric acid excreted by the kidneys is habitually below the average in health. Garrod has found the uric acid in excess in the blood in cases of lead-poisoning.

[1] *Vide* Part I. page 79.

From the facts just stated, taken in connection with the fact of a deposit of the urate of soda taking place within or around the affected joints in all cases, it is rationally concluded that the local manifestations of gout are effects of the uricæmia. But it is evident that the uricæmia is itself an effect; the primary perversions underlie the excess of uric acid in the blood. Either this principle is produced in too great abundance, or, without being unduly produced, it accumulates as a result of insufficient excretion by the kidneys. Probably both explanations are involved. Direct observation, at all events, shows deficient excretion, since the amount in the urine is less than in health. Garrod entertains the opinion that the deposit of uric acid in the form of the urates takes place within and around the joints in consequence of diminished alkalinity of the blood.

In treating of rheumatism, it has been stated that an examination of the blood in that disease with reference to the amount of uric acid, shows this principle not to be in excess. Here is a capital point of difference between gout and rheumatism, as regards pathological character. The clinical history of gout has afforded several striking points of contrast between the two diseases; these points will be reproduced under the head of diagnosis. Other points of contrast will be presented under the head of causation. The individuality of each disease is, therefore, sufficiently established.

Causation.—Gout is a diathetic disease; the diathesis in a certain proportion of cases is congenital and inherited. It is a matter of common observation that certain families are predisposed to this disease, and it is sometimes transmitted successively through a series of generations. Scudamore's statistics showed that of 523 patients affected with gout, in 309 the disease had existed in either the parents or grandparents. Of 80 cases reported to a Commission of the French Academy, in 34 the disease had been transmitted, and Garrod states that, in the cases which he has observed, an hereditary predisposition existed in 50 per cent. The diathesis, however, is by no means invariably inherited; in a certain proportion of cases it is acquired; nor, on the other hand, is the disease always transmitted to offspring. There are causes, then, which may produce it in those in whom there is no reason to suppose a congenital predisposition, and in those predisposed by inheritance other causes may be required for its production.

A causative influence relates to age; it occurs very rarely under puberty. Of 515 cases analyzed by Scudamore, with reference to age, in only 5 did the disease occur in persons under eighteen; in 142 cases, the ages at the time of the development or first occurrence of the disease were between 20 and 30 years; in 194 cases, between 30 and 40; in 118 cases, between 40 and 50; in 38, between 50 and 60; and in only 10 cases, between 60 and 66 years. The liability thus diminishes progressively after 50, and the disease is as rare, if not more so, after 70 as before puberty. In the cases in which it commences between 20 and 30, it is generally inherited. In the causative influence relating to age is a point of contrast to rheumatism, the latter disease affecting by preference young subjects.

A very marked difference exists between the two sexes in the liability to gout. Of 80 cases submitted to the French Academy, 78 were men and only 2 women. Here is another point of difference from rheumatism, the latter occurring not less frequently in females than in males.

Dietetic and regimenal habits lead to the acquirement of the diathesis, and co-operate with a congenital predisposition in producing the disease. To the habitual use of wine or malt liquors the disease is, in many cases, chiefly attributable; on the other hand, the use of distilled spirits seems to exert no influence in its production. Gout prevails in countries in which

wine and malt liquors are largely used, whereas in countries in which the use of spirits predominates the disease is comparatively rare. It is comparatively rare in Scotland, Russia, Poland, Denmark, and in this country, probably in a great measure for the reason just stated. It is proverbially prevalent among those of the opulent class of society who are addicted to luxurious habits. But doubtless the habitual indulgence in the pleasures of the table, exclusive of the use of fermented liquors, contributes largely, in this class, to the production of the disease. Physical indolence also enters into the causation. The agency of malt liquors alone is strikingly shown by the frequent occurrence of the disease among a class of laborers in London employed to raise ballast from the bottom of the Thames who are accustomed to drink from two to three gallons of porter daily. According to Budd, gout is quite common among this class. The lighter wines are less likely to produce the disease than the stronger varieties, namely, sherry, madeira, port, and the same holds true of malt liquors. There is no reason to suppose that cider tends to produce it. It is evident from the facts just stated that the causative agent in fermented liquors is not alcohol. Ascribing to the use of wine and malt liquors, to high living in other respects, and to indulgence in luxurious ease, a due causative influence, the disease is sometimes developed irrespective of these causes. Examples are occasionally met with among laborers accustomed to a plain diet, and neither wine nor beer drinkers. My clinical records contain notes of several such cases. Gout developed in individuals of the poorer classes often pursues an atypical course; the acute paroxysms may be absent.

Various causes may determine the occurrence of an attack of gout, that is, they may act as exciting causes. Attacks are sometimes attributable to prolonged intellectual exertion, anxiety of mind, bodily fatigue, exposure to cold, acts of excessive indulgence in eating or drinking, etc. But in not a few instances the disease occurs without any appreciable exciting cause. The disease is rarer in tropical than in temperate climates. Attacks are more likely to occur in the spring and autumn than at other seasons of the year. Garrod adduces facts which show that impregnation of the system with lead is among the causative agencies. Of 51 male hospital patients, 16 were either painters, plumbers, or workers in lead. This connection has been noted by other observers. The fact that in cases of lead-poisoning the uric acid is found in excess in the blood has already been stated.

Diagnosis.—The difficulties in the way of the diagnosis of gout relate to its discrimination from rheumatism and the affection called rheumatoid arthritis. The distinctive features of the latter will be presented in treating of that affection, and the differential diagnosis of gout and rheumatism only will be here considered. The points involved in this differential diagnosis embrace facts relating to anatomical characters, clinical history, pathological character, and causation, which have been presented under these respective heads.

Distinctive Features relating to Anatomical Characters. — Under this head, reference is had to the morbid changes within and around the affected joints. A distinctive anatomical change in gout is the deposit of a morbid product abounding in the urate of soda, the gouty or tophaceous matter, either in collections of a semi-solid consistence, or in hard concretions commonly called chalk-stones. These are never present in rheumatism, and are pathognomonic of gout. The deposit, however, in a situation and in sufficient quantity to be ascertained during life, occurs in only a certain proportion of cases, and chiefly in chronic gout.

Distinctive Features relating to Clinical History.—In the great majority of cases, the primary local affection is seated in the metatarso-phalangeal

joint of one of the great toes. The larger joints are affected subsequently, if at all. The local manifestations tend to the smaller joints of the toes and hands. In acute cases, the pain is more intense than in acute rheumatism, and the tenderness greater. Pain occurs in paroxysms or in marked exacerbations. Œdema, pruritus, desquamation of the cuticle, and enlargement of the veins, are distinctive of gout. Febrile movement is less marked than in acute rheumatism, and is apparently symptomatic, whereas in rheumatism the fever is essential as well as symptomatic. Endocarditis and pericarditis are very rarely, if ever, developed in the course of the disease. The deposit of small collections of the urate of soda on the helix of the ear is of frequent occurrence in cases of gout, and will serve to establish the diagnosis. They should always be sought for.

Distinctive Features relating to Pathological Character.—The uric acid in the blood is morbidly increased. This may be ascertained by obtaining serum either from a small quantity of blood, or by means of a small blister, and resorting to what Garrod calls the "uric acid thread experiment." The mode of performing this experiment, as described by Garrod, is as follows: "Take from one to two fluidrachms of the serum of the blood, and put it into a flattened glass dish or capsule; to this add ordinary strong acetic acid in the proportion of six minims to each fluidrachm of serum, which causes the evolution of a few bubbles of gas. When the fluids are well mixed, introduce one or two ultimate fibres, about an inch in length, from a piece of unwashed linen fabric, which should be depressed by means of a small rod, as a probe or point of a pencil. The glass should then be set aside in a cool place, until the serum is quite set and almost dry. Should uric acid be present in the serum above a small amount, it will crystallize and during its crystallization will be attracted to the thread, and assume forms not unlike those presented by sugar-candy upon a string. To observe this, the glass containing the dried serum should be placed under a linear magnifying power of about fifty or sixty, procured with an inch object-glass and low eye-piece, or a single lens of one-sixth of an inch focus answers perfectly. To insure perfect success, the glasses should be broad and flat; the acetic acid should be neither very strong nor too weak; the glass should not be disturbed during the drying of the serum; the temperature should be that of an ordinary sitting-room, and the glass should be protected from dust."[1]

For a diagnosis the thread experiment, according to Garrod, suffices. Crystals of uric acid do not form and adhere to the thread in the blood-serum of health. The uric acid of the blood is not morbidly increased in rheumatism.

Distinctive Features Relating to Causation.—Gout occurs very rarely under puberty, and chiefly between thirty and fifty years of age. Rheumatism affects especially young subjects. Gout is oftener hereditary than rheumatism. It rarely affects women. The use of fermented liquors, and habits of luxury as regards diet and exercise, exert an agency in producing gout, not exerted to the same extent in the causation of rheumatism. The poorer classes are as liable to rheumatism as the rich, if not more so; the reverse is true of gout.

To determine the existence of the diathesis prior to the arthritic manifestations of the disease, and to recognize the irregular or misplaced manifestations of gout, are objects of diagnosis involving not a little difficulty and doubt. Certain symptoms should excite strong suspicion of the constitutional gouty condition, if occurring within the periods of life most favorable for the development of the disease, and in a person of a gouty family, and whose

[1] This account from Garrod's work is somewhat condensed by the author.

habits of life are calculated to co-operate with an innate predisposition. The symptoms referred to are those which belong to dyspepsia, with a scanty secretion of urine which deposits the urates, and the liability to gravel or attacks of renal colic. If, with these symptoms, an examination of the blood-serum show a morbid excess of uric acid, the development of an attack of gout may be predicted with considerable confidence. The diagnosis of disorders of internal organs, imputed to gout, or to use a term which has been applied to these cases, of "visceral gout," must rest mainly on their occurrence in proximity to attacks of gout, either preceding, accompanying, or following the sudden cessation of well-marked gouty manifestations.

Prognosis.—The immediate danger to life from gout is slight. If it ever *per se* prove fatal, it is by its irregular or so-called misplaced manifestations; and in many, if not most, of the cases in which death is imputed to gouty affections of vital organs, it is probable, as already intimated, that these affections do not strictly belong to gout, but are to be regarded as co-existing or intercurrent affections. The prognosis becomes grave if the small granular kidney be developed in the course of gout. It is an error to suppose that gout is salutary as regards the duration of life. Frequently recurring attacks of transient gout, and the persistence of the disease in a chronic form, impair the constitutional powers, diminish the ability of the system to resist other diseases, and thus shorten life. It is a serious disease in certain chronic cases in which it leads to deformity and rigidity of the affected joints. It has been a favorite notion that the liability to gout lessens the liability to other diseases. There is little foundation for this notion, and, on the contrary, there is ground for the belief that, if gout do not tend to produce other diseases, it favors their inroads upon the system.

A tendency to recurrence is a law of the disease. It is extremely rare for a single attack only to occur. If life be not cut off by some other disease, frequent attacks are almost invariably experienced, and the disease may become chronic. The diathesis is thus rarely if ever extinguished.

Treatment.—Various therapeutical measures heretofore considered as having a curative influence over gout are now rarely employed. Their disuse has resulted from the clinical study of their effects and improved pathological views. Among the measures referred to are embraced blood-letting, emetics, mercurialization, and continued or often-repeated purgation. These measures are now regarded as contra-indicated in both the transient and the persistent form of gout. Other measures, long more or less in vogue, are still prized in the treatment of this disease. In the latter list are colchicum and alkaline remedies. The indications for treatment during attacks of transient gout, during the intervals between these attacks, and in cases of persistent or chronic gout, respectively claim separate consideration.

Treatment during attacks of Transient Gout.—The great Sydenham, himself for more than thirty years a sufferer from this disease, was led to conclude that an attack should not be interfered with. Regarding it as an effort of nature to get rid of a noxious material, he believed it to be undesirable to arrest or abridge it. The propriety of non-interference was also advocated by Trousseau. Few physicians, however, would feel satisfied to fold their hands and await the cessation of the disease, and still fewer patients would be content to forego measures to alleviate their sufferings. Nor is this line of conduct consistent with either reason or experience. Transient gout is a self-limited affection. It is probably rarely, if ever, arrested, and it might not be advisable to arrest it were this practicable. Perhaps its duration is not often abridged by therapeutical interference; but its severity may be

lessened, and the suffering connected with it may be materially mitigated by measures which, if judiciously employed, will not do harm. This is a mild expression of the resources of medicine in cases of transient gout.

Colchicum is an ancient remedy for gout, assuming the hermodactylus of the Grecian and Arabian physicians to have been this drug. It has been not less prized by the majority of physicians in modern times. Most, if not all, of the various secret nostrums for gout which have commended themselves to popular favor, owe their efficacy chiefly to this remedy. Its special power of controlling the inflammatory phenomena of the disease is undoubted. Our knowledge of the value of this remedy is derived wholly from experience. Its special mode of operation cannot be explained. A rational object of treatment, deduced from the pathological character of gout, so far as it is at present known, is the elimination of uric acid; but the researches of Garrod show that this remedy does not increase the amount of uric acid excreted by the kidneys, nor does it in all cases increase the quantity of urine. It may be here added that other rational objects of treatment are, prevention of an undue formation of uric acid or its undue accumulation in the blood, and neutralization of this acid, or keeping it in a state of solution in the blood until it is eliminated through some of the natural emunctories.

In an acute attack of gout, colchicum may be given at first in a tolerably full dose, that is, from half a drachm to a drachm of the wine, or an equivalent dose of the tincture or acetic extract. It should afterward be continued in small doses. It is never judicious to carry its use to the extent of producing vomiting or purging. Carried to this extent, it is objectionable on account of its depressing influence, although relief of the gouty inflammation be procured. Its special influence is independent of its operation as an emetic or a cathartic. An emetic of any kind is not indicated, unless the attack occur shortly after a full meal and there be reason to suppose that the stomach is overloaded with undigested food. If constipation exist, a free evacuation by means of a saline purgative is desirable. A saline purgative is also appropriate as a depletory measure if the patient be robust or of a full habit, and the fever be high. The purgation should be effected by salines rather than by the colchicum.

Alkaline remedies are rationally indicated with a view of promoting the solubility of uric acid. For this end, the salts of potassa are to be preferred to those of soda, the urate of potassa being more soluble than the urate of soda. Moreover, the salts of potassa have a diuretic action, and thus contribute to another rational object of treatment, namely, the elimination of uric acid by the kidneys. The bicarbonate of potassa may be selected, and the acetate and the bitartrate are appropriate. The alkaline remedy may be given in conjunction with the colchicum. The phosphate of ammonia was introduced as a remedy in gout some years since by Buckler, of Baltimore, its efficacy being supposed to consist in its forming a soluble salt readily eliminated, by the combination of uric acid and ammonia, the phosphoric acid combining with the soda and forming another soluble salt. Ten grains may be given three or four times daily. This remedy, however, is better suited to the chronic form of the disease, or to the intervals between attacks of transient gout. This remark will also apply to the benzoic acid supposed to be useful by converting the uric into hippuric acid.

The carbonate of lithia, introduced as a remedy by Garrod, has proved to be of much value.[1] The urate of lithia is highly soluble, and the remedy, in small doses, acts efficiently as a diuretic. It is a remedy which produces no

[1] This remedy was suggested as a remedy for gout, on theoretical grounds, by Buckler, in 1853. *Op. cit.*

unpleasant consequences, although continued for a considerable period. It may be given in five-grain doses three times daily. An efficient and agreeable mode of administration is to give it largely diluted in carbonated water. The citrate of lithia has the advantage of greater solubility in water than the carbonate. This remedy, as well as other remedies given to favor the solubility of uric acid in the blood and promote its elimination, is to be considered as an adjunct to colchicum.

During the paroxysms of pain, opiates may be given moderately if well borne. If they occasion unpleasant effects, the succedanea of opium must be relied upon, namely, hyoscyamus, belladonna and aconite. From its action upon the skin, the Dover's powder is an eligible form of opiate. The inconveniences of opium given by the mouth may sometimes be avoided by the hypodermic method of administration.

As regards local treatment, the affected joints may be covered with cotton, over which oiled silk should be applied. In addition, relief is sometimes afforded by applications containing opium, belladonna, or aconite, singly or combined. Chloroform as a local application has been recommended. Trousseau recommended highly tobacco fumigations, not during the paroxysms, but in the intermissions, with a view to diminish the suffering when the pain returns.

The diet for a few days should be considerably restricted, animal food being excluded. Should the attack continue, however, it is important, as in other diseases, to provide against the evils of innutrition. A nutritious but unstimulating diet should be directed, embracing milk, farinaceous articles, eggs, fowl, and fish. Without having any data for recommendation, two methods of treatment, quite opposite in character, may be mentioned. One of these, the "hot water cure," consists in taking from six to seven ounces of water as hot as can be borne every quarter of an hour, until forty-eight potions have been taken, the patient having the previous evening taken only soup, and after the potions of hot water on that day only soup. If one trial of this method prove not completely successful, it may be repeated after some days, only half the previous quantity of hot water being taken. It is stated that this method is not without danger. The other method is called the "dry biscuit cure." It consists in abstaining absolutely from liquid of any kind for five or six days.[1]

Treatment in the intervals between attacks of Transient Gout.—The ends of treatment between the attacks are, the prevention of the recurrence of the disease, the prolongation of the intervals, and the diminution of the severity of attacks. The immediate rational objects are, prevention of the undue production of uric acid, its elimination by the natural emunctories, and the promotion of its solubility in the blood. With reference to the two latter objects, it is to be borne in mind that the uric acid is probably accumulating in the blood for some time before gouty manifestations occur, and that probably the deposit of the urates within and around joints precedes, for a greater or less period, the inflammatory phenomena which belong to an attack or fit of the gout.

Removal of the known causes of gout is an essential part of the treatment. Wine and malt liquors, especially the stronger kinds, are to be interdicted. If the use of alcoholics be desirable or allowable, spirits should be substituted. Gin is to be preferred from its diuretic tendency. The diet should be plain, wholesome, and restricted to an amount required for nutrition. A certain amount of bodily exercise is an important part of the hygienic management. Travelling, a long sea-voyage, and a sojourn in a tropical climate,

[1] Kunze's Lehrbuch der praktischen Medicin.

are in some cases advisable. All exciting causes are, as far as practicable, to be avoided.

If dyspeptic or other symptoms render it probable that an attack is impending, remedies with a view to prophylaxis are indicated. Alkalies should be given in small doses, largely diluted. They should be continued for a short time, then intermitted, and afterward resumed if the indications continue or return. The salts of potassa are to be preferred to those of soda. The carbonate of lithia may also be given. If the near approach of an attack be strongly suspected, colchicum in small doses may be resorted to. There is reason to believe that this remedy sometimes wards off an impending attack.

These remarks have reference to the treatment directed especially to gout. Disorders of any kind, not of a gouty character, of course claim appropriate treatment.

Treatment of Persistent or Chronic Gout.—The removal of causes which produce or promote the gouty diathesis, and of exciting causes, ranks first in importance. This is a *sine qua non* in the treatment. In addition, in obstinate cases, when circumstances permit, travelling, a sea-voyage, and residence in a tropical climate, may be recommended as likely to effect a salutary constitutional change. Hygienic is doubtless vastly more important than medicinal treatment, but remedies are undoubtedly of much utility.

Alkalies, the carbonate of lithia, and other diuretics are indicated precisely as in the intervals between attacks of transient gout, when the symptoms denote an impending attack. It is important to bear in mind the injunction to give alkaline remedies in small doses, largely diluted, and to intermit their use after they have been continued for a short time. This injunction is also applicable to the carbonate of lithia and other diuretic remedies. Exacerbations of the disease, which are liable to occur from time to time, may be treated with colchicum in small doses, its effects upon the alimentary canal and circulation being carefully watched. Other remedies, of the value of which, in certain cases, there is abundance of testimony, are the iodide of potassium, guaiacum, and the phosphate of ammonia. Perhaps the benzoic acid is to be added. Fraxinus (European Ash) is said to have efficacy, "administered in an infusion with thirty grains of the leaves in half a pint of water, strained and sweetened, and taken twice or thrice daily."[1]

The diet should never be inadequate to nutrition, either as regards quantity, kind, or variety. The body should be well nourished, but highly seasoned dishes and indigestible articles are to be interdicted. A diet consisting of a large proportion of farinaceous food, is theoretically indicated, and is advisable on the basis of clinical experience. Patients are sometimes exempt from the disease under a milk diet, or a farinaceous diet into which milk enters more or less largely. Pure water should be taken freely, especially whenever there are gouty premonitions, in order to hold in solution, in the blood, the uric acid, and to promote its elimination. The sparkling table-waters are apt to be taken more freely than simple water, and they are therefore useful. Ripe fruits are allowable and useful.

To relieve stiffness and soreness of the joints, methodic friction or shampooing is highly useful, being careful that undue violence be not used. Small blisters, from time to time, are recommended. Collections of soft gouty matter or "gouty abscesses," as they have been called, if near the surface, may be punctured, and the creamy matter gently pressed out. Occasionally ulceration follows, which is troublesome but leading to no evil results. Deformities, nodosities, and anchylosis due to chalk-stones and structural changes, are effects of the disease which do not admit of removal.

[1] National Dispensatory, 1879.

Different mineral waters have been much resorted to in the treatment of gout, particularly the Vichy water. Of the utility of the latter and of other springs, there is much difference of opinion among those who have given more or less attention to an investigation of their effects. The Vichy water is alkaline, its alkalinity being due to the bicarbonate of soda. The imported and the artificial water are used to a considerable extent in this country. But springs which owe whatever therapeutical value they possess to other saline ingredients, such as the sulphate of soda or magnesia, the chloride of sodium or calcium, the chalybeate and the sulphur springs, are severally advocated as useful in cases of gout. It is difficult to eliminate the beneficial influence of hygienic circumstances connected with a residence at watering-places, and thus arrive at a fair judgment of the therapeutic value of the water. For the discussion of this matter the reader is referred to other works. I shall content myself with subjoining the rules which, according to Garrod, should guide the practitioner in advising or in prescribing the exhibition of mineral waters in gouty cases :—

"They should be altogether prohibited when there is considerable structural disease in any important organs, especially in the heart or kidneys; and even when the organic mischief is slight, the greatest caution is necessary in their use. They should be avoided when an acute attack is either present or threatening.

"The waters should be selected according to the nature of the case. When the patient is robust and of a full habit, the alkaline saline springs; when torpidity of the bowels predominates, the purgative waters; when there is want of vascular action, the saline waters; when the skin is inactive, the sulphur springs; lastly, when debility prevails, then the more simple thermal waters should be chosen. In all cases the use of the waters should be cautiously commenced with, and care taken not to oppress the stomach by giving too much liquid, nor to induce debility or any other injurious effects by allowing a too long sojourn in the bath."[1]

The treatment of irregular and misplaced gout involves indications derived from the character and seat of the disorders, in other words, from the symptoms in individual cases. If gout have retroceded, local measures to solicit its return are indicated. For this end, warm and stimulating applications are to be made to the part or parts in which the regular manifestations were seated.

Rheumatoid Arthritis. Deforming Arthritis.

This disease has received a variety of names, of which may be mentioned *rheumatic gout*, *nodosity of the joints* (Haygarth), *chronic rheumatic arthritis* (Adams), *nodular rheumatism*, *dry arthritis*, *proliferating arthritis*, *arthritis pauperum*, and *malum senile articulorum*. When the affection attacks the hip-joint, it has been called *malum coxæ senile*. When the vertebral articulations are affected, it is called *spondylitis deformans*. The term rheumatic gout is much used by practitioners to designate this disease, but it is objectionable. It implies that the disease is a combination of rheumatism and gout. Rheumatism and gout very rarely occur conjointly. It is quite certain that the disease under consideration has no relation with gout; and it is probable that it differs in its nature from rheumatism. The names which have been placed at the head of this article seem to be the most appropriate of those which have been suggested. Garrod introduced the name rheumatoid arthritis. Arthritis deformans is the name chiefly used by German writers.

[1] For a discussion of mineral waters in general, in gout, and the relative value of different European springs, *vide* Garrod's work.

The anatomical characters are as follows: Early in the disease there may be an accumulation within the affected joints of clear or slightly turbid fluid which in the progress of the disease is absorbed. Fluid effusion, however, does not necessarily occur at any period of the disease, and, as a rule, upon post-mortem examination the cavities of the joints are found so dry that the disease has received the name dry arthritis (arthritis sicca). Important changes occur in all of the structures which compose the joints. The articular cartilages are absorbed, more especially their central parts, where opposing cartilaginous surfaces come into contact. The ends of the bones, being denuded of cartilage, come into contact, and acquire a hard, smooth, polished appearance in consequence of the friction to which they are subjected. This condition of bone is called eburnation. Around the margin of the articulation there is a new growth, in nodular masses, of cartilage and of bone. In this way the articular extremities of the bones become enlarged by the formation of a rough, irregular, bony and cartilaginous ring which surrounds the eburnated surfaces. After the disappearance of the cartilage the process of absorption may invade the articular ends of the bones. Thus, when the hip-joint is affected, not only the head, but a considerable portion of the neck of the femur may be absorbed. In consequence of the thickened condition of the end of the bone from the marginal osseous growths, the appearance is often as if the eroded head of the femur had been pushed down nearer to the shaft. Irregular bony outgrowths or nodosities take place around the sockets. The sockets are sometimes widened, and sometimes deepened and contracted. Dislocations may have occurred and new sockets have been formed. The synovial membranes and the ligaments of the joints are also affected. The little polypoid or villous outgrowths, which are normally present to a certain extent upon the inner surface of the synovial membrane, become often greatly increased in number and size, so that the inner surface of the thickened membrane may acquire a shaggy appearance, especially where it extends for a short distance over the articular extremities. To these hypertrophied synovial villi the name dendritic vegetations of the synovial membrane is sometimes applied. Some of these hypertrophied villi may become changed into cartilaginous or even into osseous nodules which are often connected by narrow pedicles with the inner surface of the synovial membrane. The pedicles sometimes rupture, so that the bony or cartilaginous nodules are detached and exist as foreign bodies in the articular cavity. The ligaments may also become thickened. Plates of cartilage and of bone may develop in these thickened ligaments. An ossifying periostitis exists to some extent around the ends of the bones. Osseous anchylosis is said never to occur in arthritis deformans; but the joints may be rendered immovable by the thickened condition of the ligaments and by the bony new growths. The interarticular cartilages are generally destroyed; also the round ligament of the hip, and the long tendon of the biceps brachii, when the joints in which they are situated are affected. The disused muscles are atrophied. The atrophy is said to be sometimes greater than can be accounted for by the disuse of the limbs, so that some writers consider that a neuropathic element is involved.

The microscopical examination of the cartilage in this disease shows a proliferation of the cartilage-cells and a breaking up of the basement substance into fibrils. The spaces inclosed by the capsules of the cartilage-cells become greatly enlarged, especially in a vertical direction. These enlarged spaces contain proliferating cartilage-cells. The intercellular substance is thus reduced in amount. According to Cornil and Ranvier, the capsules on the surface rupture into the articular cavities, into which the cartilage-cells are discharged. The intercellular substance between the ruptured capsules projects for a time in the form of little villi from the surface

of the cartilage, to which they give a filamentous, velvety appearance. In the progress of the disease the filaments are destroyed, and the cartilage spaces are gradually opened until the whole central part of the cartilage is removed. At the periphery the articular cartilage is covered by synovial membrane. Here the cartilage spaces filled with cells do not rupture, but the proliferative process results in the formation of new cartilage, instead of in absorption. This new cartilage may undergo ossification.[1] The so-called chalky deposit of gout is wanting; but rheumatoid arthritis may occur in persons who have this deposit as an effect of attacks of gout which have previously occurred.

The disease is usually, from the first and during its course, subacute. Sometimes the local and general symptoms denote a certain degree of acuteness, causing a resemblance to acute rheumatism. A sudden invasion successively of different joints, however, does not take place as in the latter affection, and there is no liability to pericarditis or to endocarditis.

The development and the progress of the disease are slow. The smaller joints may be first affected, and subsequently the larger joints, or the reverse of this may obtain. A feature of the disease is its progressive character, as regards increase of the anatomical changes in the joints affected, and extension to other joints. It may, however, remain stationary, in both these respects, for a long time. Pyrexia, except at times, is wanting, and there may be but little constitutional disturbance. The appetite, digestion, and nutrition are sometimes but little affected. The affected joints are painful, especially on motion.

A particular deformity of the fingers is characteristic, namely, a lateral deflection in the ulnar direction. The toes sometimes present also this peculiarity. The situation and motions of the thumb are generally unaffected.

In the progress of the disease the anatomical changes lead to permanent extension or flexion of parts, dislocations, nodulations, and notable distortions. Extending, as it sometimes does, over all the joints of the body (polyarthritis deformans), the trunk is bent and rigid, the neck is immovable, the jaws are more or less fixed, the limbs distorted, the muscles attenuated from disuse, and the patient presents a most distressing spectacle of utter helplessness. Between this picture of extreme progress and the early appearances of the disease, there is every degree of gradation.

The disease may occur at all ages, but, in the majority of cases, patients are in middle life, and much oftener women than men. It occurs in the poorer classes of society, among those who suffer from hardships, exposure, and deprivations; but it is by no means confined to these. Persons are rarely affected when in full health and vigor; its victims are those whose constitutions are broken down by various circumstances affecting body and mind. Large hospitals, in which chronic cases are received, are seldom without examples of this disease in the different stages of its progress.

More than forty years ago, Prof. J. K. Mitchell maintained that diseases of the joints resulted from affections of the spinal cord. More recently attention has been directed by Remak, Benedikt, Weir Mitchell, Charcot, and others to morbid conditions of the cord and injuries of nerves as giving rise to arthritic affections. On facts exemplifying this pathological connection, together with the symmetrical occurrence of the joint affections, and apparent etiological relations in some instances, the theory that rheumatoid

[1] According to Ziegler, cartilaginous and fibrous nodules develop in the bone beneath the cartilage. These nodules may be converted into cysts. A rarefying ostitis occurs, resulting in enlargement of the medullary spaces and absorption of the bony trabeculæ. Ziegler observed changes which he interprets as proliferation of the bone-cells (Virchow's Archiv, Bd. 70, 1877).

arthritis is of nervous origin is not irrational. This theory is supported by the well-known occurrence of trophic disturbances of the muscles as effects of diseases or injuries of the cords and nerves.

The diagnosis involves discrimination from rheumatism and gout. From chronic rheumatism it is not readily discriminated prior to the occurrence of its deforming effects, especially if the affection have not been preceded by acute rheumatism. These effects constitute the diagnostic criterion. It is distinguished from gout by the larger joints being primarily affected in a certain proportion of cases; by the smaller joints of the hands being affected without a previous affection of the toes; by the absence of the paroxysms or exacerbations which are characteristic of gouty attacks, by the absence of the chalk-like deposit and of an excess of uric acid in the blood, and by its occurrence, in a certain proportion of cases, in young subjects and women.

Although not involving immediate danger to life, rheumatoid arthritis is a hopeless disease as regards recovery. All that can be hoped for is a certain measure of improvement, non-progression, and indefinite tolerance.

The first object of treatment is the improvement of the general health. Tonic remedies, long continued and varied from time to time, in conjunction with a nutritious diet and other hygienic measures calculated to invigorate the system, are to be employed for this object. Remedies which have a special influence in cases of rheumatism and gout, namely, alkalies, colchicum, and salicin or the salicylic acid, are unavailing in this affection. All depressing remedies are contra-indicated. Iodine in the form of either the iodide of iron or the iodide of potassium, guaiacum, and arsenic appear to be useful in certain cases. Cod-liver oil may be given, in conjunction with tonics, if there be a tendency to waste. Chalybeates are especially indicated if the patient be anæmic. The alkaline mineral waters, and those which act powerfully upon the bowels or kidneys, are hurtful. On the other hand, chalybeate and tonic waters may prove beneficial.

Local measures of treatment are important. Leeching or cupping and severe counter-irritation are not indicated. Small blisters and the application of iodine may be useful if there be effusion within the joints. Rest is indicated while effusion exists or when the symptoms denote inflammation; afterward, passive motion, friction, shampooing, and electricity constitute the most important part of the treatment.

CHAPTER XII.

SCORBUTUS. PURPURA HÆMORRHAGICA. HÆMATOPHILIA.

Scorbutus, or Scurvy—Anatomical Characters—Clinical History—Pathological Character—Causation — Diagnosis — Prognosis — Prevention — Treatment. Purpura Hæmorrhagica. Hæmatophilia.

THIS concluding chapter will be devoted to three affections which, as regards symptomatic events, are closely allied to each other, namely *scorbutus* or *scurvy*, *purpura hæmorrhagica*, and *hæmatophilia*. The first of these affections is of interest and importance especially in view of the fact that our knowledge of its pathology and causation, although by no means

complete, is sufficient to serve as a basis of effective treatment, and has rendered it preventable.

Scorbutus, or Scurvy.

This disease appears to have been known to the ancients, but it began to prevail frequently and extensively when, with improvements in navigation, long voyages were undertaken, and hence it was called *sea scurvy*. During the last five or six centuries, it has been pre-eminently the disease destructive to life in armies, navies, and exploring or emigrating expeditions by land and by water. Notwithstanding it has been rendered preventable by our knowledge of its pathology and causation, it has prevailed largely and proved greatly destructive to life within the present century. Hammond states that at Council Bluffs, in 1820, nearly the entire garrison was attacked, and many died; and the efficiency of the United States forces in the Florida and the Mexican war was very materially lessened by its occurrence.[1] It prevailed enormously in the English and French armies in the Crimean campaign. It contributed not inconsiderably to the mortality of our armies in the late civil war. The inconsistency between these facts and the existing state of knowledge, is in part to be explained by the inability always to secure the means of prevention in military operations; but it is in a greater measure to be accounted for by a censurable ignorance or neglect of these means.

Anatomical Characters.—It is probable that the primary and essential morbid changes relate to the blood. Our present knowledge, however, does not enable us to state in what consist the changes peculiar to the disease. Observers differ as regards the appearances, as well as the results of chemical and microscopical examinations. The color has been found sometimes darker and sometimes lighter than that of normal blood. The blood in the heart-cavities and vessels has been in some instances fluid and in other instances coagulated. The blood corpuscles have been considered by some observers diminished in number and by others unaffected in this regard. No uniform changes in their form or constituents have been determined. It is not established that a deficiency of potassa is a constant feature. Contradictory results have been obtained respecting the white corpuscles, the quantity of fibrin, and of albumen. In short, quoting Immerman, "If we take a general survey of the total analyses made of the blood of scurvy patients up to this time, we can hardly avoid a feeling of dissatisfaction. From the various and contradictory statements by different authors, we obtain but *one*, and that a decidedly *negative* result, namely, that the condition of the blood of scurvy patients, so far as we understand it at the present time, shows no peculiarities which might not occur as well in other pathological processes."

Extravasations of blood are found within and beneath the skin, where they are apparent before death, and between the fibres of muscles. The gums are swollen, ulcerated, and sometimes sloughing. A bloody serum is often found in the joints, associated sometimes with intra-articular ulcerations. A sero-sanguinolent liquid, often in considerable or large quantity, together with inflammatory products in a certain proportion of cases, is contained in the pericardial and pleural cavities. The spleen is often enlarged and softened. Parenchymatous and fatty degenerations of the heart, liver, and kidneys have been found. Ecchymoses are observed in many internal situations, namely, on the serous membranes, the bronchial mucous membrane,

[1] Report on Scurvy, United States Sanitary Commission, by William A. Hammond, M.D., 1862.

within the whole tract of the alimentary canal, and in the urinary passages. The extravasations are evidently secondary to, and dependent upon, the morbid blood-changes. The mode, however, in which the latter give rise to the former is not clearly understood. Either the blood is so altered that it escapes from the vessels; or, the nutrition of the walls of the vessels is impaired so that they do not offer adequate resistance to the pressure of the blood; or, again, paralysis affecting the vaso-motor nerves may be a pathological element. It is not impossible that each of these conditions enters into the mechanism.

Clinical History.—The symptomatic events which are characteristic of the disease are preceded by general weakness and lassitude. Patients are listless, apathetic, and indisposed to either mental or physical exertion. The appetite fails, and pallor of the surface is marked. These symptoms progressively increase. The more characteristic events are swelling and sponginess of the gums, which bleed either spontaneously or on slight pressure, hemorrhage from the mucous surfaces in other situations, and extravasation of blood within and beneath the skin. The fungous appearance of the gums is chiefly marked around the teeth; it is less marked in situations where the teeth are wanting. The teeth are apt to become loose and sometimes either fall out or may be easily removed. The prolabia are notably pale, presenting a striking contrast to the redness of the gums. Hemorrhages are frequent from the different outlets, namely, nostrils, mouth, vagina, and intestinal canal. It is rare from the bronchial tubes. The ecchymoses apparent on the cutaneous surface are either in the form of petechiæ or of patches of variable size; generally these forms are conjoined. They are either limited to, or most abundant on, the trunk and lower extremities. The ecchymoses undergo the same successive alterations in color as when due to contusion. A slight bruise suffices to produce them in any part of the surface of the body. They occur sometimes beneath the conjunctiva and within the globe of the eyes; into the joints, occasionally between the meninges of the brain, and beneath the periosteum. Fetor of the breath is usually a marked symptom.

The skin is dry and rough, compared by Larrey to that of a plucked fowl. The ankles are often œdematous, and some œdema of the face is not infrequent. The patient complains of pain in the loins and in the extremities, more especially the lower limbs. The muscles of the lower limbs are swollen and hard. Palpitation and dyspnœa are excited by slight exertion. Hæmic murmurs are heard over the heart. Pain referred to the chest is not uncommon. The bowels are in some cases constipated, and in other cases loose, or the latter may succeed the former in the progress of the disease in the same case. The urine is high-colored and its solid constituents, with the exception of potassa and phosphoric acid, are diminished. It is often albuminous. There is absence of pyrexia, except as symptomatic of an inflammatory complication. The pulse is sometimes slower than in health, but it becomes rapid on any exertion. It is always soft and compressible. The temperature of the body is somewhat lowered. The spirits are depressed. The patient frequently longs for fresh vegetables and fruit.

These symptoms are more or less marked. In extreme cases, or in an advanced stage of the disease, the prostration is great. Slight exertion occasions syncope. The patient may fall into a state of collapse. This is apt to follow abundant hemorrhage. Old ulcers and cicatrices sometimes reopen, and bones which had been fractured and united may become separated. Ulcerations occur within the mouth and over the ecchymoses on the skin. Weakness of vision, day blindness, and night blindness are not uncommon. Inability to sleep is common, but generally the mental faculties, although weakened, remain intact. In cases which are comparatively mild, general

debility, mental depression, pain in the back and lower limbs, together with the other symptoms, are more or less marked, but not excessive; and associated with these symptoms are spongy swelling of the gums and ecchymoses beneath the skin.

Scorbutus may exist as the sole affection, but it is frequently combined with other diseases. It is apt to be combined with dysentery, and the latter affection is then called *scorbutic dysentery*. It may co-exist with typhus and with typhoid fever. It may be accidentally associated with a variety of diseases which are liable to mask the scorbutic affection. The recognition of its co-existence with other diseases is of great importance with reference to appropriate treatment.

Secondary affections, or true complications, which are apt to occur are, lobar pneumonia, pulmonary hemorrhagic infarctions, pericarditis and pleuritis with bloody effusion, and acute diffuse nephritis.

Pathological Character.—The essential characteristic blood-change in this affection is not as yet determined. There is doubtless a deficiency as regards certain of the constituents of the blood, but the particular deficiency which belongs specially to the affection is a matter of question. Garrod considers that the special deficiency relates to the salts of potassa. That this deficiency enters into the pathological condition is certain, but that it constitutes the pathological condition exclusively or chiefly, in all cases, may be doubted, in view of the fact that supplying the salts of potassa, although highly useful, is not always the most effective method of treatment. With our present knowledge we must be content in saying that, owing to incomplete nutritive supplies, the constitution of the blood is impaired, giving rise to certain ascertained morbid changes common to this and other affections, and causing other changes, not yet ascertained, which are peculiar to this affection. It is noteworthy that the phenomena of scurvy are not produced by prolonged abstinence from food. This fact goes to show that the unknown blood-change in this disease is of a special character.

Causation.—Scurvy is a dietetic disease; it is the broadest expression of the causation to say that the disease is due to the want of certain alimentary supplies. A less comprehensive, but probably correct, statement is to say that the disease is caused by an insufficiency of nutritive principles contained in vegetable food. For a long time the disease was attributed to the free use of salted meat. It is, however, certain that the disease is not produced by this diet, except in so far as it displaces other articles of food containing principles necessary for the normal constitution of the blood; scurvy has repeatedly been developed when the diet has been too much restricted to fresh meat. Garrod's theory of the pathological character of the disease involves the conclusion that it is attributable to a diet wanting the requisite quantity of the salts of potassa, these salts being abundant in vegetable food. Admitting a deficient supply of the salts of potassa to be an important element in the causation, other elements are involved. The dietetic principles, the deficiency of which causes this disease, are abundant in various articles of food distinguished as anti-scorbutic, experience having shown that they prevent the development of the disease.

Although causes relating to diet are essential to the production of the disease, other causes act powerfully as auxiliaries. Among the auxiliary causes are, exposure to cold and wet, deficient ventilation, and depressing moral influences. The disease is oftener developed during the winter than during the summer. I have known an instance in which the disease appeared to be produced by great and prolonged mental depression, but probably, in

this instance, from an utter indifference to food, dietetic causes were involved. The disease is oftener developed in the aged than in young persons; the causes of the disease will act more speedily in persons in whom the constitution has been impaired by previous disease, by injurious medication, and by excesses of any kind. There is reason to believe that the morbid condition of the blood which exists in scurvy is not infrequently produced, to an extent falling short of that requisite to give rise to the striking manifestations of the disease, by an undue restriction of the diet to a few articles of food either from poverty or false notions of dietetics. It is important for the physician to recognize this fact in medical practice.

Diagnosis.—In view of the striking symptomatic features of this disease, and of the fact that generally a greater or less number of persons become affected under circumstances which sufficiently account for its development, the diagnosis is easy provided the characters of the disease be marked. In isolated cases the diagnosis involves discrimination from *purpura hæmorrhagica*. This differential diagnosis will be considered in treating of the latter affection.

But the morbid condition of the blood peculiar to scurvy may exist to a greater or less extent when the most striking symptomatic features of the disease are not present, namely, the subcutaneous ecchymoses and hemorrhages from mucous outlets. Under these circumstances the disease may be overlooked. Thus, Hammond, Woodward, and others state that in cases called in army sick-reports cases of *general debility*, the disease is, not infrequently, incipient or not fully developed scorbutus. The pain in the back and muscles of the lower limbs is apt to lead the practitioner for a time to consider the disease as muscular rheumatism or myalgia. When associated with other diseases, such as dysentery and the essential fevers, it is liable to be overlooked. The appearance of the gums is highly important with reference to the diagnosis, in the cases in which petechiæ or vibices are wanting; and when, from the appearance of the gums and other symptoms, the scorbutic condition is suspected, an investigation of the diet may lead to the knowledge of facts which will tend to settle the diagnosis. This investigation is important, not only in army or naval practice, and in public institutions, but in private cases in which the symptoms point to scurvy. It is to be added that in children before dentition, and in aged persons who have lost their teeth, the characteristic appearances of the gums may be wanting. They are also wanting in rare instances irrespective of these circumstances.

Prognosis.—In cases of scurvy in which the ecchymoses are many and large, or in which hemorrhage from the mucous outlets is profuse, the danger to life is great. Life may be destroyed by rapid hemorrhagic effusion into the pleural or pericardial cavities. Meningeal hemorrhage is sometimes the immediate cause of death. Sudden death sometimes occurs from syncope induced by muscular exertion. If the causes which have produced the disease continue in operation, it proves fatal in a large proportion of cases. Before the pathology and causation were as well understood as now, the mortality from this disease among soldiers and seamen was often very large. Associated with other diseases, it contributes indirectly to their fatal termination, and it stands in the way of recovery from wounds and surgical operations which otherwise would not prove serious.

Promptly recognized and judiciously treated, the disease may be expected to end in recovery in a large proportion of cases. It has no definite duration. It continues for a longer or shorter period, according to the extent to which it has advanced, the amount and situations of hemorrhagic extrava-

sation, the previous condition of the patient, etc. The recovery is usually gradual, not infrequently tedious, and the system is apt to remain for a long time debilitated.

Prevention.—The disease may be prevented by a diet embracing the requisite variety of alimentary principles, and this is secured by a proper variety of animal and vegetable food. With the knowledge of this fact and due attention to its practical application, scurvy should never occur except under circumstances which render the means of its prevention unavailable. Its occurrence is always an occasion for reproach when articles of food containing adequate supplies for the healthful constitution of the blood can be obtained. It is chiefly in military campaigns and long sea-voyages that there are difficulties in the way of prevention. These difficulties, however, may generally be met by providing antiscorbutic articles of diet; and, with reference to these difficulties, the knowledge of the numerous articles which may furnish the needed alimentary principles is of vast importance. The prevention of this disease has been made practicable under all circumstances by the preservation of meats, vegetables, and fruits in hermetically sealed cans.

Lemon or lime juice has long been known as a most valuable antiscorbutic. Experience has abundantly shown that from one to two ounces *per diem* of the fresh juice will prove an effectual preventive against scurvy during very long voyages without fresh provisions. Orange juice is also an effectual antiscorbutic. Pure citric acid, although it appears to be useful, is not a substitute for the fresh juice of the fruit. One of the most efficient of antiscorbutic vegetables is the potato. It is most efficient when eaten raw. Pickles, onions, raw cabbage or *sauerkraut*, the water-cress, and other of the *cruciferæ*, are to be reckoned among the valuable antiscorbutic vegetables. Green corn, green apples, and most of the esculent fruits are preventives. They are more so unripe than ripe. Spruce and birch beer are anti-scorbutics; also yeast. Numerous vegetables which do not enter much into ordinary diet may often be used as antiscorbutics in military campaigns when the articles which have been named are not to be obtained. Among the vegetables now referred to, which experience has shown to be effectual in the prevention of scurvy, are the *sorrel* (*rumex acetosella*), *lamb's quarter* (*chenopodium album*), the bulb of the wild artichoke, a species of *cactus* known as the *agave Americana* or *magney*, indigenous in Texas, California, and Mexico, the *prickly pear* (*cactus opuntii*), and the *dandelion* (*leontodon taraxacum*).[1]

That the antiscorbutic virtue of certain vegetables and fruits depends, to a greater or less extent, on the presence of the salts of potassa is altogether probable. These salts, isolated, are useful in the prevention as well as the treatment; but experience has shown that they cannot take the place of antiscorbutic articles of diet.

Finally, in addition to dietetic means, attention to ventilation, cleanliness, avoidance of unnecessary exposure and physical exertions, and to measures calculated to produce cheerfulness, constitutes an important part of the prophylaxis.

Treatment.—The dietetic means of prevention constitute an essential part of the treatment. The juice of lemon, orange, and other fruits should be taken freely, but, of course, not to such an extent as to produce disorder of the stomach. The antiscorbutic vegetables and fruits should enter into the diet as abundantly as the digestive powers permit, in conjunction with

[1] *Vide* Hamilton and Hammond, *op. cit.*

meat, milk, and farinaceous food. Remedies to improve the appetite and strengthen digestion are indicated, namely, quinia, salicin, the bitter infusions or tinctures, the mineral acids, and chalybeate preparations. The salts of potassa are useful. The bitartrate may be selected or the chlorate. Wine or spirit or cider, in small quantities, if they produce an agreeable cordial effect, will be useful. In short, the chief objects of treatment are, the assimilation of alimentary principles needed for the healthy constitution of the blood, and the invigoration of the system.

Particular symptoms or disorders claim appropriate measures in addition to those having reference to the objects just stated. Constipation is to be relieved by mild laxatives or simple enemas, and, on the other hand, diarrhœa, by anodyne and astringent remedies. The dryness of the skin indicates sponging with tepid water or the tepid bath. Pain in the back and limbs may be alleviated by friction with anodyne and mildly stimulating liniments. Stiffness of the joints, which sometimes occurs, is to be prevented or removed by passive movements. The condition of the mouth calls for astringent collutories. Ulcerations in the mouth or on the skin are to be treated locally on general principles. Hemorrhage from the different outlets is to be restrained by hæmostatic remedies.

It is hardly necessary to add that the scorbutic condition, when associated with dysentery, typhus or typhoid fever, and any disease, claims the same dietetic and other measures of treatment as scorbutus existing alone.

Purpura Simplex. Purpura Hæmorrhagica.

The term purpura, or the purples, denotes an affection characterized by a truly petechial eruption, or petechiæ. This affection is included among the cutaneous diseases, and is treated of in works devoted to these diseases. A truly petechial eruption consists of small spots, or maculæ, sometimes a mere point, and then called *stigmata*, the color either being at first or becoming purple or livid, and not disappearing under pressure. The spots are due to minute extravasations of blood; they are small ecchymoses, and are frequently associated with vibices and still larger extravasations beneath the skin. True petechiæ are to be distinguished from the characteristic eruption of typhus fever, which is often called petechial.

Petechiæ occur in the affection which has just been considered, namely, scorbutus, associated with vibices and ecchymoses of variable size and form. They occur not infrequently in other diseases, for example, epidemic cerebro-spinal meningitis, typhus, and typhoid fever. They may be accidentally present in the course of any disease. Disconnected from any other affection, and not accompanied by hemorrhage elsewhere than beneath or within the skin, they characterize the variety of purpura called *purpura simplex*. Accompanied with hemorrhage elsewhere than beneath or within the skin, especially from mucous surfaces, and with graver symptoms than the variety just named, the affection is known as *purpura hæmorrhagica*. As a distinct affection it was first described in 1735, by Werlhof, under the name *morbus hæmorrhagicus maculosus*, and it is called by German authors Werlhof's disease.[1]

Purpura hæmorrhagica presents hemorrhagic phenomena identical with those which belong to scorbutus. The petechiæ, vibices, and larger ecchymoses apparent on the surface of the body are the same. Similar extravasations are found after death in the mucous membrane of the alimentary canal,

[1] For an analysis of 199 cases of purpura hæmorrhagica, *vide* Pathologie Interne par E. Gintrac, tome troisième.

and less frequently beneath serous membranes. Hemorrhage from the different outlets occurs in both affections. The two affections are by some considered as identical. Our knowledge of their pathological character is not sufficient to base thereon a positive statement concerning their identity or non-identity, but there is sufficient ground for considering them as nosologically distinct affections. With reference to clinical history, causation, and diagnosis, it will suffice to notice the points in which the purpura hæmorrhagica differs from scorbutus.

In purpura there is not that fungus-like swelling of the gums which is a characteristic feature of scorbutus. The gums are either unaffected or but slightly affected. Extravasations within the muscles, the joints, and internal viscera are comparatively rare in purpura. Those which occur in this disease do not give rise to inflammation, ulcerations, and sloughing as in cases of scorbutus. Purpura is not, like scorbutus, distinctly traceable to an insufficient supply of alimentary principles contained in vegetable food. It is met with in isolated cases, whereas, the causes of scorbutus generally affecting masses, the latter affection usually prevails as if it were an endemic. Isolated cases of scorbutus, however, are sometimes observed. It is stated that cases of purpura are most apt to occur in the summer and autumn, while scorbutus prevails especially in the winter or spring months. There is less depression of the vital powers in purpura than in scorbutus. Finally, the dietetic treatment which has a special efficacy in scorbutus, is not to the same extent curative in purpura. According full force to the points of difference, it must be admitted that they do not establish conclusively the non-identity of purpura and scorbutus, nor do they always suffice to enable the practitioner to make with positiveness the differential diagnosis. In some cases of purpura simplex, the disease seems to be essentially a febrile disease, the pulse and temperature denoting fever, with anorexia, prostration, etc. Pain in the back, limbs, and joints is a prominent symptom in some of these cases. Cases of this description are included under the name purpura simplex, because the eruptive and the continued fevers may be excluded, together with cerebro-spinal meningitis, and other affections in the course of which purpura is liable to occur as an incidental event. It is, however, perhaps more correct to consider the occurrence of fever with, or sometimes preceding, the purpuric phenomena (purpura febrilis) as denoting a febrile disease to which the purpura is incidental, as it is when connected with cerebro-spinal meningitis and other fevers. Exclusive of these cases, purpura is not accompanied by pyrexia unless some inflammatory complication occurs. The purpuric phenomena in some cases are associated with fever and local arthritic symptoms which resemble those of acute rheumatism. The latter disease does not exist in these cases, as the term *purpura rheumatica* implies. In the majority of cases, patients with purpura were feeble before the occurrence of this disease. It affects especially those suffering from unhygienic conditions; but, in a certain proportion of cases, it affects persons previously in apparently good health.

With or without extravasation from mucous surfaces, the pathological conditions standing in immediate connection with the hemorrhage, as in cases of scorbutus, relate either to an abnormal condition of the capillary vessels, to morbid blood-changes, or to vaso-motor paralysis, these different conditions being perhaps combined. It has been conjectured that the hemorrhage may depend on multiple capillary embolism.

Simple purpura does not in general denote a grave condition. But purpura hæmorrhagica involves danger from the same sources as scorbutus, namely, loss of blood from the different outlets of the body and extravasation into serous cavities, the brain, lungs, etc. Exclusive of these sources of danger,

recovery, under judicious treatment, may be expected. Occurring in connection with other important diseases, it adds greatly to the danger from the latter.

The objects of treatment in cases of purpura hæmorrhagica are, the restoration of the normal constitution of the blood, increase of the vital powers, and arrest or restraint of hemorrhage. With reference to these objects, the diet should be nutritious and varied, and digestion is to be aided by tonic remedies, together with wine or spirits in small quantity if the immediate effect be good. In view of the difficulty in always discriminating purpura from scorbutus, and of there being ground for supposing that the same morbid condition of the blood exists in both affections, the treatment should embrace the dietetic and other measures which experience has shown to be useful in cases of scorbutus. Of tonic remedies, the dilute sulphuric acid is especially recommended. This remedy has the advantage of being agreeable to the taste, if added to a proper quantity of water and syrup. It may be given in doses of from five to fifteen drops every two hours. Hæmostatics are to be given with reference to the hemorrhage. The gallic acid, the muriated tincture of iron, and the acetate of lead are remedies which may be employed. The oil of turpentine has been recommended as a valuable remedy in this affection. According to a German author, Henoch, ergot, in large doses, is useful in arresting or restraining the hemorrhage, and he cites this fact in support of the hypothesis that paralysis of the vaso-motor nerves is a pathological element.[1]

Hæmatophilia, or a Hemorrhagic Diathesis.

A remarkable liability to hemorrhages exists in some persons as an innate constitutional peculiarity. A hemorrhagic diathesis is sometimes manifested directly after birth by bleeding from the umbilicus, with difficulty restrained, and death often taking place from the loss of blood. The diathesis is generally manifested during, or shortly after, dentition; and is shown by profuse bleeding from slight wounds. Persons having this diathesis in a marked degree continue to lose blood from an insignificant wound, all efforts to arrest the hemorrhage proving ineffectual, until syncope occurs, which may prove fatal; and, if not fatal, the loss of blood induces a notable degree of anæmia. The hemorrhagic diathesis also leads to extensive extravasations within and beneath the integument, resulting from slight contusions. Hemorrhage, not traumatic, is apt to occur in persons with this diathesis, especially taking place from the nostrils, but sometimes from the bronchial tubes, the stomach, intestinal canal, and the kidneys. Children affected in a marked degree with this diathesis rarely live to adult age; but in some instances the diathesis diminishes or ceases after childhood; and, if it continue in a moderate or slight degree, it may not interfere with good health and longevity. The diathesis is often, not always, hereditary, and is sometimes perpetuated in several successive generations, being confined to certain members of a family. Persons with this diathesis have been called "bleeders." In the latter part of the last century, an account was given in the New York Medical Repository of a bleeder family in which the diathesis could be traced back nearly one hundred years. Males are affected oftener than females.

Like other inherited conditions, this diathesis sometimes skips over one generation and appears in the next. It is oftener transmitted to sons than to daughters. There may be nothing indicative of either this diathesis or aught abnormal prior to the occurrence of a hemorrhage, which is with diffi-

[1] *Vide* Jaccoud, *op. cit.*

culty controlled, following an accidental puncture or abrasion, or, perhaps, the extraction of a tooth. Nothing has been ascertained respecting the blood which will account for the diathesis. It is not dependent on hypinosis, although the continuance of the hemorrhage is due, in part at least, to deficient coagulation. Late researches have shown that the coagulability of fibrin is not inherent altogether in this constituent, but that other factors are requisite. There may be defects pertaining to the latter which are yet to be ascertained. An abnormal thinness of the inner membrane of the arteries has been found in several instances. Paralysis of the vaso-motor nerves has been conjectured as affording a rational explanation.

The treatment having reference to the diathesis consists of measures to promote assimilation and invigorate the system, namely, a nutritious diet, out-of-door life, and tonic remedies. By these measures we may hope to aid in removing the diathesis. Wounds are, of course, as far as possible, to be avoided. The diathesis may constitute an insuperable objection to all surgical operations which are not unavoidable. When hemorrhage occurs, either from wounds or spontaneously, local measures to arrest the flow of blood are to be resorted to if practicable; and hæmostatic remedies are to be given internally.

WORKS BY AUSTIN FLINT, M.D.,

Professor of the Principles and Practice of Medicine in Bellevue Hospital Medical College, N. Y.

A TREATISE

ON THE

PRINCIPLES AND PRACTICE OF MEDICINE.

DESIGNED FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE.

Fifth edition, thoroughly revised and largely rewritten.

In one very handsome octavo volume of 1150 *pages. Cloth*, $5 50; *leather*, $6 50; *very handsome half Russia*, $7 00. (*Now ready.*)

CLINICAL MEDICINE; A SYSTEMATIC TREATISE ON THE DIAGNOSIS AND TREATMENT OF DISEASES. Designed for Students and Practitioners of Medicine. In one large and handsome octavo volume of 795 pages: cloth, $4 50; leather, $5 50; half Russia, $6. (*Just Issued.*)

The eminent teacher who has written the volume under consideration has recognized the needs of the American profession, and the result is all that we could wish. The style in which it is written is peculiarly the author's; it is clear and forcible, and marked by those characteristics which have rendered him one of the best writers and teachers this country has ever produced. We have not space for so full a consideration of this remarkable work as we would desire.—*St. Louis Clin. Rec.*, Oct. 1879.

It is here that the skill and learning of the great clinician are displayed. He has given us a storehouse of medical knowledge, excellent for the student, convenient for the practitioner, the result of a long life of the most faithful clinical work, collected by an energy as vigilant and systematic as untiring, and weighed by a judgment no less clear than his observation is close.—*Archives of Medicine*, Dec. 1879.

A MANUAL OF PERCUSSION AND AUSCULTATION; EMBRACING THE PHYSICAL DIAGNOSIS OF DISEASES OF THE LUNGS AND HEART, AND OF THORACIC ANEURISM. Second edition. In one handsome royal 12mo. volume; cloth, $1 63. (*Just Ready.*)

Prof. Flint is so well known as a medical teacher and writer that it seems superfluous to state that the subject has been treated in a thorough and systematic manner. In revising it for a second edition the author has confined himself to such additions as seem likely to render it more useful, not only to students engaged in the practical study of the subject, but also to practitioners as a hand-book for ready reference, and we do not hesitate in saying that it would prove a valuable addition to every physician's library.—*Medical and Surgical Reporter*, March 18, 1880.

The little work before us has already become a standard one, and has been extensively adopted as a text-book. There is certainly none better. It contains the substance of the lessons which the author has for many years given, in connection with practical instruction in auscultation and percussion, to private classes, composed of medical students and practitioners.—*Cincinnati Med. News*, Feb. 1880.

PHTHISIS—ITS MORBID ANATOMY, ETIOLOGY, SYMPTOMATIC EVENTS AND COMPLICATIONS, FATALITY AND PROGNOSIS, TREATMENT AND PHYSICAL DIAGNOSIS. In a series of Clinical Studies. By AUSTIN FLINT, M.D., Professor of the Principles and Practice of Medicine in Bellevue Hospital Medical College, New York. In one handsome octavo volume: $3 50. (*Lately Issued.*)

A PRACTICAL TREATISE ON THE DIAGNOSIS, PATHOLOGY, AND TREATMENT OF DISEASES OF THE HEART. Second revised and enlarged edition. In one octavo volume of 550 pages, with a plate: cloth, $4.

Dr. Flint chose a difficult subject for his researches, and has shown remarkable powers of observation and reflection, as well as great industry, in his treatment of it. His book must be considered the fullest and clearest practical treatise on those subjects, and should be in the hands of all practitioners and students. It is a credit to American medical literature. —*Amer. Journ. of the Med. Sciences*, July, 1870.

A PRACTICAL TREATISE ON THE PHYSICAL EXPLORATION OF THE CHEST AND THE DIAGNOSIS OF DISEASES AFFECTING THE RESPIRATORY ORGANS. Second and revised edition. In one handsome octavo volume of 595 pages: cloth, $4 50.

ESSAYS ON CONSERVATIVE MEDICINE AND KINDRED TOPICS. In one very handsome royal 12mo. volume. Cloth, $1 38. (*Just Issued.*)

HENRY C. LEA'S SON & CO., Philadelphia.

THOMAS ON DISEASES OF WOMEN—Fifth Edition—Now Ready.

A PRACTICAL TREATISE ON THE DISEASES OF WOMEN. By T. Gaillard Thomas, M.D., Professor of Obstetrics, etc., in the College of Physicians and Surgeons, New York, etc. Fifth edition, thoroughly revised and rewritten. In one large and handsome 8vo. volume of 806 pages, with 266 illustrations. Cloth, $5; leather, $6; very handsome half Russia, $6 50.

The author has taken advantage of the opportunity afforded by the call for a new edition of this work to render it worthy a continuance of the very remarkable favor with which it has been received. Every portion of the work has been carefully revised, very much of it has been rewritten, and additions and alterations introduced wherever the advance of science and the increased experience of the author have shown them desirable. At the same time special care has been exercised to avoid undue increase in the size of the volume. To accommodate the numerous additions, a more condensed but very clear letter has been used, notwithstanding which, the number of pages has been increased by more than fifty. The series of illustrations has been extensively changed; many which seemed to be superfluous have been omitted, and a large number of new and superior drawings have been inserted. In its improved form, therefore, it is hoped that the volume will maintain the character it has acquired of a standard authority on every detail of its important subject.

PLAYFAIR'S MIDWIFERY—Third Edition—Now Ready.

A TREATISE ON THE SCIENCE AND PRACTICE OF MIDWIFERY. By W. S. Playfair, M.D., F.R.C.P., Professor of Medicine in King's College, etc. etc. Third American edition, revised by the author. Edited, with additions, by Robert P. Harris, M.D. In one handsome octavo volume of about 700 pages, with nearly 200 illustrations. Cloth, $4; leather, $5; half Russia, $5 50.

The medical profession has now the opportunity of adding to their stock of standard medical works one of the best volumes on midwifery ever published. The subject is taken up with a master hand. —*N. O. Med. and Surg. Journ.*, March, 1880.

If inquired of by a medical student what work on obstetrics we should recommend for him, as *par excellence*, we would undoubtedly advise him to choose Playfair's. It is of convenient size, but what is of chief importance, its treatment of the various subjects is concise and plain. While the discussions and descriptions are sufficiently elaborate to render a very intelligent idea of them, yet all details not necessary for a full understanding of the subject are omitted.—*Cincinnati Med. News*, Jan. 1880.

The rapidity with which one edition of this work follows another is proof alike of its excellence and of the estimate that the profession has formed of it. It is indeed so well known and so highly valued that nothing need be said of it as a whole. All things considered, we regard this treatise as the very best on Midwifery in the English language.—*New York Med. Journal*, May, 1880.

SMITH ON CHILDREN—Fourth Edition—Just Issued.

A COMPLETE PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. By J. Lewis Smith, M.D., Clinical Professor of Diseases of Children in the Bellevue Hospital Medical College, New York. Fourth edition, revised and enlarged. In one handsome octavo volume of about 750 pages, with illustrations. Cloth, $4 50; leather, $5 50; half Russia, $6.

In the period which has elapsed since the third edition of the work, so extensive have been the advances, that whole chapters required to be rewritten and hardly a page could pass without some material correction or additions. This labor has occupied the writer closely, and he has performed it conscientiously, so that the book may be considered a faithful portraiture of an exceptionally wide clinical experience in infantile diseases, corrected by a careful study of the recent literature of the subject. —*Medical and Surgical Reporter*, April 5, 1879.

Probably no other work ever published in this country upon a medical subject has reached such a height of popularity as has this well known treatise. As a text and reference book it is pre-eminently the authority upon diseases of children. It stands deservedly higher in the estimation of the profession than any other work upon the same subject.—*Nashville Journal of Medicine and Surgery*, May, 1879.

BUMSTEAD ON VENEREAL—Fourth Edition—Just Issued.

THE PATHOLOGY AND TREATMENT OF VENEREAL DISEASES. Including the results of recent investigations upon the subject. By J. Freeman Bumstead, M.D., LL.D. Fourth edition, revised and largely rewritten with the co-operation of R. W. Taylor, M.D., of New York, Professor of Dermatology in the University of Vermont. In one large and handsome octavo volume of 835 pages, with 138 illustrations. Cloth, $4 75; leather, $5 75; half Russia, $6 25.

We take pleasure in repeating that we believe this to be the best treatise on venereal disease in the English language, and we congratulate the authors upon their brilliant addition to American literature. —*Chicago Med. Journ. and Exam.*, Feb. 1880.

We find that we have here practically a new book —that the statement of the title-page, as to the fact that it has been largely rewritten, is a sufficiently modest announcement for the important changes in the text. After a thorough examination of the present edition, we can assert confidently that the enormous labor we have described has been here most faithfully and conscientiously performed.—*Amer. Journ. Med. Sci.*, January, 1880.

It is one of the best general treatises on venereal diseases with which we are acquainted, and is especially to be recommended as a guide to the treatment of syphilis.—*London Practitioner*, March, 1880.

HENRY C. LEA'S SON & CO., Philadelphia.

HENRY C. LEA'S SON & CO.'S

(LATE HENRY C. LEA)

CLASSIFIED CATALOGUE

OF

MEDICAL AND SURGICAL PUBLICATIONS.

In asking the attention of the profession to the works advertised in the following pages, the publishers would state that no pains are spared to secure a continuance of the confidence earned for the publications of the house by their careful selection and accuracy and finish of execution.

The large number of inquiries received from the profession for a finer class of bindings than is usually placed on medical books has induced us to put certain of our standard publications in half Russia, and that the growing taste may be encouraged, the prices have been fixed at so small an advance over the cost of sheep, as to place it within the means of all to possess a library that shall have attractions as well for the eye as for the mind of the reading practitioner.

The printed prices are those at which books can generally be supplied by booksellers throughout the United States, who can readily procure for their customers any works not kept in stock. Where access to bookstores is not convenient, books will be sent by mail post-paid on receipt of the price, and as the limit of mailable weight has been removed, no difficulty will be experienced in obtaining through the post-office any work in this catalogue. No risks, however, are assumed either on the money or on the books, and no publications but our own are supplied, so that gentlemen will in most cases find it more convenient to deal with the nearest bookseller.

HENRY C. LEA'S SON & CO.

Nos. 706 and 708 SANSOM ST., PHILADELPHIA, October, 1881.

INCREASED INDUCEMENT FOR SUBSCRIBERS TO

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES.

TWO MEDICAL JOURNALS, containing nearly 2000 LARGE PAGES,

Free of Postage, for FIVE DOLLARS Per Annum.

TERMS FOR 1881.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, published quarterly (1150 pages per annum), with
THE MEDICAL NEWS AND ABSTRACT, monthly (768 pp. per annum), } Five Dollars per annum, in advance.

SEPARATE SUBSCRIPTIONS TO

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, when not paid for in advance, Five Dollars.

THE MEDICAL NEWS AND ABSTRACT, free of postage, in advance, Two Dollars and a Half.

*** Advance paying subscribers can obtain at the close of the year cloth covers, gilt-lettered, for each volume of the Journal (two annually), and of the News and Abstract (one annually), free by mail, by remitting ten cents for each cover.

It will thus be seen that for the moderate sum of FIVE DOLLARS in advance, the subscriber will receive, free of postage, the equivalent of four large octavo volumes, stored with the choicest matter, original and selected, that can be furnished by the medical literature of both hemispheres. Thus taken together, the "JOURNAL" and the "NEWS AND ABSTRACT" combine the advantages of the elaborate preparation that can be devoted to the Quarterly with the prompt conveyance of intelligence by the Monthly; while, the whole being under a single editorial supervision, the subscriber is secured against the duplication of matter inevitable when periodicals from different sources are taken together.

The periodicals thus offered at this unprecedented rate are universally known for

their high professional standing.

I.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES,

EDITED BY I. MINIS HAYS, M.D.,

for more than half a century has maintained its position in the front rank of the medical literature of the world. Cordially supported by the profession of America, it circulates wherever the language is read, and is universally regarded as the national exponent of American medicine—a position to which it is entitled by the distinguished names from every section of the Union which are to be found among its collaborators.* It is issued quarterly, in January, April, July, and October, each number containing about three hundred octavo pages, appropriately illustrated wherever necessary. A large portion of this space is devoted to Original Communications, embracing papers from the most eminent members of the profession throughout the country.

Following this is the REVIEW DEPARTMENT, containing extended reviews by competent writers of prominent new works and topics of the day, together with numerous elaborate Analytical and Bibliographical Notices, giving a fairly complete survey of medical literature.

Then follows the QUARTERLY SUMMARY OF IMPROVEMENTS AND DISCOVERIES IN THE MEDICAL SCIENCES, classified and arranged under different heads, and furnishing a digest of medical progress, abroad and at home.

Thus during the year 1880 the "JOURNAL" contained 67 Original Communications, mostly elaborate in character, 170 Reviews and Bibliographical Notices, and 147 articles in the Quarterly Summaries, illustrated with 47 wood engravings.

That the efforts thus made to maintain the high reputation of the "JOURNAL" are successful, is shown by the position accorded to it in both America and Europe as the leading organ of medical progress:—

This is universally acknowledged as the leading American Journal, and has been conducted by Dr. Hays alone until 1869, when his son was associated with him. We quite agree with the critic. that this journal is second to none in the language, and cheerfully accord to it the first place, for nowhere shall we find more able and more impartial criticism, and nowhere such a repertory of able original articles. Indeed, now that the "British and Foreign Medico-Chirurgical Review" has terminated its career, the American Journal stands without a rival.—*London Med. Times and Gazette*, Nov. 24, 1877.

The best medical journal on the continent.—*Boston Med. and Surg. Journal*, April, 1879.

The present number of the American Journal is an exceedingly good one, and gives every promise of maintaining the well-earned reputation of the review. Our venerable contemporary has our best wishes, and we can only express the hope that it may continue its work with as much vigor and excellence for the next fifty years as it has exhibited in the past.—*London Lancet*, Nov. 24, 1877.

The Philadelphia Medical and Physical Journal issued its first number in 1820, and, after a brilliant career, was succeeded in 1827 by the American Journal of the Medical Sciences, a periodical of world-wide reputation; the ablest and one of the oldest periodicals in the world—a journal which has an unsullied record.—*Gross's History of American Med. Literature* 1876.

The best medical journal ever published in Europe or America.—*Va. Med. Monthly*, May, 1879.

It is universally acknowledged to be the leading American medical journal, and, in our opinion, is second to none in the language.—*Boston Med. and Surg. Journal*, Oct. 1877.

This is the medical journal of our country to which the American physician abroad will point with the greatest satisfaction, as reflecting the state of medical culture in his country. For a great many years it has been the medium through which our ablest writers have made known their discoveries and observations.—*Address of L. P. Yandell, M.D., before International Med. Congress*, Sept. 1876.

And that it was specifically included in the award of a medal of merit to the Publishers in the Vienna Exhibition in 1873.

The subscription price of the "AMERICAN JOURNAL OF THE MEDICAL SCIENCES" has never been raised during its long career. It is still FIVE DOLLARS per annum; and when paid for in advance, the subscriber receives in addition the "MEDICAL NEWS AND ABSTRACT," making in all nearly 2000 large octavo pages per annum, free of postage.

II.

THE MEDICAL NEWS AND ABSTRACT.

Thirty-eight years ago the "MEDICAL NEWS" was commenced as a monthly to convey to the subscribers of the "AMERICAN JOURNAL" the clinical instruction and

* Communications are invited from gentlemen in all parts of the country. Articles inserted by the Editor are liberally paid for by the publishers.

current information which could not be accommodated in the Quarterly. It consisted of sixteen pages of such matter, together with sixteen more known as the Library Department and devoted to the publishing of books. With the increased progress of science, however, this was found insufficient, and some years since another periodical, known as the "MONTHLY ABSTRACT," was started, and was furnished at a moderate price to subscribers to the "AMERICAN JOURNAL." These two monthlies have been consolidated, under the title of "THE MEDICAL NEWS AND ABSTRACT," and are furnished *free of charge* in connection with the "AMERICAN JOURNAL."

The "NEWS AND ABSTRACT" consists of 64 pages monthly, in a neat cover. It contains a CLINICAL DEPARTMENT in which will be continued the series of ORIGINAL AMERICAN CLINICAL LECTURES, by gentlemen of the highest reputation throughout the United States, together with a choice selection of foreign Lectures and Hospital Notes and Gleanings. Then follows the MONTHLY ABSTRACT, systematically arranged and classified, and presenting five or six hundred articles yearly; and each number concludes with an EDITORIAL and a NEWS DEPARTMENT, giving current professional intelligence, domestic and foreign, the whole fully indexed at the close of each volume, rendering it of permanent value for reference.

As stated above, the subscription price to the "NEWS AND ABSTRACT" is Two Dollars and a Half per annum, invariably in advance, at which rate it ranks as one of the cheapest medical periodicals in the country. But it is also furnished, free of all charge, in commutation with the "AMERICAN JOURNAL OF THE MEDICAL SCIENCES," to all who remit FIVE DOLLARS in advance, thus giving to the subscriber, for that very moderate sum, a complete record of medical progress throughout the world, in the compass of about two thousand large octavo pages.

In this effort to furnish so large an amount of practical information at a price so unprecedentedly low, and thus place it within the reach of every member of the profession, the publishers confidently anticipate the friendly aid of all who feel an interest in the dissemination of sound medical literature. They trust, especially, that the subscribers to the "AMERICAN MEDICAL JOURNAL," will call the attention of their acquaintances to the advantages thus offered, and that they will be sustained in the endeavor to permanently establish medical periodical literature on a footing of cheapness never heretofore attempted.

PREMIUM FOR OBTAINING NEW SUBSCRIBERS TO THE "JOURNAL."

Any gentleman who will remit the amount for two subscriptions for 1881, one of which at least must be for a *new subscriber*, will receive as a PREMIUM, free by mail, a copy of any one of the following recent works:—

"SEILER ON THE THROAT" (see p. 19),
"BARNES'S MANUAL OF MIDWIFERY" (see p. 24),
"BROWNE ON THE USE OF THE OPHTHALMOSCOPE" (see p. 29),
"FLINT'S ESSAYS ON CONSERVATIVE MEDICINE" (see p. 15),
"STURGES'S CLINICAL MEDICINE" (see p. 15),
"TANNER'S CLINICAL MANUAL" (see p. 5),
"WEST ON NERVOUS DISORDERS OF CHILDREN" (see p. 21).

*** Gentlemen desiring to avail themselves of the advantages thus offered will do well to forward their subscriptions at an early day, in order to insure the receipt of complete sets for the year 1881.

☞ The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. Where these are not accessible, remittances for the "JOURNAL" may be made at the risk of the publishers, by forwarding in REGISTERED letters. Address,

HENRY C. LEA'S SON & CO., Nos. 706 and 708 Sansom St., Phila., Pa.

DUNGLISON (*ROBLEY*), *M.D.*,

Late Professor of Institutes of Medicine in Jefferson Medical College, Philadelphia.

MEDICAL LEXICON; A DICTIONARY OF MEDICAL SCIENCE: Containing a concise explanation of the various Subjects and Terms of Anatomy, Physiology, Pathology, Hygiene, Therapeutics, Pharmacology, Pharmacy, Surgery, Obstetrics, Medical Jurisprudence and Dentistry. Notices of Climate and of Mineral Waters; Formulæ for Officinal, Empirical and Dietetic Preparations; with the Accentuation and Etymology of the Terms, and the French and other Synonymes; so as to constitute a French as well as English Medical Lexicon. A New Edition. Thoroughly Revised, and very greatly Modified and Augmented. By RICHARD J. DUNGLISON, M.D. In one very large and handsome royal octavo volume of over 1100 pages. Cloth, $6 50; leather, raised bands, $7 50; half Russia, $8. (*Lately Issued.*)

The object of the author from the outset has not been to make the work a mere lexicon or dictionary of terms, but to afford, under each, a condensed view of its various medical relations, and thus to render the work an epitome of the existing condition of medical science. Starting with this view, the immense demand which has existed for the work has enabled him, in repeated revisions, to augment its completeness and usefulness, until at length it has attained the position of a recognized and standard authority wherever the language is spoken.

Special pains have been taken in the preparation of the present edition to maintain this enviable reputation During the ten years which have elapsed since the last revision, the additions to the nomenclature of the medical sciences have been greater than perhaps in any similar period of the past, and up to the time of his death the author labored assiduously to incorporate everything requiring the attention of the student or practitioner. Since then, the editor has been equally industrious, so that the additions to the vocabulary are more numerous than in any previous revision. Especial attention has been bestowed on the accentuation, which will be found marked on every word. The typographical arrangement has been much improved, rendering reference much more easy, and every care has been taken with the mechanical execution. The work has been printed on new type, small but exceedingly clear, with an enlarged page, so that the additions have been incorporated with an increase of but little over a hundred pages, and the volume now contains the matter of at least four ordinary octavos.

A book well known to our readers, and of which every American ought to be proud. When the learned author of the work passed away, probably all of us feared lest the book should not maintain its place in the advancing science whose terms it defines. Fortunately, Dr. Richard J. Dunglison, having assisted his father in the revision of several editions of the work, and having been, therefore, trained in the methods and imbued with the spirit of the book, has been able to edit it, not in the patchwork manner so dear to the heart of book editors, so repulsive to the taste of intelligent book readers, but to edit it as a work of the kind should be edited—to carry it on steadily, without jar or interruption, along the grooves of thought it has travelled during its lifetime. To show the magnitude of the task which Dr. Dunglison has assumed and carried through, it is only necessary to state that more than six thousand new subjects have been added in the present edition.—*Phila. Med. Times*, Jan. 3, 1874.

About the first book purchased by the medical student is the Medical Dictionary. The lexicon explanatory of technical terms is simply a *sine qua non*. In a science so extensive, and with such collaterals as medicine, it is as much a necessity also to the practising physician. To meet the wants of students and most physicians, the dictionary must be condensed while comprehensive, and practical while perspicacious. It was because Dunglison's met these indications that it became at once the dictionary of general use wherever medicine was studied in the English language. In no former revision have the alterations and additions been so great. More than six thousand new subjects and terms have been added. The chief terms have been set in black letter, while the derivatives follow in small caps; an arrangement which greatly facilitates reference. We may safely confirm the hope ventured by the editor "that the work, which possesses for him a filial as well as an individual interest, will be found worthy a continuance of the position so long accorded to it as a standard authority."—*Cincinnati Clinic*, Jan. 10, 1874.

It has the rare merit that it certainly has no rival in the English language for accuracy and extent of references.—*London Medical Gazette*.

As a standard work of reference, as one of the best, if not the very best, medical dictionary in the English language, Dunglison's work has been well known for about forty years, and needs no words of praise on our part to recommend it to the members of the medical, and, likewise, of the pharmaceutical profession. The latter especially are in need of such a work, which gives ready and reliable information on thousands of subjects and terms which they are liable to encounter in pursuing their daily avocations, but with which they cannot be expected to be familiar. The work before us fully supplies this want.—*Am. Journ. of Pharm.*, Feb. 1874.

A valuable dictionary of the terms employed in medicine and the allied sciences, and of the relations of the subjects treated under each head. It reflects great credit on its able American author, and well deserves the authority and popularity it has obtained.—*British Med. Journ.*, Oct. 31, 1874.

Few works of this class exhibit a grander monument of patient research and of scientific lore The extent of the sale of this lexicon is sufficient to testify to its usefulness, and to the great service conferred by Dr. Robley Dunglison on the profession, and indeed on others, by its issue.—*London Lancet*, May 13 1875.

HOBLYN (*RICHARD D.*), *M.D.*

A DICTIONARY OF THE TERMS USED IN MEDICINE AND THE COLLATERAL SCIENCES. Revised, with numerous additions, by ISAAC HAYS, M.D., Editor of the "American Journal of the Medical Sciences." In one large royal 12mo. volume of over 500 double-columned pages; cloth, $1 50; leather, $2 00

It is the best book of definitions we have, and ought always to be upon the student's table.—*Southern Med. and Surg. Journal.*

RODWELL (*G. F.*), *F.R.A.S., &c.*

A DICTIONARY OF SCIENCE: Comprising Astronomy, Chemistry, Dynamics, Electricity, Heat, Hydrodynamics, Hydrostatics, Light, Magnetism, Mechanics, Meteorology, Pneumatics, Sound and Statics. Preceded by an Essay on the History of the Physical Sciences. In one handsome octavo volume of 694 pages, with many illustrations: cloth, $5.

A CENTURY OF AMERICAN MEDICINE, 1776–1876. By Doctors E. H. Clarke, H. J. Bigelow, S. D. Gross, T. G. Thomas and J. S. Billings. In one very handsome 12mo. volume of about 350 pages: cloth, $2 25.

This work appeared in the pages of the American Journal of the Medical Sciences during the year 1876. As a detailed account of the development of medical science in America, by gentlemen of the highest authority in their respective departments, the profession will no doubt welcome it in a form adapted for preservation and reference.

NEILL (JOHN), M.D., and SMITH (FRANCIS G.), M.D.,
Prof. of the Institutes of Medicine in the Univ. of Penna.

AN ANALYTICAL COMPENDIUM OF THE VARIOUS BRANCHES OF MEDICAL SCIENCE; for the Use and Examination of Students. A new edition, revised and improved. In one very large and handsomely printed royal 12mo. volume, of about one thousand pages, with 374 wood-cuts, cloth, $4; strongly bound in leather, with raised bands, $4 75.

HARTSHORNE (HENRY), M.D.,
Professor of Hygiene in the University of Pennsylvania.

A CONSPECTUS OF THE MEDICAL SCIENCES; containing Handbooks on Anatomy, Physiology, Chemistry, Materia Medica, Practical Medicine, Surgery and Obstetrics. Second Edition, thoroughly revised and improved. In one large royal 12mo. volume of more than 1000 closely printed pages, with 477 illustrations on wood. Cloth, $4 25; leather, $5 00.

We can say with the strictest truth that it is the best work of the kind with which we are acquainted. It embodies in a condensed form all recent contributions to practical medicine, and is therefore useful to every busy practitioner throughout our country, besides being admirably adapted to the use of students of medicine. The book is faithfully and ably executed.—*Charleston Med. Journ.*, April, 1875.

The work is intended as an aid to the medical student, and as such appears to admirably fulfil its object by its excellent arrangement, the full compilation of facts, the perspicuity and terseness of language, and the clear and instructive illustrations in some parts of the work.—*American Journ. of Pharmacy*, Philadelphia, July, 1874.

The volume will be found useful, not only to students, but to many others who may desire to refresh their memories with the smallest possible expenditure of time.—*N. Y. Med. Journal*, Sept. 1874.

The student will find this the most convenient and useful book of the kind on which he can lay his hand.—*Pacific Med. and Surg. Journ.*, Aug. 1874.

This is the best book of its kind that we have ever examined. It is an honest, accurate, and concise compend of medical sciences, as fairly as possible representing their present condition. The changes and the additions have been so judicious and thorough as to render it, so far as it goes, entirely trustworthy. If students must have a conspectus, they will be wise to procure that of Dr. Hartshorne.—*Detroit Rev. of Med. and Pharm.*, Aug. 1874.

The work before us has many redeeming features not possessed by others, and is the best we have seen. Dr. Hartshorne exhibits much skill in condensation. It is well adapted to the physician in active practice, who can give but limited time to the familiarizing of himself with the important changes which have been made since he attended lectures. The manual of physiology has also been improved and gives the most comprehensive view of the latest advances in the science possible in the space devoted to the subject. The mechanical execution of the book leaves nothing to be wished for.—*Peninsular Journal of Medicine*, Sept. 1874.

After carefully looking through this conspectus, we are constrained to say that it is the most complete work, especially in its illustrations, of its kind that we have seen.—*Cincinnati Lancet*, Sept. 1874.

The favor with which the first edition of this Compendium was received, was an evidence of its various excellences. The present edition bears evidence of a careful and thorough revision. Dr. Hartshorne possesses a happy faculty of seizing upon the salient points of each subject, and of presenting them in a concise and yet perspicuous manner.—*Leavenworth Med. Herald*, Oct. 1874

LUDLOW (J. L.), M.D.

A MANUAL OF EXAMINATIONS upon Anatomy, Physiology, Surgery, Practice of Medicine, Obstetrics, Materia Medica, Chemistry, Pharmacy and Therapeutics. To which is added a Medical Formulary. Third edition, thoroughly revised and greatly extended and enlarged. With 370 illustrations In one handsome royal 12mo. volume of 816 large pages. Cloth, $3 25; leather, $3 75.

The arrangement of this volume in the form of question and answer renders it especially suitable for the office examination of students, and for those preparing for graduation.

TANNER (THOMAS HAWKES), M.D., &c.

A MANUAL OF CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS. Third American from the Second London Edition. Revised and Enlarged by TILBURY FOX, M. D., Physician to the Skin Department in University College Hospital, London, &c. In one neat volume, small 12mo., of about 375 pages, cloth, $1 50.

*** On page 3, it will be seen that this work is offered as a premium for procuring new subscribers to the "AMERICAN JOURNAL OF THE MEDICAL SCIENCES."

GRAY (HENRY), F.R.S.,
Lecturer on Anatomy at St. George's Hospital, London.

ANATOMY, DESCRIPTIVE AND SURGICAL.

The Drawings by H. V. CARTER, M.D., and Dr. WESTMACOTT. The Dissections jointly by the AUTHOR and Dr. CARTER. With an Introduction on General Anatomy and Development by T. HOLMES, M.A., Surgeon to St. George's Hospital. A new American, from the Eighth enlarged and improved London edition. To which is added "LANDMARKS, MEDICAL AND SURGICAL," by LUTHER HOLDEN, F.R.C.S., author of "Human Osteology," "A Manual of Dissections," etc. In one magnificent imperial octavo volume of 983 pages, with 522 large and elaborate engravings on wood. Cloth, $6; leather, raised bands, $7; half Russia, $7 50.

The author has endeavored in this work to cover a more extended range of subjects than is customary in the ordinary text-books, by giving not only the details necessary for the student, but also the application of those details in the practice of medicine and surgery, thus rendering it both a guide for the learner, and an admirable work of reference for the active practitioner. The engravings form a special feature in the work, many of them being the size of nature, nearly all original, and having the names of the various parts printed on the body of the cut, in place of figures of reference, with descriptions at the foot. They thus form a complete and splendid series, which will greatly assist the student in obtaining a clear idea of Anatomy, and will also serve to refresh the memory of those who may find in the exigencies of practice the necessity of recalling the details of the dissecting room; while combining, as it does, a complete Atlas of Anatomy, with a thorough treatise on systematic, descriptive and applied Anatomy, the work will be found of essential use to all physicians who receive students in their offices, relieving both preceptor and pupil of much labor in laying the groundwork of a thorough medical education.

Since the appearance of the last American Edition, the work has received three revisions at the hands of its accomplished editor, Mr. Holmes, who has sedulously introduced whatever has seemed requisite to maintain its reputation as a complete and authoritative standard text-book and work of reference. Still further to increase its usefulness, there has been appended to it the recent work by the distinguished anatomist, Mr. Luther Holden—"Landmarks, Medical and Surgical"—which gives in a clear, condensed and systematic way, all the information by which the practitioner can determine from the external surface of the body the position of internal parts. Thus complete, the work, it is believed, will furnish all the assistance that can be rendered by type and illustration in anatomical study. No pains have been spared in the typographical execution of the volume, which will be found in all respects superior to former issues. Notwithstanding the increase of size, amounting to over 100 pages and 57 illustrations, it will be kept, as heretofore, at a price rendering it one of the cheapest works ever offered to the American profession.

The recent work of Mr. Holden, which was noticed by us on p. 53 of this volume, has been added as an appendix, so that, altogether, this is the most practical and complete anatomical treatise available to American students and physicians. The former finds in it the necessary guide in making dissections; a very comprehensive chapter on minute anatomy; and about all that can be taught him on general and special anatomy; while the latter, in its treatment of each region from a surgical point of view, and in the valuable addition of Mr. Holden, will find all that will be essential to him in his practice.—*New Remedies*, Aug 1878.

This work is as near perfection as one could possibly or reasonably expect any book intended as a text-book or a general reference book on anatomy to be. The American publisher deserves the thanks of the profession for appending the recent work of Mr. Holden, "*Landmarks, Medical and Surgical*," which has already been commended as a separate book. The latter work—treating of topographical anatomy—has become an essential to the library of every intelligent practitioner. We know of no book that can take its place, written as it is by a most distinguished anatomist. It would be simply a waste of words to say anything further in praise of Gray's Anatomy, the text-book in almost every medical college in this country, and the daily reference book of every practitioner who has occasion to consult his books on anatomy. The work is simply indispensable, especially this present American edition.—*Va. Med. Monthly*, Sept. 1878.

The addition of the recent work of Mr. Holden, as an appendix, renders this the most practical and complete treatise available to American students, who find in it a comprehensive chapter on minute anatomy, about all that can be taught on general and special anatomy, while its treatment of each region, from a surgical point of view, in the valuable section by Mr Holden, is all that will be essential to them in practice.—*Ohio Medical Recorder*, Aug 1878.

It is difficult to speak in moderate terms of this new edition of "Gray." It seems to be as nearly perfect as it is possible to make a book devoted to any branch of medical science. The labors of the eminent men who have successively revised the eight editions through which it has passed, would seem to leave nothing for future editors to do. The addition of Holden's "Landmarks" will make it as indispensable to the practitioner of medicine and surgery as it has been heretofore to the student. As regards completeness, ease of reference, utility, beauty, and cheapness, it has no rival. No student should enter a medical school without it; no physician can afford to have it absent from his library.—*St. Louis Clin. Record*, Sept. 1878.

ALSO FOR SALE SEPARATE—

HOLDEN (LUTHER), F.R.C.S.,
Surgeon to St. Bartholomew's and the Foundling Hospitals.

LANDMARKS, MEDICAL AND SURGICAL.

Second American, from the Latest Revised English Edition, with additions by W. W. KEEN, M.D., Prof. of Artistic Anatomy in the Penna. Academy of the Fine Arts, formerly Lecturer on Anatomy in the Phila. School of Anatomy. In one handsome 12mo. volume, of about 140 pages. Cloth, $1.00. (*Just Ready.*)

HEATH (CHRISTOPHER), F.R.C.S.,
Teacher of Operative Surgery in University College, London.

PRACTICAL ANATOMY: A Manual of Dissections.

From the Second revised and improved London edition. Edited, with additions, by W. W. KEEN, M. D., Lecturer on Pathological Anatomy in the Jefferson Medical College, Philadelphia. In one handsome royal 12mo. volume of 578 pages, with 247 illustrations. Cloth, $3 50; leather, $4 00.

ALLEN (HARRISON), M.D.

Professor of Physiology in the Univ. of Pa.

A SYSTEM OF HUMAN ANATOMY: INCLUDING ITS MEDICAL and Surgical Relations. For the Use of Practitioners and Students of Medicine. With an Introductory Chapter on Histology. By E. O. SHAKESPEARE, M. D., Ophthalmologist to the Phila. Hosp. In one large and handsome quarto volume, with several hundred original illustrations on lithographic plates, and numerous wood-cuts in the text. (*Shortly.*)

In this elaborate work, which has been in active preparation for several years, the author has sought to give, not only the details of descriptive anatomy in a clear and condensed form, but also the practical applications of the science to medicine and surgery. The work thus has claims upon the attention of the general practitioner, as well as of the student, enabling him not only to refresh his recollections of the dissecting room, but also to recognize the significance of all variations from normal conditions. The marked utility of the object thus sought by the author is self-evident, and his long experience and assiduous devotion to its thorough development are a sufficient guarantee of the manner in which his aims have been carried out. No pains have been spared with the illustrations. Those of normal anatomy are from original dissections, drawn on stone by Mr. Hermann Faber, with the name of every part clearly engraved upon the figure, after the manner of "Holden" and "Gray," and in every typographical detail it will be the effort of the publishers to render the volume worthy of the very distinguished position which is anticipated for it.

ELLIS (GEORGE VINER).

Emeritus Professor of Anatomy in University College, London.

DEMONSTRATIONS OF ANATOMY; Being a Guide to the Knowledge of the Human Body by Dissection. By GEORGE VINER ELLIS, Emeritus Professor of Anatomy in University College, London. From the Eighth and Revised London Edition. In one very handsome octavo volume of over 700 pages, with 256 illustrations. Cloth, $4.25; leather, $5.25. (*Lately Issued.*)

This work has long been known in England as the leading authority on practical anatomy, and the favorite guide in the dissecting-room, as is attested by the numerous editions through which it has passed. In the last revision, which has just appeared in London, the accomplished author has sought to bring it on a level with the most recent advances of science by making the necessary changes in his account of the microscopic structure of the different organs, as developed by the latest researches in textural anatomy.

Ellis's Demonstrations is the favorite text-book of the English student of anatomy. In passing through eight editions it has been so revised and adapted to the needs of the student that it would seem that it had almost reached perfection in this special line. The descriptions are clear, and the methods of pursuing anatomical investigations are given with such detail that the book is honestly entitled to its name.—*St. Louis Clinical Record*, June, 1879.

The success of this old manual seems to be as well deserved in the present as in the past volumes. The book seems destined to maintain yet for years its leadership over the English manuals upon dissecting.—*Phila. Med. Times*, May 24, 1879.

As a dissector, or a work to have in hand and studied while one is engaged in dissecting, we regard it as the very best work extant, which is certainly saying a very great deal. As a text-book to be studied in the dissecting-room, it is superior to any of the works upon anatomy.—*Cincinnati Med. News*, May 24, 1879.

We most unreservedly recommend it to every practitioner of medicine who can possibly get it.—*Va. Med. Monthly*, June, 1879.

WILSON (ERASMUS), F.R.S.

A SYSTEM OF HUMAN ANATOMY, General and Special. Edited by W. H. GOBRECHT, M.D., Professor of General and Surgical Anatomy in the Medical College of Ohio. Illustrated with three hundred and ninety-seven engravings on wood. In one large and handsome octavo volume, of over 600 pages; cloth, $4; leather, $5.

SMITH (HENRY H.), M.D., and HORNER (WILLIAM E.), M.D.,

Prof. of Surgery in the Univ. of Penna., &c. *Late Prof. of Anatomy in the Univ. of Penna.*

AN ANATOMICAL ATLAS; Illustrative of the Structure of the Human Body. In one volume, large imperial octavo, cloth, with about six hundred and fifty beautiful figures. $4 50.

SCHÄFER (EDWARD ALBERT), M.D.,

Assistant Professor of Physiology in University College, London.

A COURSE OF PRACTICAL HISTOLOGY: Being an Introduction to the Use of the Microscope. In one handsome royal 12mo. volume of 304 pages, with numerous illustrations: cloth, $2 00. (*Lately Issued.*)

HORNER'S SPECIAL ANATOMY AND HISTOLOGY. Eighth edition, extensively revised and modified. In 2 vols. 8vo., of over 1000 pages, with 320 wood-cuts: cloth, $6 00.

SHARPEY AND QUAIN'S HUMAN ANATOMY. Revised, by JOSEPH LEIDY, M.D., Prof of Anat. in Univ. of Penn. In two octavo vols. of about 1300 pages, with 511 illustrations Cloth, $6 00.

BELLAMY'S STUDENT'S GUIDE TO SURGICAL ANATOMY: A Text-book for Students preparing for their Pass Examination. With engravings on wood. In one handsome royal 12mo. volume. Cloth, $2 25.

CLELAND'S DIRECTORY FOR THE DISSECTION OF THE HUMAN BODY. In one small volume, royal 12mo. of 182 pages: cloth $1 25.

HARTSHORNE'S HANDBOOK OF ANATOMY AND PHYSIOLOGY. Second edition, revised. In one royal 12mo. vol., with 220 wood-cuts; cloth $1 75.

DALTON (*J. C.*), *M.D.*,

Professor of Physiology in the College of Physicians and Surgeons, New York, &c.

A TREATISE ON HUMAN PHYSIOLOGY. Designed for the use

of Students and Practitioners of Medicine. Seventh edit., thoroughly revised and rewritten, with about three hundred and sixty illustrations on wood. In one very beautiful octavo volume, of about 900 pages. (*Nearly Ready.*)

A few notices of the previous edition are appended.

Prof. Dalton has discussed conflicting theories and conclusions regarding physiological questions with a fairness, a fulness, and a conciseness which lend freshness and vigor to the entire book. But his discussions have been so guarded by a refusal of admission to those speculative and theoretical explanations, which at best exist in the minds of observers themselves as only probabilities, that none of his readers need be led into grave errors while making them a study.—*The Medical Record*, Feb. 19, 1876.

For clearness and perspicuity, Dalton's Physiology commended itself to the student years ago, and was a pleasant relief from the verbose productions which it supplanted. Physiology has, however, made many advances since then—and while the style has been preserved intact, the work in the present edition has been brought up fully abreast of the times. The new chemical notation and nomenclature have also been introduced into the present edition. Notwithstanding the multiplicity of text-books on physiology, this will lose none of its old time popularity. The mechanical execution of the work is all that could be desired.—*Peninsular Journal of Medicine*, Dec. 1875.

This popular text-book on physiology comes to us in its sixth edition with the addition of about fifty per cent. of new matter, chiefly in the departments of pathological chemistry and the nervous system, where the principal advances have been realized. With so thorough revision and additions, that keep the work well up to the times, its continued popularity may be confidently predicted, notwithstanding the competition it may encounter. The publisher's work is admirably done.—*St. Louis Med. and Surg. Journ.*, Dec. 1875.

The revision of this great work has brought it forward with the physiological advances of the day, and renders it, as it has ever been, the finest work for students extant.—*Nashville Journ. of Med. and Surg.*, Jan. 1876.

CARPENTER (*WILLIAM B.*), *M. D., F. R. S., F.G.S., F.L.S.*,

Registrar to University of London, etc.

PRINCIPLES OF HUMAN PHYSIOLOGY; Edited by HENRY POWER,

M.B. Lond., F.R.C.S., Examiner in Natural Sciences, University of Oxford. A new American from the Eighth Revised and Enlarged English Edition, with Notes and Additions, by FRANCIS G. SMITH, M.D., Professor of the Institutes of Medicine in the University of Pennsylvania, etc. In one very large and handsome octavo volume, of 1083 pages, with two plates and 373 engs. on wood. Cloth, $5 50; leather, $6 50; half Russia, $7.

We have been agreeably surprised to find the volume so complete in regard to the structure and functions of the nervous system in all its relations, a subject that, in many respects, is one of the most difficult of all, in the whole range of physiology, upon which to produce a full and satisfactory treatise of the class to which the one before us belongs. The additions by the American editor give to the work as it is a considerable value beyond that of the last English edition. In conclusion, we can give our cordial recommendation to the work as it now appears. The editors have, with their additions to the only work on physiology in our language that, in the full est sense of the word, is the production of a philosopher as well as a physiologist, brought it up as fully as could be expected, if not desired, to the standard of our knowledge of its subject at the present day. It will deservedly maintain the place it has always had in the favor of the medical profession.—*Journ. of Nervous and Mental Disease*, April, 1877.

Such enormous advances have recently been made in our physiological knowledge, that what was perfectly new a year or two ago, looks now as if it had been a received and established fact for years. In this encyclopædic way it is unrivalled. Here, as it seems to us, is the great value of the book; one is safe in sending a student to it for information on almost any given subject, perfectly certain of the fulness of information it will convey, and well satisfied of the accuracy with which it will there be found stated.—*London Med. Times and Gazette*, Feb. 17, 1877.

The merits of "Carpenter's Physiology" are so widely known and appreciated that we need only allude briefly to the fact that in the latest edition will be found a comprehensive embodiment of the results of recent physiological investigation. Care has been taken to preserve the practical character of the original work. In fact the entire work has been brought up to date, and bears evidence of the amount of labor that has been bestowed upon it by its distinguished editor, Mr. Henry Power. The American editor has made the latest additions, in order fully to cover the time that has elapsed since the last English edition.—*N. Y. Med. Journal*, Jan. 1877.

FOSTER (*MICHAEL*), *M.D., F.R.S.*,

Prof. of Physiology in Cambridge Univ., England.

TEXT-BOOK OF PHYSIOLOGY. Second American from the Latest

English Edition. Edited, with Extensive Notes and Additions, by EDWARD T. REICHERT, M.D., Late Demonstrator of Experimental Therapeutics in the Univ. of Penna. In one handsome royal 12mo. volume of about 1000 pages, with 260 illust. (*Nearly Ready.*)

In the preparation of a second American edition of Mr. Foster's Physiology, the editor has endeavored to render it more than ever acceptable to the student as a clear and comprehensive text-book, presenting the science in its latest developments. The original work being an exposition of functional, rather than general physiology, it seemed desirable to introduce the details of structure, in order to render more intelligible to the student the views and theories of the science. These the editor has added, in as concise a manner as possible; and in aid of this end has freely introduced illustrations from recognized authorities.

LEHMANN'S MANUAL OF CHEMICAL PHYSIOLOGY. Translated from the German, with Notes and Additions, by J. CHESTON MORRIS, M.D. With Illustrations on wood. In one octavo volume of 336 pages. Cloth, $2 25.

LEHMANN'S PHYSIOLOGICAL CHEMISTRY. Complete in two large octavo volumes of 1200 pages, with 200 illustrations; cloth, $6.

ATTFIELD (JOHN), Ph.D.,

Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, &c.

CHEMISTRY, GENERAL, MEDICAL AND PHARMACEUTICAL;

Including the Chemistry of the U. S. Pharmacopœia. A Manual of the General Principles of the Science, and their Application to Medicine and Pharmacy. Eighth edition, revised by the author. In one handsome royal 12mo. volume of 700 pages, with illustrations. Cloth, $2 50; leather, $3 00. (*Now Ready.*)

We have repeatedly expressed our favorable opinion of this work, and on the appearance of a new edition of it, little remains for us to say, except that we expect this eighth edition to be as indispensable to us as the seventh and previous editions have been. While the general plan and arrangement have been adhered to, new matter has been added covering the observations made since the former edition. The present differs from the preceding one chiefly in these alterations and in about ten pages of useful tables added in the appendix.—*Am. Journ. of Pharmacy*, May, 1879.

A standard work like Attfield's Chemistry need only be mentioned by its name, without further comments. The present edition contains such alterations and additions as seemed necessary for the demonstration of the latest developments of chemical principles, and the latest applications of chemistry to pharmacy. The author has bestowed arduous labor on the revision, and the extent of the information thus introduced may be estimated from the fact that the index contains three hundred new references relating to additional material.—*Druggists' Circular and Chemical Gazette*, May, 1879.

This very popular and meritorious work has now reached its eighth edition, which fact speaks in the highest terms in commendation of its excellence. It has now become the principal text-book of chemistry in all the medical colleges in the United States. The present edition contains such alterations and additions as seemed necessary for the demonstration of the latest developments of chemical principles, and the latest applications of chemistry to pharmacy. It is scarcely necessary for us to say that it exhibits chemistry in its present advanced state.—*Cincinnati Medical News*, April, 1879.

The popularity which this work has enjoyed is owing to the original and clear disposition of the facts of the science, the accuracy of the details, and the omission of much which freights many treatises heavily without bringing corresponding instruction to the reader. Dr. Attfield writes for students, and primarily for medical students; he always has an eye to the pharmacopœia and its officinal preparations; and he is continually putting the matter in the text so that it responds to the questions with which each section is provided. Thus the student learns easily, and can always refresh and test his knowledge.—*Med. and Surg. Reporter*, April 19, '79.

We noticed only about two years and a half ago the publication of the preceding edition, and remarked upon the exceptionally valuable character of the work. The work now includes the whole of the chemistry of the pharmacopœia of the United States, Great Britain, and India.—*New Remedies*, May, 1879.

GREENE (WILLIAM H.), M.D.,

Demonstrator of Chemistry in Med. Dept., Univ. of Penna.

A MANUAL OF MEDICAL CHEMISTRY. For the Use of Students.

Based upon Bowman's Medical Chemistry. In one royal 12mo. volume of 312 pages With illustrations. Cloth, $1 75. (*Now Ready.*)

It is well written, and gives the latest views on vital chemistry, a subject with which most physicians are not sufficiently familiar. To those who may wish to improve their knowledge in that direction, we can heartily recommend this work as being worthy of a careful perusal.—*Phila. Med. and Surg. Reporter*, April 24, 1880.

The little work before us is one which we think will be studied with pleasure and profit. The descriptions, though brief, are clear, and in most cases sufficient for the purpose. This book will, in nearly all cases, meet general approval.—*Am. Journ. of Pharmacy*, April, 1880.

CLASSEN (ALEXANDER),

Professor in the Royal Polytechnic School, Aix-la-Chapelle.

ELEMENTARY QUANTITATIVE ANALYSIS. Translated with

notes and additions by EDGAR F. SMITH, Ph.D., Assistant Prof. of Chemistry in the Towne Scientific School, Univ. of Penna. In one handsome royal 12mo. volume, of 324 pages, with illustrations; cloth, $2 00. (*Lately Issued.*)

It is probably the best manual of an elementary nature extant, insomuch as its methods are the best. It teaches by examples, commencing with single determinations, followed by separations, and then advancing to the analysis of minerals and such products as are met with in applied chemistry. It is an indispensable book for students in chemistry.—*Boston Journ. of Chemistry*, Oct. 1878.

GALLOWAY (ROBERT), F.C.S.,

Prof. of Applied Chemistry in the Royal College of Science for Ireland, etc.

A MANUAL OF QUALITATIVE ANALYSIS. From the Fifth London Edition.

In one neat royal 12mo. volume, with illustrations; cloth, $2 75.

REMSEN (IRA), M.D., Ph.D.,

Professor of Chemistry in the Johns Hopkins University, Baltimore.

PRINCIPLES OF THEORETICAL CHEMISTRY, with special reference

to the Constitution of Chemical Compounds. In one handsome royal 12mo. vol. of over 232 pages: cloth, $1 50.

BOWMAN'S INTRODUCTION TO PRACTICAL CHEMISTRY, INCLUDING ANALYSIS. Sixth American, from the Sixth and revised London edition. With numerous illustrations. In one neat vol., royal 12mo., cloth, $2 25.

WÖHLER AND FITTIG'S OUTLINES OF ORGANIC CHEMISTRY. Translated, with additions, from the Eighth German Edition. By IRA REMSEN, M.D., Ph.D., Prof. of Chemistry and Physics in Williams College, Mass. In one volume, royal 12mo. of 530 pp., cloth, $3.

FOWNES (GEORGE), Ph.D.

A MANUAL OF ELEMENTARY CHEMISTRY; Theoretical and Practical.

Revised and corrected by HENRY WATTS, B.A., F R.S., author of "A Dictionary of Chemistry," etc. With a colored plate, and one hundred and seventy-seven illustrations. A new American, from the Twelfth and enlarged London edition. Edited by ROBERT BRIDGES, M.D. In one large royal 12mo. volume, of over 1000 pages; cloth, $2 75; leather, $3 25. (*Lately Issued.*)

This work, inorganic and organic, is complete in one convenient volume. In its earliest editions it was fully up to the latest advancements and theories of that time. In its present form, it presents, in a remarkably convenient and satisfactory manner, the principles and leading facts of the chemistry of *to-day*. Concerning the manner in which the various subjects are treated, much deserves to be said, and mostly, too, in praise of the book. A review of such a work as *Fownes's Chemistry* within the limits of a book-notice for a medical weekly is simply out of the question.—*Cincinnati Lancet and Clinic*, Dec. 14, 1878.

When we state that, in our opinion, the present edition sustains in every respect the high reputation which its predecessors have acquired and enjoyed, we express therewith our full belief in its intrinsic value as a text-book and work of reference.—*Am. Journ. of Pharm.*, Aug. 1878.

The conscientious care which has been bestowed upon it by the American and English editors renders it still, perhaps, the best book for the student and the practitioner who would keep alive the acquisitions of his student days. It has, indeed, reached a somewhat formidable magnitude with its more than a thousand pages, but with less than this no fair representation of chemistry as it now is can be given. The type is small but very clear, and the sections are very lucidly arranged to facilitate study and reference.—*Med and Surg. Reporter*, Aug 3, 1878.

The work is too well known to American students to need any extended notice; suffice it to say that the revision by the English editor has been faithfully done, and that Professor Bridges has added some fresh and valuable matter, especially in the inorganic chemistry. The book has always been a favorite in this country, and in its new shape bids fair to retain all its former *prestige*.—*Boston Jour. of Chemistry*, Aug. 1878.

It will be entirely unnecessary for us to make any remarks relating to the general character of Fownes' Manual. For over twenty years it has held *the* foremost place as a text-book, and the elaborate and thorough revisions which have been made from time to time leave little chance for any wide awake rival to step before it.—*Canadian Pharm. Jour.*, Aug. 1878.

As a manual of chemistry it is without a superior in the language.—*Md. Med. Jour.*, Aug. 1878.

BLOXAM (C. L.),

Professor of Chemistry in King's College, London.

CHEMISTRY, INORGANIC AND ORGANIC. From the Second London Edition.

In one very handsome octavo volume, of 700 pages, with about 300 illustrations. Cloth, $4 00; leather, $5 00.

We have in this work a complete and most excellent text-book for the use of schools, and can heartily recommend it as such.—*Boston Med. and Surg. Journ.*, May 28, 1874.

The above is the title of a work which we can most conscientiously recommend to students of chemistry. It is as easy as a work on chemistry could be made, at the same time that it presents a full account of that science as it now stands. We have spoken of the work as admirably adapted to the wants of students; it is quite as well suited to the requirements of practitioners who wish to review their chemistry, or have occasion to refresh their memories on any point relating to it. In a word, it is a book to be read by all who wish to know what is the chemistry of the present day.—*American Practitioner*, Nov. 1873.

It would be difficult for a practical chemist and teacher to find any material fault with this most admirable treatise. The author has given us almost a cyclopædia within the limits of a convenient volume, and has done so without penning the *useless* paragraphs too commonly making up a great part of the bulk of many cumbrous works. The progressive scientist is not disappointed when he looks for the record of new and valuable processes and discoveries, while the cautious conservative does not find its pages monopolized by uncertain theories and speculations. A peculiar point of excellence is the crystallized form of expression in which great truths are expressed in very short paragraphs. One is surprised at the brief space allotted to an important topic, and yet, after reading it, he feels that little, if any more should have been said. Altogether, it is seldom you see a text-book so nearly faultless. — *Cincinnati Lancet*, Nov. 1873.

CLOWES (FRANK), D.Sc., London.

Senior Science-Master at the High School, Newcastle-under-Lyme, etc.

AN ELEMENTARY TREATISE ON PRACTICAL CHEMISTRY AND QUALITATIVE INORGANIC ANALYSIS.

Specially adapted for Use in the Laboratories of Schools and Colleges and by Beginners. Second American from the Third and Revised English Edition. In one very handsome royal 12mo. volume of 372 pages, with 47 illustrations. Cloth, $2 50. (*Just Ready.*)

This is a valuable work for those about to commence chemistry, the more so as by its use they are simultaneously acquainted with the manipulation of chemical analysis, a method which is the most valuable to impart a thorough knowledge of chemistry. It is a very good little book, and will make for itself many warm friends and supporters. It treats the subject well and the tables are very clear and valuable.—*St Louis Med. and Surg. Journ.*, Mar. 1881.

This work is not only well adapted for use as a text-book in medical colleges, but is also one of the best that a practitioner can have for convenient reference and instruction in his library. As a rule, such volumes are too technical and abstruse for study without some didactic aid, but the volume presented is easy of comprehension, and will be of great value to college students and busy practitioners.—*N. Y. Am. Med. Bi-Weekly*, April 9, 1881.

The tables particularly demand praise, for they are admirably formed, both for convenience of reference and fulness of information. In short, we do not remember to have met with a book which could better serve the student as a guide to the systematic study of inorganic chemistry.—*Louisville Med. News*, March 12, 1881.

KNAPP'S TECHNOLOGY; or Chemistry Applied to the Arts and to Manufactures. With American additions by Prof. WALTER R. JOHNSON. In two very handsome octavo volumes, with 500 wood engravings, cloth, $6 00.

HOFFMAN (FRED.), Ph.D. and POWER (FRED. B.), Ph.D.

Prof of Anat. Chem. in Phil. Coll. of Pharmacy

MANUAL OF CHEMICAL ANALYSIS, as Applied to the Examination of Medical Chemicals and their Preparations.

Being a Guide for the Determination of their Identity and Quality, and for the Detection of Impurities and Adulterations. For the Use of Pharmacists, Physicians, Druggists and Manufacturing Chemists, and Pharmaceutical and Medical Students. Third edition, entirely rewritten and much enlarged. In one very handsome octavo volume, fully illustrated. (*Preparing.*)

PARRISH (EDWARD),

Late Professor of Materia Medica in the Philadelphia College of Pharmacy.

A TREATISE ON PHARMACY. Designed as a Text-Book for the Student, and as a Guide for the Physician and Pharmaceutist.

With many Formulæ and Prescriptions. Fourth Edition, thoroughly revised, by THOMAS S. WIEGAND. In one handsome octavo volume of 977 pages, with 280 illustrations; cloth, $5 50; leather, $6 50; half Russia, $7

Of Dr Parrish's great work on pharmacy it only remains to be said that the editor has accomplished his work so well as to maintain, in this fourth edition, the high standard of excellence which it had attained in previous editions, under the editorship of its accomplished author. This has not been accomplished without much labor, and many additions and improvements, involving changes in the arrangement of the several parts of the work, and the addition of much new matter. With the modifications thus effected it constitutes, as now presented, a compendium of the science and art indispensable to the pharmacist, and of the utmost value to every practitioner of medicine desirous of familiarizing himself with the pharmaceutical preparation of the articles which he prescribes for his patients.—*Chicago Med. Journ.*, July, 1874.

The work is eminently practical, and has the rare merit of being readable and interesting, while it preserves a strictly scientific character The whole work reflects the greatest credit on author, editor, and publisher. It will convey some idea of the liberality which has been bestowed upon its production when we mention that there are no less than 280 carefully executed illustrations. In conclusion, we heartily recommend the work, not only to pharmacists, but also to the multitude of medical practitioners who are obliged to compound their own medicines. It will ever hold an honored place on our own bookshelves.—*Dublin Med. Press and Circular*, Aug. 12, 1874.

Perhaps one, if not the most important book upon pharmacy which has appeared in the English language has emanated from the transatlantic press. "Parrish's Pharmacy" is a well-known work on this side of the water, and the fact shows us that a really useful work never becomes merely local in its fame. Thanks to the judicious editing of Mr. Wiegand, the posthumous edition of "Parrish" has been saved to the public with all the mature experience of its author, and perhaps none the worse for a dash of new blood.—*Lond. Pharm. Journal*, Oct. 17, 1874.

GRIFFITH (ROBERT E.), M.D.

A UNIVERSAL FORMULARY, Containing the Methods of Preparing and Administering Officinal and other Medicines.

The whole adapted to Physicians and Pharmaceutists. Third edition, thoroughly revised, with numerous additions, by JOHN M. MAISCH, Professor of Materia Medica in the Philadelphia College of Pharmacy. In one large and handsome octavo volume of about 800 pages. Cloth, $4 50; leather, $5 50.

A more complete formulary than it is in its present form the pharmacist or physician could hardly desire To the first some such work is indispensable, and it is hardly less essential to the practitioner who compounds his own medicines. Much of what is contained in the introduction ought to be committed to memory by every student of medicine. As a help to physicians it will be found invaluable, and doubtless will make its way into libraries no already supplied with a standard work of the kind. —*The American Practitioner*, Louisville, July, '74.

FARQUHARSON (ROBERT), M.D.,

Lecturer on Materia Medica at St. Mary's Hospital Medical School.

A GUIDE TO THERAPEUTICS AND MATERIA MEDICA.

Second American edition, revised by the Author. Enlarged and adapted to the U. S. Pharmacopœia. By FRANK WOODBURY, M.D. In one neat royal 12mo. volume of 498 pages: cloth, $2.25. (*Lately Issued.*)

The appearance of a new edition of this convenient and handy book in less than two years may certainly be taken as an indication of its usefulness. Its convenient arrangement, and its terseness, and, at the same time, completeness of the information given, make it a handy book of reference.—*Am. Journ. of Pharmacy*, June, 1879.

This work contains in moderate compass such well-digested facts concerning the physiological and therapeutical action of remedies as are reasonably established up to the present time. By a convenient arrangement the corresponding effects of each article in health and disease are presented in parallel columns, not only rendering reference easier, but also impressing the facts more strongly upon the mind of the reader. The book has been adapted to the wants of the American student, and copious notes have been introduced, embodying the latest revision of the Pharmacopœia, together with the antidotes to the more prominent poisons, and such of the newer remedial agents as seemed necessary to the completeness of the work. Tables of weights and measures, and a good alphabetical index end the volume.—*Druggists' Circular and Chemical Gazette*, June, 1879.

It is a pleasure to think that the rapidity with which a second edition is demanded may be taken as an indication that the sense of appreciation of the value of reliable information regarding the use of remedies is not entirely overwhelmed in the cultivation of pathological studies, characteristic of the present day. This work certainly merits the success it has so quickly achieved.—*New Remedies*, July, '79.

CHRISTISON'S DISPENSATORY. With copious additions, and 213 large wood engravings By R. EGLESFIELD GRIFFITH, M.D. One vol. 8vo., pp. 1000 cloth, $4 00.

CARPENTER'S PRIZE ESSAY ON THE USE OF ALCOHOLIC LIQUORS IN HEALTH AND DISEASE. New edition, with a Preface by D. F. CONDIE, M.D., and explanations of scientific words. In one neat 12mo. volume, pp. 178, cloth, 60 cents.

STILLÉ (*ALFRED*), *M.D., LL.D., and Prof. of Theory and Practice of Medicine and of Clinical Med. in Univ. of Pa.*

MAISCH (*JOHN M.*), *Ph.D., Prof. of Mat. Med. and Bot. in Phila. Coll. Pharmacy, Secy. to the American Pharmaceutical Association.*

THE NATIONAL DISPENSATORY: Containing the Natural History, Chemistry, Pharmacy, Actions and Uses of Medicines, including those recognized in the Pharmacopœias of the United States, Great Britain and Germany, with numerous references to the French Codex. Second edition, thoroughly revised, with numerous additions. In one very handsome octavo volume of 1692 pages, with 239 illustrations. Extra cloth, $6 75; leather, raised bands, $7 50; half Russia, raised bands and open back, $8 25. (*Now Ready.*)

PREFACE TO THE SECOND EDITION.

The demand which has exhausted in a few months an unusually large edition of the National Dispensatory is doubly gratifying to the authors, as showing that they were correct in thinking that the want of such a work was felt by the medical and pharmaceutical professions, and that their efforts to supply that want have been acceptable. This appreciation of their labors has stimulated them in the revision to render the volume more worthy of the very marked favor with which it has been received. The first edition of a work of such magnitude must necessarily be more or less imperfect; and though but little that is new and important has been brought to light in the short interval since its publication, yet the length of time during which it was passing through the press rendered the earlier portions more in arrears than the later. The opportunity for a revision has enabled the authors to scrutinize the work as a whole, and to introduce alterations and additions wherever there has seemed to be occasion for improvement or greater completeness. The principal changes to be noted are the introduction of several drugs under separate headings, and of a large number of drugs, chemicals and pharmaceutical preparations classified as allied drugs and preparations under the heading of more important or better known articles: these additions comprise in part nearly the entire German Pharmacopœia and numerous articles from the French Codex. All new investigations which came to the authors' notice up to the time of publication have received due consideration.

The series of illustrations has undergone a corresponding thorough revision. A number have been added, and still more have been substituted for such as were deemed less satisfactory.

The new matter embraced in the text is equal to nearly one hundred pages of the first edition. Considerable as are these changes as a whole, they have been accommodated by an enlargement of the page without increasing unduly the size of the volume.

While numerous additions have been made to the sections which relate to the physiological action of medicines and their use in the treatment of disease, great care has been taken to make them as concise as was possible without rendering them incomplete or obscure. The doses have been expressed in the terms both of troy weight and of the metrical system, for the purpose of making those who employ the Dispensatory familiar with the latter, and paving the way for its introduction into general use.

The Therapeutical Index has been extended by about 2250 new references, making the total number in the present edition about 6000.

The articles there enumerated as remedies for particular diseases are not only those which, in the authors' opinion, are curative, or even beneficial, but those also which have at any time been employed on the ground of popular belief or professional authority. It is often of as much consequence to be acquainted with the worthlessness of certain medicines or with the narrow limits of their power, as to know the well attested virtues of others and the conditions under which they are displayed. An additional value possessed by such an Index is, that it contains the elements of a natural classification of medicines, founded upon an analysis of the results of experience, which is the only safe guide in the treatment of disease.

This evidence of success, seldom paralleled, shows clearly how well the authors have met the existing needs of the pharmaceutical and medical professions. Gratifying as it must be to them, they have embraced the opportunity offered for a thorough revision of the whole work, striving to embrace within it all that might have been omitted in the former edition, and all that has newly appeared of sufficient importance during the time of its collaboration, and the short interval elapsed since the previous publication. After having gone carefully through the volume we must admit that the authors have labored faithfully, and with success, in maintaining the high character of their work as a compendium meeting the requirements of the day, to which one can safely turn in quest of the latest information concerning everything worthy of notice in connection with Pharmacy, Materia Medica, and Therapeutics.—*Am. Jour. of Pharmacy*, Nov. 1879.

It is with great pleasure that we announce to our readers the appearance of a *second* edition of the National Dispensatory. The total exhaustion of the first edition in the short space of six months, is a sufficient testimony to the value placed upon the work by the profession. It appears that the rapid sale of the first edition must have induced both the editors and the publisher to make preparations for a new edition immediately after the first had been issued, for we find a large amount of new matter added and a good deal of the previous text altered and improved, which proves that the authors do not intend to let the grass grow under their feet, but to keep the work up to the time.—*New Remedies*, Nov. 1879.

This is a great work by two of the ablest writers on materia medica in America The authors have produced a work which, for accuracy and comprehensiveness, is unsurpassed by any work on the subject. There is no book in the English language which contains so much valuable information on the various articles of the materia medica. The work has cost the authors years of laborious study, but they have succeeded in producing a dispensatory which is not only *national*, but will be a lasting memorial of the learning and ability of the authors who produced it.—*Edinburgh Medical Journal*, Nov. 1879.

It is by far more international or universal than any other book of the kind in our language, and more comprehensive in every sense.—*Pacific Med. and Surg. Journ.*, Oct. 1879.

The National Dispensatory is beyond dispute the very best authority. It is throughout complete in all the necessary details, clear and lucid in its explanations, and replete with references to the most recent writings, where further particulars can be obtained, if desired. Its value is greatly enhanced by the extensive indices—a general index of materia medica, etc., and also an index of therapeutics It would be a work of supererogation to say more about this well-known work. No practising physician can afford to be without the National Dispensatory.—*Canada Med. and Surg. Journ.*, Feb. 1880.

MAISCH (*JOHN M.*), *Phar. D.*,

Prof. of Materia Medica and Botany in the Phila. Coll. of Pharmacy.

A MANUAL OF ORGANIC MATERIA MEDICA.

Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms. For the use of Students, Druggists, Pharmacists and Physicians. In one handsome 12mo. volume, with numerous illustrations on wood. (*Preparing.*)

EXTRACT FROM THE AUTHOR'S PREFACE.

When in 1866 the author was called to the chair of Materia Medica in the institution named (the Philadelphia College of Pharmacy), he seriously felt the need of a suitable text book which could be used in connection with his lectures, and made preparations for the publication of such a work at an early date. To elaborate a system of classification, which should be without difficulty comprehended and readily applied by those for whom it was intended, was by no means an easy task, and the author found occasion, almost every year, to either remodel that previously selected, or to make what in his opinion seemed to be desirable improvements. The publication of the "National Dispensatory" in a measure supplied the want felt, at least as far as a work of reference is concerned, but owing to its local arrangement, it is not adapted to systematic instruction. However, its publication rendered a modification of the original plan for a treatise on Materia Medica desirable, and it is now presented in a form giving an outline of the substance of the lectures and embracing what are considered the essential physical, histological, and chemical characters of the organic drug, so as to render the work also a useful and reliable guide in business transactions. Regarding the classification, the author is conscious of its imperfections, but he believes it to be convenient and capable of practical application.

In reference to the scope of the work, the main aim has been to embrace all the drugs recognized by the U. S. Pharmacopœia, together with the old, but now unofficinal ones, and such others, the use of which has been recently revived or suggested, and which seem to deserve attention. The medical properties and doses of the various drugs are merely briefly stated as subjects of general important information; the present work is not intended for giving instruction in the therapeutic application of drugs.

STILLÉ (*ALFRED*), *M. D.*,

Professor of Theory and Practice of Medicine in the University of Penna.

THERAPEUTICS AND MATERIA MEDICA; a Systematic Treatise

on the Action and Uses of Medicinal Agents, including their Description and History. Fourth edition, revised and enlarged. In two large and handsome 8vo. vols. of about 2000 pages. Cloth, $10; leather, $12; half Russia, $13.

It is unnecessary to do much more than to announce the appearance of the fourth edition of this well known and excellent work.—*Brit. and For. Med.-Chir. Review*, Oct 1875.

For all who desire a complete work on therapeutics and materia medica for reference, in cases involving medico-legal questions, as well as for information concerning remedial agents, Dr. Stillé's is "*par excellence*" the work. Being out of print, by the exhaustion of former editions, the author has laid the profession under renewed obligations, by the careful revision, important additions, and timely reissuing a work not exactly supplemented by any other in the English language, if in any language. The mechanical execution handsomely sustains the well-known skill and good taste of the publisher.—*St. Louis Med. and Surg. Journal*, Dec 1874.

From the publication of the first edition "Stillé's Therapeutics" has been one of the classics; its absence from our libraries would create a vacuum which could be filled by no other work in the language, and its presence supplies, in the two volumes of the present edition, a whole cyclopædia of therapeutics.—*Chicago Medical Journal*, Feb. 1875.

The rapid exhaustion of three editions and the universal favor with which the work has been received by the medical profession, are sufficient proof of its excellence as a repertory of practical and useful information for the physician. The edition before us fully sustains this verdict, as the work has been carefully revised and in some portions rewritten, bringing it up to the present time by the admission of chloral and croton-chloral, nitrite of amyl, bichloride of methylene, methylic ether, lithium compounds, gelseminum, and other remedies.—*Am. Journ. of Pharmacy*, Feb. 1875.

We can hardly admit that it has a rival in the multitude of its citations and the fulness of its research into clinical histories, and we must assign it a place in the physician's library; not, indeed, as fully representing the present state of knowledge in pharmacodynamics, but as by far the most complete treatise upon the clinical and practical side of the question.—*Boston Med. and Surg. Journal*, Nov. 5, 1874.

CORNIL (*V.*), *Prof. in the Faculty of Med., Paris.* AND RANVIER (*L.*), *Prof in the College of France.*

MANUAL OF PATHOLOGICAL HISTOLOGY.

Translated, with Notes and Additions, by E. O. SHAKESPEARE, M.D., Pathologist and Ophthalmic Surgeon to Philada. Hospital, Lecturer on Refraction and Operative Ophthalmic Surgery in Univ. of Penna., and by HENRY C. SIMES, M D., Demonstrator of Pathological Histology in the Univ. of Pa. In one very handsome octavo volume of over 700 pages, with over 350 illustrations. Cloth, $5 50; leather, $6 50; half Russia, $7. (*Just Ready.*)

We have no hesitation in cordially recommending the English translation of Cornil & Ranvier's "Pathological Histology" as the best work of the kind in any language, and as giving to its readers a trustworthy guide in obtaining a broad and solid basis for the appreciation of the practical bearings of pathological anatomy.—*Am. Journ. of Med. Sciences*, April, 1880.

This important work, in its American dress, is a welcome offering to all students of the subjects which it treats. The great mass of material is arranged naturally and comprehensively. The classification of tumors is clear and full, so far as the subject admits of definition, and this one chapter is worth the price of the book. The illustrations are copious and well chosen. Without the slightest hesitation, the translators deserve honest thanks for placing this indispensable work in the hands of American students.—*Phila. Med. Times*, April 24, 1880

This volume we cordially commend to the profession. It will prove a valuable, almost necessary, addition to the libraries of students who are to be physicians, and to the libraries of students who are physicians.—*American Practitioner*, June, 1880.

FENWICK (SAMUEL), M.D.,

Assistant Physician to the London Hospital.

THE STUDENT'S GUIDE TO MEDICAL DIAGNOSIS. From the Third Revised and Enlarged English Edition. With eighty-four illustrations on wood. In one very handsome volume, royal 12mo., cloth, $2 25. (*Lately Issued.*)

GREEN (T. HENRY), M.D.,

Lecturer on Pathology and Morbid Anatomy at Charing-Cross Hospital Medical School, etc.

PATHOLOGY AND MORBID ANATOMY. Fourth American, from the Fifth Enlarged and Revised English Edition. In one very handsome octavo volume of about 350 pages, with 138 fine engravings; cloth, $2 25. (*Just Ready.*)

EXTRACT FROM THE AUTHOR'S PREFACE.

In preparing the fifth edition of my Text-book on Pathology and Morbid Anatomy, I have again added much new matter, with the object of making the work a more complete guide for the student. All the chapters have been carefully revised, some alterations have been made in the arrangement of the work, and an addition has been made to the number of wood-cuts. The new wood cuts, as in previous editions, have been drawn by Mr. Collings from my own microscopical preparations.

We have long considered this the best guide yet presented to the student for the identification of various morbid tissues. We have found it more satisfactory than any other. The present edition has been thoroughly revised, and much new matter has been added. To the physician as a guide in diagnosis, we recommend this volume.—*Physician and Surgeon*, May, 1881.

BRISTOWE (JOHN SYER), M.D., F.R.C.P.,

Physician and Joint Lecturer on Medicine, St Thomas's Hospital.

A TREATISE ON THE PRACTICE OF MEDICINE. Second American edition, revised by the Author. Edited, with Additions, by JAMES H. HUTCHINSON, M.D., Physician to the Penna. Hospital. In one handsome octavo volume of nearly 1200 pages. With illustrations. Cloth, $5 00; leather, $6 00; half Russia, $6 50. (*Now Ready.*)

The second edition of this excellent work, like the first, has received the benefit of Dr. Hutchinson's annotations, by which the phases of disease which are peculiar to this country are indicated, and thus a treatise which was intended for British practitioners and students is made more practically useful on this side of the water. We see no reason to modify the high opinion previously expressed with regard to Dr. Bristowe's work, except by adding our appreciation of the careful labors of the author in following the lateral growth of medical science. —*Boston Medical and Surgical Journal*, February, 1880.

What we said of the first edition, we can, with increased emphasis, repeat concerning this: "Every page is characterized by the utterances of a thoughtful man. What has been said, has been well said, and the book is a fair reflex of all that is *certainly known* on the subjects considered."—*Ohio Med. Recorder*, Jan. 7, 1880.

The views of the author are expressed with precision and sufficient promptness to impress the student with the weight of his authority; and should the medical professor differ on any subject from his doctrine, he will need to find strong arguments to carry his class to the opposite conclusion.—*N. O. Med. and Surg. Journ*, Feb. 1880.

The reader will find every conceivable subject connected with the practice of medicine ably presented, in a style at once clear interesting, and concise. The additions made by Dr. Hutchinson are appropriate and practical, and greatly add to its usefulness to American readers.—*Buffalo Med. and Surg. Journ.*, March, 1880.

We regard it as an excellent work for students and for practitioners. It is clearly written, the author's style is attractive, and it is especially to be commended for its excellent exposition of the pathology and clinical phenomena of disease.—*St. Louis Clin. Record*, Feb. 1880.

HABERSHON (S. O.) M.D.

Senior Physician to, and late Lecturer on the Principles and Practice of Medicine at, Guy's Hospital, etc.

ON THE DISEASES OF THE ABDOMEN, COMPRISING THOSE of the Stomach, and other parts of the Alimentary Canal, Œsophagus, Cæcum, Intestines and Peritoneum. Second American, from the Third enlarged and revised English edition. With illustrations. In one handsome octavo volume of over 500 pages. Cloth, $3 50. (*Lately Issued.*)

This valuable treatise on diseases of the stomach and abdomen has been out of print for several years, and is therefore not so well known to the profession as it deserves to be. It will be found a cyclopædia of information, systematically arranged, on all diseases of the alimentary tract, from the mouth to the rectum. A fair proportion of each chapter is devoted to symptoms, pathology, and therapeutics. The present edition is fuller than former ones in many particulars, and has been thoroughly revised and amended by the author. Several new chapters have been added, bringing the work fully up to the times, and making it a volume of interest to the practitioner in every field of medicine and surgery. Perverted nutrition is in some form associated with all diseases we have to combat, and we need all the light that can be obtained on a subject so broad and general. Dr Habershon's work is one that every practitioner should read and study for himself.—*N. Y. Med. Journ*, April, 1879.

GLUGE'S ATLAS OF PATHOLOGICAL HISTOLOGY. Translated, with Notes and Additions, by JOSEPH LEIDY, M.D. In one volume, very large imperial quarto, with 320 copper-plate figures, plain and colored, cloth. $4 00

LA ROCHE ON YELLOW FEVER, considered in its Historical, Pathological, Etiological and Therapeutical Relations. In two large and handsome octavo volumes of nearly 1500 pp., cloth. $7 00.

STOKES' LECTURES ON FEVER. Edited by JOHN WILLIAM MOORE, M.D., Assistant Physician to the Cork Street Fever Hospital. In one neat 8vo. volume cloth, $2 00.

PAVY'S TREATISE ON THE FUNCTION OF DIGESTION: its Disorders and their Treatment. From the Second London edition. In one handsome volume, small octavo, cloth, $2 00.

HOLLAND'S MEDICAL NOTES AND REFLECTIONS. 1 vol. 8vo., pp. 500, cloth. $3 50

BARLOW'S MANUAL OF THE PRACTICE OF MEDICINE. With Additions by D. F. CONDIE, M.D. 1 vol. 8vo., pp. 600, cloth. $2 50.

TODD'S CLINICAL LECTURES ON CERTAIN ACUTE DISEASES. In one neat octavo volume, of 320 pp. cloth. $2 50.

FLINT (*AUSTIN*), *M.D.*,

Professor of the Principles and Practice of Medicine in Bellevue Med. College, N. Y.

A TREATISE ON THE PRINCIPLES AND PRACTICE OF MEDICINE; designed for the use of Students and Practitioners of Medicine. Fifth edition, entirely rewritten and much improved. In one large and closely printed octavo volume of 1153 pp. Cloth, $5 50; leather, $6 50; very handsome half Russia, raised bands, $7. (*Just Ready.*)

This work has been so long and favorably known, and has obtained so high a position amongst modern treatises on medicine, that it is hardly necessary to do more than announce the publication of this fifth edition. All who peruse it must be struck by the extensive research which has been undertaken in the revision of this edition, combined with much original thought. There is hardly a subject which does not receive fresh illustration and discussion, opening up new lines of inquiry which had not been thought of when the previous edition appeared. We cannot conclude this notice without expressing our admiration of this volume, which is certainly one of the standard text-books on medicine, and we may safely affirm that, taken altogether, it exhibits a fuller and wider acquaintance with recent pathological inquiry than any similar work with which we are acquainted, whilst at the same time it shows its author to be possessed of the rare facilities of clear exposition, thoughtful discrimination, and sound judgment.—*London Lancet*, July 23, 1881.

Practically, this edition is a new work; for so many additions and changes have been made that one well acquainted with previous editions would hardly recognize this as an old friend. The size of the volume is somewhat increased. An entire new section and several new chapters have been added. It is universally conceded that no text book upon this subject was ever published in this country that can at all compare with it. It has long been at the very head of American text book literature, and there can be no doubt but that it will be many years before it yields the place to others.—*Nashville Journ. of Med. and Surg.*, Feb. 1881.

"Flint's Practice" is recognized to be a standard treatise of high rank upon the principles and the practice of medicine wherever the English language is read. The opinions everywhere reveal the man of extensive experience, diligent study, calm judgment, and unbiassed criticism. The work should be in the hands of every practitioner.—*New York Med. Record*, Feb. 26, 1881.

The style and character of this work are too well known to the profession to require an introduction. For a number of years this volume has occupied a leading position as a text-book in the majority of medical schools, and the high position accorded to it in the past is a guarantee of a hearty welcome in this new edition. The book may be said to represent the present state of the science of medicine as now understood and taught. It is a safe guide to students and practitioners of medicine.—*Maryland Medical Journal*, March 1, 1881.

The author has, in this edition, revised and rewritten a great part and made it accord with the more advanced ideas which have been developed within the past few years. He is the more fitted to do so, as he is actively engaged in his profession, and can make deductions, not from the work of others, but from his own labors. It is a treatise which every American physician should have upon his table, and which he should consult on occasions when his leisure permits him to do so.—*St. Louis Med and Surg. Journal*, March, 1881.

BY THE SAME AUTHOR.

CLINICAL MEDICINE; a Systematic Treatise on the Diagnosis and Treatment of Diseases. Designed for Students and Practitioners of Medicine. In one large and handsome octavo volume of 795 pages; cloth, $4 50; leather, $5 50; half Russia, $6. (*Now Ready.*)

The eminent teacher who has written the volume under consideration has recognized the needs of the American profession, and the result is all that we could wish. The style in which it is written is peculiarly the author's; it is clear and forcible, and marked by those characteristics which have rendered him one of the best writers and teachers this country has ever produced. We have not space for so full a consideration of this remarkable work as we would desire.—*St. Louis Clin. Record*, Oct. 1879.

It is here that the skill and learning of the great clinician are displayed. He has given us a storehouse of medical knowledge, excellent for the student, convenient for the practitioner, the result of a long life of the most faithful clinical work, collected by an energy as vigilant and systematic as untiring, and weighed by a judgment no less clear than his observation is close.—*Archives of Medicine*, Dec. 1879.

To give an adequate and useful conspectus of the extensive field of modern clinical medicine is a task of no ordinary difficulty; but to accomplish this consistently, with brevity and clearness, the different subjects and their several parts receiving the attention which, relatively to their importance, medical opinion claims for them, is still more difficult. This task we feel bound to say has been executed with more than partial success by Dr Flint, whose name is already familiar to students of advanced medicine in this country as that of the author of two works of great merit on special subjects, and of numerous papers, exhibiting much originality and extensive research.—*The Dublin Journal*, Dec. 1879.

There is every reason to believe that this book will be well received. The active practitioner is frequently in need of some work that will enable him to obtain information in the diagnosis and treatment of cases with comparatively little labor. Dr. Flint has the faculty of expressing himself clearly, and at the same time so concisely as to enable the searcher to traverse the entire ground of his search, and at the same time obtain all that is essential, without plodding through an interminable space.—*N. Y. Med. Journ.*, Nov. 1879.

The great object is to place before the reader the latest observations and experience in diagnosis and treatment. Such a work is especially valuable to students. It is complete in its special design, and yet so condensed, that he can by its aid, keep up with the lectures on practice without neglecting other branches. It will not escape the notice of the practitioner that such a work is most valuable in culling points in diagnosis and treatment in the intervals between the daily rounds of visits since he can in a few minutes refresh his memory, or learn the latest advance in the treatment of diseases which demand his instant attention.—*Cincinnati Lancet and Clinic*, Oct. 25, 1879.

PREVENTIVE MEDICINE. In one octavo volume of about 500 pages. (*Shortly.*)

HARTSHORNE (*HENRY*), *M.D.*,
Professor of Hygiene in the University of Pennsylvania

ESSENTIALS OF THE PRINCIPLES AND PRACTICE OF MEDICINE. A handy book for Students and Practitioners Fifth edition, thoroughly revised and rewritten. With 140 illustrations. In one handsome royal 12mo. volume, of about 600 pages. (*In Press.*)

The very great success which has exhausted four large editions of this work shows that the author has succeeded in supplying a want felt by a large portion of the profession. It has also enabled him in successive revisions to perfect the details of his plan, and to render the work still more worthy of the favor with which it has been received. The present edition has had sedulous attention at the hands of the author to bring it in every way on a level with the most advanced condition of the subject, and no effort has been spared to make the volume worthy a continuance of the very great favor with which it has hitherto been received.

WOODBURY (*FRANK*). *M.D.*,
Physician to the German Hospital, Philadelphia, late Chief Assist. to Med. Clinic, Jeff. College Hospital, etc.

A HANDBOOK OF THE PRINCIPLES AND PRACTICE OF Medicine; for the use of Students and Practitioners. In one neat volume, royal 12mo., with illustrations. (*In Press.*)

FOTHERGILL (*J. MILNER*). *M.D. Edin., M.R.C.P. Lond.*,
Asst. Phys. to the West Lond. Hosp.; Asst. Phys. to the City of Lond. Hosp., etc.

THE PRACTITIONER'S HANDBOOK OF TREATMENT; Or, the Principles of Therapeutics. Second edition, revised and enlarged. In one very neat octavo volume of about 650 pages. Cloth, $4 00; very handsome half Russia, $5 50. (*Just Ready.*)

The junior members of the profession will find in it a work that should not only be read, but carefully studied. It will assist them in the proper selection and combination of therapeutical agents best adapted to each case and condition, and enable them to prescribe intelligently and successfully. To do full justice to a work of this scope and character will be impossible in a review of this kind. The book itself must be read to be fully appreciated. —*St. Louis Courier of Medicine*, Nov. 1880.

The author merits the thanks of every well-educated physician for his efforts toward rationalizing the treatment of diseases upon the scientific basis of physiology. Every chapter, every line, has the impress of a master hand, and while the work is thoroughly scientific in every particular, it presents to the thoughtful reader all the charms and beauties of a well-written novel. No physician can well afford to be without this valuable work, for its originality makes it fill a niche in medical literature hitherto vacant.—*Nashville Journ. of Med. and Surg.*, Oct. 1880.

Throughout the work, while room is left for difference of opinion in matters of detail, the main courses of treatment are so carefully founded on well-established principles, that no essential difference is felt to be possible. The closing chapter contains much concentrated worldly wisdom; and, if carefully read, digested, and assimilated, will, in many an emergency, stand the young medical man in good stead.—*Lond. Med. Record*, Oct. 12, 1880.

FINLAYSON (*JAMES*), *M.D.*,
Physician and Lecturer on Clinical Medicine in the Glasgow Western Infirmary, etc.

CLINICAL DIAGNOSIS; A Handbook for Students and Practitioners of Medicine. In one handsome 12mo. volume, of 546 pages, with 85 illustrations. Cloth, $2 63. (*Lately Issued.*)

The book is an excellent one, clear, concise, convenient, practical. It is replete with the very knowledge the student needs when he quits the lecture-room and the laboratory for the ward and sick-room, and does not lack in information that will meet the wants of experienced and older men.—*Phila. Med. Times*, Jan. 4, 1879.

This is one of the really useful books. It is attractive from preface to the final page, and ought to be given a place on every office table, because it contains in a condensed form all that is valuable in semeiology and diagnostics to be found in bulkier volumes, and because in its arrangement and complete index, it is unusually convenient for quick reference in any emergency that may come upon the busy practitioner. —*N. C. Med. Journ.*, Jan. 1879.

WATSON (*THOMAS*), *M.D., &c.*

LECTURES ON THE PRINCIPLES AND PRACTICE OF PHYSIC. Delivered at King's College, London. A new American, from the Fifth revised and enlarged English edition. Edited, with additions, and several hundred illustrations, by HENRY HARTSHORNE, M.D., Professor of Hygiene in the University of Pennsylvania. In two large and handsome 8vo. vols. Cloth, $9 00; leather, $11 00.

WILLIAMS'S PULMONARY CONSUMPTION; its Nature, Varieties and Treatment. With an Analysis of One Thousand Cases to exemplify its duration. In one neat octavo volume of about 350 pages; cloth, $2 50.

SLADE ON DIPHTHERIA; its Nature and Treatment, with an account of the History of its Prevalence in various Countries Second and revised edition. In one neat royal 12mo. volume, cloth, $1 25.

WALSHE ON THE DISEASES OF THE HEART AND GREAT VESSELS. Third American Edition. In 1 vol. 8vo., 420 pp., cloth, $3 00.

SMITH ON CONSUMPTION; ITS EARLY AND REMEDIABLE STAGES 1 vol. 8vo. pp. 254 $2 25.

FULLER ON DISEASES OF THE LUNGS AND AIR-PASSAGES. Their Pathology, Physical Diagnosis, Symptoms and Treatment. From the Second and revised English edition. In one handsome octavo volume of about 500 pages: cloth, $3 50.

REYNOLDS (*J. RUSSELL*), *M.D.*,

Prof. of the Principles and Practice of Medicine in Univ. College, London.

A SYSTEM OF MEDICINE WITH NOTES AND ADDITIONS BY HENRY HARTSHORNE, M.D., late Professor of Hygiene in the University of Penna. In three large and handsome octavo volumes, containing 3052 closely printed double-columned pages, with numerous illustrations. *Sold only by subscription.* Price per vol., in cloth, $5.00; in sheep, $6.00: half Russia, raised bands, $6.50. Per set in cloth, $15; sheep, $18; half Russia, $19.50

VOLUME I. (*just ready*) contains GENERAL DISEASES and DISEASES OF THE NERVOUS SYSTEM.

VOLUME II. (*just ready*) contains DISEASES OF RESPIRATORY and CIRCULATORY SYSTEMS.

VOLUME III. (*just ready*) contains DISEASES OF THE DIGESTIVE and BLOOD GLANDULAR SYSTEMS, OF THE URINARY ORGANS, OF THE FEMALE REPRODUCTIVE SYSTEM, and OF THE CUTANEOUS SYSTEM.

Reynolds's SYSTEM OF MEDICINE, recently completed, has acquired, since the first appearance of the first volume, the well-deserved reputation of being the work in which modern British medicine is presented in its fullest and most practical form. This could scarce be otherwise in view of the fact that it is the result of the collaboration of the leading minds of the profession, each subject being treated by some gentleman who is regarded as its highest authority—as for instance, Diseases of the Bladder by Sir HENRY THOMPSON, Malpositions of the Uterus by GRAILY HEWITT, Insanity by HENRY MAUDSLEY, Consumption by J. HUGHES BENNET, Diseases of the Spine by CHARLES BLAND RADCLIFFE, Pericarditis by FRANCIS SIBSON. Alcoholism by FRANCIS E. ANSTIE, Renal Affections by WILLIAM ROBERTS, Asthma by HYDE SALTER, Cerebral Affections by H CHARLTON BASTIAN, Gout and Rheumatism by ALFRED BARING GARROD, Constitutional Syphilis by JONATHAN HUTCHINSON, Diseases of the Stomach by WILSON FOX, Diseases of the Skin by BALMANNO SQUIRE, Affections of the Larynx by MORELL MACKENZIE, Diseases of the Rectum by BLIZARD CURLING, Diabetes by LAUDER BRUNTON, Intestinal Diseases by JOHN SYER BRISTOWE, Catalepsy and Somnambulism by THOMAS KING CHAMBERS, Apoplexy by J. HUGHLINGS JACKSON, Angina Pectoris by Professor GAIRDNER, Emphysema of the Lungs by Sir WILLIAM JENNER, etc. etc. All the leading schools in Great Britain have contributed their best men in generous rivalry, to build up this monument of medical science. St. Bartholomew's, Guy's, St Thomas's, University College, St. Mary's, in London, while the Edinburgh, Glasgow, and Manchester schools are equally well represented, the Army Medical School at Netley, the military and naval services, and the public health boards. That a work conceived in such a spirit, and carried out under such auspices should prove an indispensable treasury of facts and experience, suited to the daily wants of the practitioner, was inevitable, and the success which it has enjoyed in England, and the reputation which it has acquired on this side of the Atlantic, have sealed it with the approbation of the two pre-eminently practical nations.

Its large size and high price having kept it beyond the reach of many practitioners in this country who desire to possess it, a demand has arisen for an edition at a price which shall render it accessible to all. To meet this demand the present edition has been undertaken. The five volumes and five thousand pages of the original have, by the use of a smaller type and double columns, been compressed into three volumes of over three thousand pages, clearly and handsomely printed, and offered at a price which renders it one of the cheapest works ever presented to the American profession.

But not only is the American edition more convenient and lower priced than the English; it is also better and more complete. Some years having elapsed since the appearance of a portion of the work, additions are required to bring up the subjects to the existing condition of science. Some diseases, also, which are comparatively unimportant in England, require more elaborate treatment to adapt the articles devoted to them to the wants of the American physician; and there are points on which the received practice in this country differs from that adopted abroad. The supplying of these deficiencies has been undertaken by HENRY HARTSHORNE, M.D., late Professor of Hygiene in the University of Pennsylvania, who has endeavored to render the work fully up to the day, and as useful to the American physician as it has proved to be to his English brethren. The number of illustrations has also been largely increased, and no effort spared to render the typographical execution unexceptionable in every respect.

Really too much praise can scarcely be given to this noble book. It is a cyclopædia of medicine written by some of the best men of Europe. It is full of useful information such as one finds frequent need of in one's daily work As a book of reference it is invaluable. It is up with the times. It is clear and concentrated in style, and its form is worthy of its famous publisher.—*Louisville Med. News*, Jan. 31, 1880.

"Reynolds' System of Medicine" is justly considered the most popular work on the principles and practice of medicine in the English language The contributors to this work are gentlemen of well-known reputation on both sides of the Atlantic. Each gentleman has striven to make his part of the work as practical as possible, and the information contained is such as is needed by the busy practitioner.—*St. Louis Med. and Surg. Journ.*, Jan. '80.

Dr. Hartshorne has made ample additions and revisions, all of which give increased value to the volume, and render it more useful to the American practitioner There is no volume in English medical literature more valuable, and every purchaser will, on becoming familiar with it, congratulate himself on the possession of this vast storehouse of information, in regard to so many of the subjects with which he should be familiar.—*Gaillard's Med. Journ.*, Feb. 1880.

There is no medical work which we have in times past more frequently and fully consulted when perplexed by doubts as to treatment, or by having unusual or apparently inexplicable symptoms presented to us than "Reynolds' System of Medicine." Among its contributors are gentlemen who are as well known by reputation upon this side of the Atlantic as in Great Britain, and whose right to speak with authority upon the subjects about which they have written, is recognized the world over. They have evidently striven to make their essays as practical as possible, and while these are sufficiently full to entitle them to the name of monographs, they are not loaded down with such an amount of detail as to render them wearisome to the general reader. In a word, they contain just that kind of information which the busy practitioner frequently finds himself in need of. In order that any deficiencies may be supplied, the publishers have committed the preparation of the book for the press to Dr. Henry Hartshorne, whose judicious notes distributed throughout the volume afford abundant evidence of the thoroughness of the revision to which he has subjected it.—*Am. Jour. Med. Sciences*, Jan. 1880.

BARTHOLOW (ROBERTS), A.M., M.D., LL.D.

Prof. of Materia Medica and General Therapeutics in the Jeff. Med. Coll. of Phila, etc.

A PRACTICAL TREATISE ON ELECTRICITY IN ITS APPLICATION TO MEDICINE.

In one very handsome 8vo. volume of about 270 pages, with 98 illustrations. Cloth, $2 50. (*Just ready.*)

EXTRACT FROM THE AUTHOR'S PREFACE.

I have attempted in the preparation of this work to avoid these errors; to prepare one so simple in statement that a student without previous acquaintance with the subject, may readily master the essentials; so complete as to embrace the whole subject of medical electricity, and so condensed as to be complete in a moderate compass. I have endeavored to keep constantly in view the needs of the two classes for whom the work is prepared—students and practitioners. I have assumed an entire unacquaintance with the elements of the subject as the point of departure—for I am addressing those who have either failed to acquire this preliminary knowledge, or having acquired it, find that after the lapse of years, it has become misty and confused. In the accounts of electrical phenomena I have adhered to the modes of expression with which the medical electrical text-books have made us familiar.

This book, then, must be regarded as the exposition of electricity as a remedial agent, made by a medical practitioner for the use of medical practitioners. No claim is made on the ground of pure science. It is believed, however, that the work makes an adequate presentation of the subject, regarding electricity as a remedial agent—as one of the means employed for the treatment and cure of disease.

So far as we know, the need of a clear, simple, untechnical, reliable, concise, and modern treatise upon the subject of medical electricity is only supplied by the volume under consideration. It is not too much to say that, if availed of, it will render accessible to a vast number of members of the profession a therapeutic agent of the greatest value, but which has heretofore been practically of no use whatever to them.—*Maryland Med. Journal*, June 1, 1881.

We have not yet come across a book that can compare with this in clearness and simplicity of statement. We have for a long time needed a text-book on medical electricity, condensed and yet complete, and this want has been well supplied by the distinguished author. The illustrations are elegant, and the book as a whole is a valuable addition to the collection of any student or practitioner.—*Buffalo Med. and Surg. Journal*, June, 1881.

As a whole, the book must be looked upon as an exposition of electricity for remedial purposes, written by a medical practitioner for the use of medical practitioners. From this standpoint the work is worthy of the careful study of all who desire to investigate this subject for purely practical purposes. This work meets a want of very many students and medical practitioners. We greatly err if it be not gladly welcomed by them. The author, from his long experience as a practitioner, is admirably fitted to perform the task of writing a work of this kind for this special class of men.—*Detroit Lancet*, June, 1881.

This book is expressive of careful research and a nice discrimination in the selection of such matter from that at the author's command as is best adapted for the guidance and instruction of the physician whose interest in electricity is proportionate to its practical bearing on diagnosis and treatment. It is thorough, it is accurate, it is readable, and above all is essentially utilizable, if we may use the word, and renders easy of access to the general practitioner the *modus operandi* of employing this very valuable therapeutic agent.—*N. Y. Medical Gaz.*, June 11, 1881.

MITCHELL (S. WEIR), M.D.,

Phys. to Orthopædic Hospital and the Infirmary for Dis. of the Nervous System, Phila., etc. etc.

LECTURES ON DISEASES OF THE NERVOUS SYSTEM, ESPECIALLY IN WOMEN.

In one very handsome 12mo. volume of about 250 pages, with five lithographic plates. Cloth, $1 75 (*Just Ready*)

The life-long devotion of the author to the subjects discussed in this volume has rendered it eminently desirable that the results of his labors should be embodied for the benefit of those who may experience the difficulties connected with the treatment of this class of disease. Many of these lectures are fresh studies of hysterical affections; others treat of the modifications his views have undergone in regard to certain forms of treatment, while, throughout the whole work he has been careful to keep in view the practical lessons of his cases.

It is a record of a number of very remarkable cases, with acute analyses and discussions, clinical, physiological, and therapeutical. It is a book to which the physician meeting with a new hysterical experience, or in doubt whether his new experience is hysterical, may well turn with a well-grounded hope of finding a parallelism; it will be a new experience, indeed, if no similar one is here recorded.—*Phila. Med. Times*, June 4, 1881.

The name of the author is sufficient guarantee that these topics are ably and appreciatively discussed; suffice it to say that the principles of treatment, both hygienic and therapeutic, are clearly indicated. The articles being in the form of clinical lectures, abound in illustrative cases, and are much easier reading than a systematic treatise on the same topics.—*College and Clinical Record*, May 15, 1 81.

It is needless to say that these lectures are extraordinarily rich in acute observation and sound instruction. The reputation of the author is a guarantee of that, and no reader will be disappointed. Nor can too much be said in praise of the admirable style of his medical writings, and each of these lectures reads with the finished grace of a polished essay. Indeed, the book throughout is so fascinating a one that it could not fail to be read entire by every one who begins its pages.—*Phila. Med. and Surg. Reporter*, May 7, 1881.

The book throughout is not only intensely entertaining, but it contains a large amount of rare and valuable information. Dr Mitchell has recorded not only the results of his most careful observation, but has added to the knowledge of the subjects treated by his original investigation and practical study. The book is one we can commend to all of our readers.—*Maryland Med. Journal*, May 1, 1881.

HAMILTON (ALLAN McLANE), M.D.,

Attending Physician at the Hospital for Epileptics and Paralytics, Blackwell's Island, N.Y., and at the Out-Patients' Department of the New York Hospital.

NERVOUS DISEASES; THEIR DESCRIPTION AND TREATMENT.

Second edition, thoroughly revised and rewritten. In one handsome octavo volume of about 600 pages, with numerous illustrations. (*In Press.*)

MORRIS (MALCOLM), M.D.,

Joint Lecturer on Dermatology, St. Mary's Hospital Med. School.

SKIN DISEASES, Including their Definitions, Symptoms, Diagnosis, Prognosis, Morbid Anatomy and Treatment. A Manual for Students and Practitioners.

In one 12mo. volume of over 300 pages. With illustrations. Cloth, $1 75. (*Now Ready.*)

To physicians who would like to know something about skin diseases, so that when a patient presents himself for relief they can make a correct diagnosis and prescribe a rational treatment, we unhesitatingly recommend this little book of Dr. Morris. The affections of the skin are described in a terse, lucid manner, and their several characteristics so plainly set forth that diagnosis will be easy. The treatment in each case is such as the experience of the most eminent dermatologists advise.—*Cincinnati Medical News*, April, 1880.

This is emphatically a learner's book; for we can safely say, so far as our judgment goes, that in the whole range of medical literature of a like scope there is no book which for clearness of expression and methodical arrangement is better adapted to promote a rational conception of dermatology, a branch confessedly difficult and perplexing to the beginner.—*St. Louis Courier of Medicine*, April, 1880.

The author of this manual has evidently a full and intimate acquaintance with the literature of dermatology, and with the most recent developments and appliances of cutaneous medicine. He has produced a plain, practical book, by aid of which, who so chooses may train his eye to the recognition of light but significant differences. The descriptions are neither too vague nor over-refined: the directions for treatment are clear and succinct.—*London Brain*, April, 1880

The author's task has been well done and has produced one of the best recent works upon the difficult subject of which it treats; there is no work published which gives a better view of the elementary facts and principles of dermatology.—*New Orleans Medical and Surgical Journal*, April, 1880.

FOX (TILBURY), M.D., F.R.C.P., and T. C. FOX, B.A., M.R.C.S.,

Physician to the Department for Skin Diseases, University College Hospital.

EPITOME OF SKIN DISEASES. WITH FORMULÆ. For Students and Practitioners.

Second edition, thoroughly revised and greatly enlarged. In one very handsome 12mo. volume of 216 pages. Cloth, $1 38.

FLINT (AUSTIN), M.D.,

Professor of the Principles and Practice of Medicine in Bellevue Hospital Med. College, N. Y.

A MANUAL OF PERCUSSION AND AUSCULTATION; of the Physical Diagnosis of Diseases of the Lungs and Heart, and of Thoracic Aneurism.

Second edition. In one handsome royal 12mo. volume: cloth, $1 63. (*Just Ready.*)

The little work before us has already become a standard one, and has become extensively adopted as a text-book. There is certainly none better. It contains the substance of the lessons which the author has for many years given, in connection with practical instruction in auscultation and percussion, to private classes, composed of medical students and practitioners.—*Cincinnati Med. News*, Feb. 1880.

BY THE SAME AUTHOR.

PHTHISIS: ITS MORBID ANATOMY, ETIOLOGY, SYMPTOMATIC EVENTS AND COMPLICATIONS, FATALITY AND PROGNOSIS, TREATMENT AND PHYSICAL DIAGNOSIS; in a series of Clinical Studies.

By Austin Flint, M.D., Prof. of the Principles and Practice of Medicine in Bellevue Hospital Med. College, New York. In one handsome octavo volume: $3 50.

BY THE SAME AUTHOR.

A PRACTICAL TREATISE ON THE DIAGNOSIS, PATHOLOGY, AND TREATMENT OF DISEASES OF THE HEART.

Second revised and enlarged edition. In one octavo volume of 550 pages, with a plate, cloth, $4.

BY THE SAME AUTHOR.

A PRACTICAL TREATISE ON THE PHYSICAL EXPLORATION OF THE CHEST AND THE DIAGNOSIS OF DISEASES AFFECTING THE RESPIRATORY ORGANS.

Second and revised edition. In one handsome octavo volume of 595 pages, cloth, $4 50.

BROWN (LENNOX), F.R.C.S. Ed.,

Senior Surgeon to the Central London Throat and Ear Hospital, etc.

THE THROAT AND ITS DISEASES.

Second American, from the Second English Edition, thoroughly revised. With one hundred Typical Illustrations in colors, and fifty wood engravings, designed and executed by the author. In one very handsome imperial octavo volume of over 350 pages. (*Preparing.*)

SEILER (CARL), M.D.,

Lecturer on Laryngoscopy at the Univ. of Penna., Chief of the Throat Dispensary at the Univ. Hospital, Phila., etc.

HANDBOOK OF DIAGNOSIS AND TREATMENT OF DISEASES OF THE THROAT AND NASAL CAVITIES.

In one handsome royal 12mo. volume, of 156 pages, with 35 illustrations; cloth, $1. (*Lately Issued.*)

We most heartily commend this book as showing sound judgment in practice, and perfect familiarity with the literature of the specialty it so ably epitomizes.—*Philada. Med. Times*, July 5, 1879.

A convenient little handbook, clear, concise, and accurate in its method, and admirably fulfilling its purpose of bringing the subject of which it treats within the comprehension of the general practitioner.—*N. C. Med. Jour.*, June, 1879.

CLINICAL OBSERVATIONS ON FUNCTIONAL NERVOUS DISORDERS By C. Handfield Jones, M.D., Physician to St. Mary's Hospital, &c. Second American Edition. In one handsome octavo volume of 348 pages, cloth, $3 25.

HILLIER'S HANDBOOK OF SKIN DISEASES, for Students and Practitioners. Second Am Ed In one royal 12mo. vol. of 358 pp. With illustrations. Cloth, $2 25.

BUMSTEAD (FREEMAN J.), M.D., LL.D.,

Late Professor of Venereal Diseases at the Col. of Phys. and Surg., New York, &c.

THE PATHOLOGY AND TREATMENT OF VENEREAL DISEASES.

Including the results of recent investigations upon the subject. Fourth Edition, revised and largely rewritten with the co-operation of R. W. Taylor, M.D., of New York, Prof. of Dermatology in the Univ. of Vt. In one large and handsome octavo volume of 835 pages, with 138 illustrations. Cloth, $4 75; leather, $5 75; half Russia, $6 25. (*Now Ready.*)

We have to congratulate our countrymen upon the truly valuable addition which they have made to American literature. The careful estimate of the value of the volume, which we have made, justifies us in declaring that this is the best treatise on venereal diseases in the English language, and we might add, if there is a better in any other tongue we cannot name it; there are certainly no books in which the student or the general practitioner can find such an excellent *résumé* of the literature of any topic, and such practical suggestions regarding the treatment of the various complications of every venereal disease. We take pleasure in repeating that we believe this to be the best treatise on venereal disease in the English language, and we congratulate the authors upon their brilliant addition to American medical literature.—*Chicago Med. Journal and Examiner*, February, 1880.

It is, without exception, the most valuable single work on all branches of the subject of which it treats in any language. The pathology is sound, the work is, at the same time, in the highest degree practical, and the hints that he will get from it for the management of any one case, at all obscure or obstinate, will more than repay him for the outlay.—*Archives of Medicine*, April, 1880.

This now classical work on venereal disease comes to us in its fourth edition rewritten, enlarged, and materially improved in every way. Dr. Taylor, as we had every reason to expect, has performed this part of his work with unusual excellence. We feel that what has been written has done but scanty justice to the merits of this truly great treatise.—*St. Louis Courier of Medicine*, Feb. 1880

We find that we have here practically a new book—that the statement of the title-page, as to the fact that it has been largely rewritten, is a sufficiently modest announcement for the important changes in the text. After a thorough examination of the present edition, we can assert confidently that the enormous labor we have described has been here most faithfully and conscientiously performed.—*Amer Journ. Med. Sci.*, Jan. 1880.

It is one of the best general treatises on venereal diseases with which we are acquainted, and is especially to be recommended as a guide to the treatment of syphilis.—*London Practitioner*, March, 1880.

GROSS (SAMUEL W.), A.M., M.D.,

Lecturer on Genito-Urinary and Venereal Diseases in the Jefferson Medical College, Phila.

A PRACTICAL TREATISE ON IMPOTENCE, STERILITY

AND ALLIED DISORDERS OF THE MALE SEXUAL ORGANS. In one very hand some octavo volume of 174 pages, with 16 illustrations. Cloth, $1 50. (*Just Ready.*)

EXTRACT FROM THE AUTHOR'S PREFACE.

"My aim has been to supply, in a compact form, practical and strictly scientific information, especially adapted to the wants of the general practitioner, in regard to a class of common and grave disorders, upon the correction of which so much of human happiness depends. In the chapter on Sterility, the abnormal conditions of the semen and the causes which deprive it of its fecundating properties are fully considered—a portion of the work intended to supplement the subject of sterility in the female. From answers to letters addressed to many of the most prominent writers in this country on gynæcology, I find that, with few exceptions, the woman alone commands attention in unfruitful marriages. The importance of examining the husband before subjecting the wife to operation will be best appreciated when I state that he is, as a rule, at fault in at least one example in every six."

CULLERIER (A.), *Surgeon to the Hôpital du Midi.* and BUMSTEAD (FREEMAN J.), *Professor of Venereal Diseases in the College of Physicians and Surgeons, N. Y.*

AN ATLAS OF VENEREAL DISEASES. Translated and Edited by

FREEMAN J. BUMSTEAD. In one large imperial 4to. volume of 328 pages, double-columns, with 26 plates, containing about 150 figures, beautifully colored, many of them the size of life; strongly bound in cloth, $17 00; also, in five parts, stout wrappers, at $3 per part. Anticipating a very large sale for this work, it is offered at the very low price of THREE DOLLARS a Part, thus placing it within the reach of all who are interested in this department of practice. Gentlemen desiring early impressions of the plates would do well to order it without delay. A specimen of the plates and text sent free by mail, on receipt of 25 cents.

LEE'S LECTURES ON SYPHILIS AND SOME FORMS OF LOCAL DISEASE AFFECTING PRINCIPALLY THE ORGANS OF GENERATION. In one handsome octavo volume; cloth, $2 25.

CONDIE'S PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. Sixth edition, revised and augmented. In one large octavo volume of nearly 800 closely-printed pages, cloth, $5 25; leather, $6 25.

WILSON'S STUDENT'S BOOK OF CUTANEOUS MEDICINE and DISEASES OF THE SKIN. In one very handsome royal 12mo volume. $3 50.

CHAMBERS'S MANUAL OF DIET AND REGIMEN IN HEALTH AND SICKNESS. In one handsome octavo volume. Cloth, $2 75.

BASHAM ON RENAL DISEASES: a Clinical Guide to their Diagnosis and Treatment. With Illustrations. In one 12mo. vol. of 304 pages, cloth, $2 00.

LECTURES ON THE STUDY OF FEVER. By A. HUDSON, M.D., M.R.I.A., Physician to the Meath Hospital. In one vol. 8vo., cloth, $2 50.

A TREATISE ON FEVER. By ROBERT D. LYONS, K.C.C. In one octavo volume of 362 pages, cloth $2 25.

HILL ON SYPHILIS AND LOCAL CONTAGIOUS DISORDERS. In one handsome octavo volume; cloth $3 25.

SMITH'S PRACTICAL TREATISE ON THE WASTING DISEASES OF INFANCY AND CHILDHOOD. Second American, from the Second revised and enlarged English edition. In one handsome octavo volume, cloth, $2 50.

LA ROCHE ON PNEUMONIA. 1 vol. 8vo., cloth, of 500 pages. Price, $3 00.

SMITH (*J. LEWIS*), *M.D.*,

Clinical Professor of Diseases of Children in the Bellevue Hospital Med. College, N. Y.

A COMPLETE PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. Fifth Edition, thoroughly revised and rewritten. In one handsome octavo volume of about 800 pages, with illustrations. (*In Press.*)

The very marked favor with which this work has been received wherever the English language is spoken, has stimulated the author, in the preparation of the Fifth Edition, to spare no pains in the endeavor to render it worthy in every respect of a continuance of professional confidence. Many portions of the volume have been rewritten, and much new matter introduced, but by an earnest effort at condensation, the size of the work will not be materially increased.

KEATING (*JOHN M.*), *M.D.*,

Lecturer on the Diseases of Children at the University of Pennsylvania, etc.

THE MOTHER'S GUIDE IN THE MANAGEMENT AND FEEDING OF INFANTS. In one handsome 12mo. vol. of 118 pages. Cloth, $1 00. (*Now Ready.*)

In the preparation of this volume, it has been the object of the author to provide a work that physicians can safely place in the hands of their patients for the purpose of instructing them as to the care and management of their children throughout the first three years of their life. While there already exist a number of such manuals, there is yet lacking one of native origin, especially adapted to the peculiarities of American climate, modes of living, and the various minor circumstances in which the customs of our country differ from those of the old world. The position occupied by the author as lecturer on Diseases of Children at the Univ. of Penna., is a guarantee of the satisfactory manner in which his labor has been performed.

WEST (*CHARLES*), *M.D.*,

Physician to the Hospital for Sick Children, London, &c.

LECTURES ON THE DISEASES OF INFANCY AND CHILDHOOD. Fifth American from the Sixth revised and enlarged English edition. In one large and handsome octavo volume of 678 pages. Cloth, $4 50; leather, $5 50.

BY THE SAME AUTHOR. (*Lately Issued.*)

ON SOME DISORDERS OF THE NERVOUS SYSTEM IN CHILDHOOD; being the Lumleian Lectures delivered at the Royal College of Physicians of London, in March, 1871. In one volume small 12mo., cloth, $1 00.

BY THE SAME AUTHOR.

LECTURES ON THE DISEASES OF WOMEN. Third American, from the Third London edition. In one neat octavo volume of about 550 pages, cloth, $3 75; leather, $4 75.

SWAYNE (*JOSEPH GRIFFITHS*), *M.D.*,

Physician-Accoucheur to the British General Hospital, &c.

OBSTETRIC APHORISMS FOR THE USE OF STUDENTS COMMENCING MIDWIFERY PRACTICE. Second American, from the Fifth and Revised London Edition, with Additions by E. R. HUTCHINS, M.D. With Illustrations. In one neat 12mo. volume. Cloth, $1 25.

CHURCHILL ON THE PUERPERAL FEVER AND OTHER DISEASES PECULIAR TO WOMEN. 1 vol. 8vo., pp. 450, cloth $2 50.

DEWEES'S TREATISE ON THE DISEASES OF FEMALES. With illustrations. Eleventh Edition, with the Author's last improvements and corrections. In one octavo volume of 536 pages, with plates, cloth. $3 00.

MEIGS ON THE NATURE, SIGNS AND TREATMENT OF CHILDBED FEVER. 1 vol. 8vo., pp. 365, cloth. $2 00.

ASHWELL'S PRACTICAL TREATISE ON THE DISEASES PECULIAR TO WOMEN. Third American, from the Third and revised London edition. 1 vol. 8vo., pp. 528, cloth. $3 50.

WINCKEL (*F.*),

Professor and Director of the Gynæcological Clinic in the University of Rostock.

A COMPLETE TREATISE ON THE PATHOLOGY AND TREATMENT OF CHILDBED, for Students and Practitioners. Translated, with the consent of the author, from the Second German Edition, by JAMES READ CHADWICK, M.D. In one octavo volume. Cloth, $4 00.

MONTGOMERY'S EXPOSITION OF THE SIGNS AND SYMPTOMS OF PREGNANCY. With two exquisite colored plates, and numerous wood-cuts. In 1 vol. 8vo., of nearly 600 pp., cloth, $3 75.

RIGBY'S SYSTEM OF MIDWIFERY. With notes and Additional Illustrations. Second American edition. One volume octavo, cloth, 422 pages, $2 50.

THOMAS (*T. GAILLARD*), *M.D.*,

Professor of Obstetrics, &c., in the College of Physicians and Surgeons, N. Y., &c

A PRACTICAL TREATISE ON THE DISEASES OF WOMEN. Fifth

Edition, thoroughly revised and rewritten. In one large and handsome octavo volume of over 800 pages, with 266 illustrations. Cloth, $5; leather, $6; very handsome half Russia, raised bands, $6 50. (*Just Ready.*)

The author has taken advantage of the opportunity afforded by the call for a new edition of this work to render it worthy a continuance of the very remarkable favor with which it has been received. Every portion of the work has been carefully revised, very much of it has been rewritten, and additions and alterations introduced wherever the advance of science and the increased experience of the author have shown them desirable. At the same time special care has been exercised to avoid undue increase in the size of the volume. To accommodate the numerous additions a more condensed but very clear letter has been used, notwithstanding which, the number of pages has been increased by more than fifty. The series of illustrations has been extensively changed; many which seemed to be superfluous have been omitted, and a large number of new and superior drawings have been inserted. In its improved form, therefore, it is hoped that the volume will maintain the character it has acquired of a standard authority on every detail of its important subject.

An examination of the work will satisfy that it is one of great merit. It is not a mere compilation from other works, but is the fruit of the ripe thought, sound judgment, and critical observations of a learned, scientific man. It is a treasury of knowledge of the department of medicine to which it is devoted In its present revised state it certainly holds a foremost position as a gynæcological work, and will continue to be regarded as a standard authority —*Cincinnati Med. News*, Dec. 1880.

This work needs no introduction to any of the civilized nations of the world. The edition before us adds to the strength of former volumes. With the wisdom of a master teacher he here gives the results that, in his judgment, are most trustworthy at the present time. In its own place it has no rival, because the author is the best teacher on this subject to the masses of the profession As hitherto this work will be the text-book on diseases of women We only wish that in other branches of medicine as capable teachers could be found to write our text-books.—*Detroit Lancet*, Jan. 1881.

Since its first appearance, twelve years ago, until the present day, it has held a position of high regard, and is generally conceded to be one of the most practical and trustworthy volumes yet presented to the physician and student in the department of gynæcology. The work embodies not only its author's large experience, but reflects his careful study among other authorities in this branch, both at home and abroad Dr. Thomas is an able and conscientious teacher. His writings convey his meaning in the same practical and instructive manner. The last edition of this work is fresh from his pen, with decided changes and improvements over former editions. His book presents generally accepted facts, and as a guide to the student is more useful and reliable than any work in the language on diseases of women. This last edition will add new laurels to those already won. —*Md. Med. Journ.*, Nov. 15, 1880.

It has been enlarged and carefully revised. The author has brought it fully abreast with the times, and as the wave of gynæcological progression has been widespread and rapid during the twelve years that have elapsed since the issue of the first edition, one can conceive of the great improvement this edition must be upon the earlier. It is a condensed encyclopædia of gynæcological medicine. The style of arrangement, the masterly manner in which each subject is treated, and the honest convictions derived from probably the largest clinical experience in that specialty of any in this country, all serve to commend it in the highest terms to the practitioner. —*Nashville Journ. of Med. and Surg.*, Jan. 1881.

EDIS (*ARTHUR W.*), *M.D., Lond. F.R.C.P., M.R.C.S.*

Assist. Obstetric Physician to Middlesex Hospital, late Physician to British Lying-in Hospital.

THE DISEASES OF WOMEN. Including their Pathology, Causation, Symptoms, Diagnosis, and Treatment. A manual for Students and Practitioners.

In one handsome volume with numerous illustrations. (*Shortly.*)

BARNES (*ROBERT*), *M.D., F.R.C.P.*,

Obstetric Physician to St. Thomas's Hospital, &c.

A CLINICAL EXPOSITION OF THE MEDICAL AND SURGICAL DISEASES OF WOMEN. Second American, from the Second Enlarged and Revised English Edition.

In one handsome octavo volume, of 784 pages, with 181 illustrations. Cloth, $4 50; leather, $5 50; half Russia, $6. (*Lately Issued.*)

Dr. Barnes stands at the head of his profession in the old country, and it requires but scant scrutiny of his book to show that it has been sketched by a master. It is plain, practical common sense; shows very deep research without being pedantic; is eminently calculated to inspire enthusiasm without inculcating rashness; points out the dangers to be avoided as well as the success to be achieved in the various operations connected with this branch of medicine; and will do much to smooth the rugged path of the young gynæcologist and relieve the perplexity of the man of mature years. —*Canadian Journ. of Med. Science*, Nov. 1878.

Dr. Barnes's work is one of a practical character, largely illustrated from cases in his own experience, but by no means confined to such, as will be learned from the fact that he quotes from no less than 628 medical authors in numerous countries. Coming from such an author, it is not necessary to say that the work is a valuable one, and should be largely consulted by the profession.—*Am. Supp Obstetrical Journ. Gt. Britain and Ireland*, Oct. 1878.

HODGE (*HUGH L.*), *M.D.*,

Emeritus Professor of Obstetrics, &c., in the University of Pennsylvania.

ON DISEASES PECULIAR TO WOMEN; including Displacements of the Uterus.

With original illustrations. Second edition, revised and enlarged. In one beautifully printed octavo volume of 531 pages, cloth, $4 50.

EMMET (*THOMAS ADDIS*), *M.D.*,

Surgeon to the Woman's Hospital, New York, etc.

THE PRINCIPLES AND PRACTICE OF GYNÆCOLOGY, for the use of Students and Practitioners of Medicine. Second Edition. Thoroughly Revised. In one large and very handsome octavo volume of 875 pages, with 133 illustrations. Cloth, $5; leather, $6; half Russia, raised bands, $6 50. (*Just Ready.*)

PREFACE TO THE SECOND EDITION.

The unusually rapid exhaustion of a large edition of this work, while flattering to the author as an evidence that his labors have proved acceptable, has in a great measure heightened his sense of responsibility. He has therefore endeavored to take full advantage of the opportunity afforded to him for its revision Every page has received his earnest scrutiny; the criticisms of his reviewers have been carefully weighed; and while no marked increase has been made in the size of the volume, several portions have been rewritten, and much new matter has been added. In this minute and thorough revision, the labor involved has been much greater than is perhaps apparent in the results, but it has been cheerfully expended in the hope of rendering the work more worthy of the favor which has been accorded to it by the profession.

In no country of the world has gynæcology received more attention than in America. It is, then, with a feeling of pleasure that we welcome a work on diseases of women from so eminent a gynæcologist as Dr. Emmet, and the work is essentially clinical, and leaves a strong impress of the author's individuality. To criticize, with the care it merits, the book throughout, would demand far more space than is at our command. In parting, we can say that the work teems with original ideas, fresh and valuable methods of practice, and is written in a clear and elegant style, worthy of the literary reputation of the country of Longfellow and Oliver Wendell Holmes.—*Brit. Med. Journ.* Feb 21, 1880.

No gynæcological treatise has appeared which contains an equal amount of original and useful matter; nor does the medical and surgical history of America include a book more novel and useful. The tabular and statistical information which it contains is marvellous, both in quantity and accuracy, and cannot be otherwise than invaluable to future investigators. It is a work which demands not careless reading but profound study. Its value as a contribution o gynæcology is, perhaps, greater than that of all previous literature on the subject combined.—*Chicago Med Gaz.*, April 5, 1880

The wide reputation of the author makes its publication an event in the gynæcological world; and a glance through its pages shows that it is a work to be studied with care. . . . It must always be a work to be carefully studied and frequently consulted by those who practise this branch of our profession.—*Lond. Med. Times and Gaz.*, Jan. 10, 1880.

The character of the work is too well known to require extended notice—suffice it to say that no recent work upon any subject has attained such great popularity so rapidly As a work of general reference upon the subject of Diseases of Women it is invaluable As a record of the largest clinical experience and observation it has no equal. No physician who pretends to keep up with the advances of this department of medicine can afford to be without it.—*Nashville Journ. of Medicine and Surgery*, May, 1880.

DUNCAN (*J. MATTHEWS*), *M.D., LL.D., F.R.S.E., etc.*

CLINICAL LECTURES ON THE DISEASES OF WOMEN, Delivered in Saint Bartholomew's Hospital. In one very neat octavo volume of 173 pages. Cloth, $1 50. (*Just Ready.*)

They are in every way worthy of their author; indeed, we look upon them as among the most valuable of his contributions They are all upon matters of great interest to the general practitioner Some of them deal with subjects that are not, as a rule, adequately handled in the text-books; others of them, while bearing upon topics that are usually treated of at length in such works, yet bear such a stamp of individuality that, if widely read, as they certainly deserve to be, they cannot fail to exert a wholesome restraint upon the undue eagerness with which many young physicians seem bent upon following the wild teachings which so infest the gynæcology of the present day.—*N. Y. Med. Journ.*, March, 1880.

The author is a remarkably clear lecturer, and his discussion of symptoms and treatment is full and suggestive. It will be a work which will not fail to be read with benefit by practitioners as well as by students.—*Phila. Med. and Surg. Reporter*, Feb. 7, 1880.

We have read this book with a great deal of pleasure. It is full of good things The hints on pathology and treatment scattered through the book are sound, trustworthy, and of great value. A healthy scepticism, a large experience, and a clear judgment are everywhere manifest. Instead of bristling with advice of doubtful value and unsound character, the book is in every respect a safe guide.—*The London Lancet*, Jan. 21, 1880.

RAMSBOTHAM (*FRANCIS H.*), *M.D.*

THE PRINCIPLES AND PRACTICE OF OBSTETRIC MEDICINE AND SURGERY, in reference to the Process of Parturition. A new and enlarged edition, thoroughly revised by the author. With additions by W. V. KEATING, M. D., Professor of Obstetrics, &c., in the Jefferson Medical College, Philadelphia. In one large and handsome imperial octavo volume of 650 pages, strongly bound in leather, with raised bands; with sixty-four beautiful plates, and numerous wood-cuts in the text, containing in all nearly 200 large and beautiful figures. $7 00

PARRY (*JOHN S.*), *M.D.*,

Obstetrician to the Philadelphia Hospital, Vice-Prest of the Obstet Society of Philadelphia.

EXTRA-UTERINE PREGNANCY: ITS CLINICAL HISTORY, DIAGNOSIS, PROGNOSIS AND TREATMENT. In one handsome octavo volume. Cloth, $2 50.

TANNER (*THOMAS H.*), *M.D.*

ON THE SIGNS AND DISEASES OF PREGNANCY. First American from the Second and Enlarged English Edition. With four colored plates and illustrations on wood. In one handsome octavo volume of about 500 pages, cloth, $4 25.

LEISHMAN (*WILLIAM*), *M.D.*,

Regius Professor of Midwifery in the University of Glasgow, &c.

A SYSTEM OF MIDWIFERY, INCLUDING THE DISEASES OF PREGNANCY AND THE PUERPERAL STATE.

Third American edition, revised by the Author, with additions by JOHN S. PARRY, M.D., Obstetrician to the Philadelphia Hospital, &c. In one large and very handsome octavo volume, of 733 pages, with over two hundred illustrations. Cloth, $4 50; leather, $5 50; half Russia, $6. (*Just Ready*)

Few works on this subject have met with as great a demand as this one appears to have. To judge by the frequency with which its author's views are quoted, and its statements referred to in obstetrical literature, one would judge that there are few physicians devoting much attention to obstetrics who are without it. The author is evidently a man of ripe experience and conservative views, and in no branch of medicine are these more valuable than in this.—*New Remedies*, Jan. 1880.

We gladly welcome the new edition of this excellent text-book of midwifery. The former editions have been most favorably received by the profession on both sides of the Atlantic In the preparation of the present edition the author has made such alterations as the progress of obstetrical science seems to require, and we cannot but admire the ability with which the task has been performed. We consider it an admirable text-book for students during their attendance upon lectures, and have great pleasure in recommending it. As an exponent of the midwifery of the present day it has no superior in the English language.—*Canada Lancet*, Jan. 1880.

To the American student the work before us must prove admirably adapted, complete in all its parts, essentially modern in its teachings and with demonstrations noted for clearness and precision, it will gain in favor and be recognized as a work of standard merit. The work cannot fail to be popular, and is cordially recommended.—*N. O. Med. and Surg. Journ.*, March, 1880.

PLAYFAIR (*W. S.*), *M.D., F.R.C.P.*,

Professor of Obstetric Medicine in King's College, etc. etc.

A TREATISE ON THE SCIENCE AND PRACTICE OF MIDWIFERY.

Third American edition, revised by the author. Edited, with additions, by ROBERT P. HARRIS, M.D. In one handsome octavo volume of about 700 pages, with nearly 200 illustrations. Cloth, $4; leather, $5; half Russia, $5 50. (*Just Ready.*)

The medical profession has now the opportunity of adding to their stock of standard medical works one of the best volumes on midwifery ever published. The subject is taken up with a master hand. The part devoted to labor in all its various presentations, the management and results, is admirably arranged, and the views entertained will be found essentially modern, and the opinions expressed trustworthy. The work abounds with plates, illustrating various obstetrical positions; they are admirably wrought, and afford great assistance to the student.—*N. O. Med. and Surg. Journ.*, March, 1880.

If inquired of by a medical student what work on obstetrics we should recommend for him, as *par excellence*, we would undoubtedly advise him to choose Playfair's. It is of convenient size, but what is of chief importance, its treatment of the various subjects is concise and plain. While the discussions and descriptions are sufficiently elaborate to render a very intelligent idea of them, yet all details not necessary for a full understanding of the subject are omitted.—*Cincinnati Med. News*, Jan. 1880.

The rapidity with which one edition of this work follows another is proof alike of its excellence and of the estimate that the profession has formed of it. It is indeed so well known and so highly valued that nothing need be said of it as a whole. All things considered, we regard this treatise as the very best on Midwifery in the English language.—*N. Y. Medical Journal*, May, 1880

It certainly is an admirable exposition of the Science and Practice of Midwifery. Of course the additions made by the American editor, Dr. R. P. Harris, who never utters an idle word, and whose studious researches in some special departments of obstetrics are so well known to the profession, are of great value.—*The American Practitioner*, April, 1880

BARNES (*FANCOURT*), *M.D.*,

Physician to the General Lying-in Hospital, London.

A MANUAL OF MIDWIFERY FOR MIDWIVES AND MEDICAL STUDENTS.

With 50 illustrations. In one neat royal 12mo. volume of 200 pages; cloth, $1 25. (*Now Ready.*)

PARVIN (*THEOPHILUS*), *M.D.*,

Prof. of Obstetrics and of the Med. and Surg. Diseases of Women in the Med. Coll. of Indiana.

A TREATISE ON MIDWIFERY.

In one very handsome octavo volume of about 550 pages, with numerous illustrations. (*Preparing.*)

HODGE (*HUGH L.*), *M.D.*,

Emeritus Professor of Midwifery, &c., in the University of Pennsylvania, &c.

THE PRINCIPLES AND PRACTICE OF OBSTETRICS.

Illustrated with large lithographic plates containing one hundred and fifty-nine figures from original photographs, and with numerous wood-cuts. In one large and beautifully printed quarto volume of 550 double-columned pages, strongly bound in cloth, $14.

The work of Dr. Hodge is something more than a simple presentation of his particular views in the department of Obstetrics; it is something more than an ordinary treatise on midwifery; it is, in fact, a cyclopædia of midwifery. He has aimed to embody in a single volume the whole science and art of Obstetrics. An elaborate text is combined with accurate and varied pictorial illustrations, so that no fact or principle is left unstated or unexplained. —*Am. Med. Times*, Sept. 3, 1864

*** Specimens of the plates and letter-press will be forwarded to any address, free by mail, on receipt of six cents in postage stamps.

CHADWICK (*JAMES R.*), *A.M., M.D.*

A MANUAL OF THE DISEASES PECULIAR TO WOMEN.

In one neat volume, royal 12mo., with illustrations. (*Preparing.*)

HAMILTON (FRANK H.) M.D., LL.D.,

Surgeon to the Bellevue Hospital, New York.

A PRACTICAL TREATISE ON FRACTURES AND DISLOCATIONS

Sixth Edition, thoroughly revised, and much improved. In one very handsome octavo volume of over 900 pages, with 352 illustrations. Cloth, $5 50; leather, $6 50; half Russia, raised bands, $7 00. (*Just Ready.*)

So many kind expressions of welcome have been showered upon each successive edition of this valuable treatise, that scarcely anything remains for us to do but to extend the customary cordial greeting. It is the only complete work on the subject of Fractures in the English language We congratulate the accomplished author on the deserved success of his work, and hope that he may live to have many succeeding editions pass under his skilled supervision.—*Phila. Coll. and Clin. Record.* Nov. 15, 1880.

Universal verdict has pronounced it, humanly speaking, a perfect treatise upon this subject. As it is the only complete and illustrated work in any language treating of fractures and dislocations, it is safe to affirm that every wide-awake surgeon and general practitioner will regard it as indispensable to the safe and pleasant conduct of their professional work.—*Detroit Lancet*, Nov. 18, 1880.

Dr Hamilton has devoted great labor to the study of these subjects. His large experience, extended research, and patient investigation have made him one of the highest authorities among living writers in this branch of surgery This work is systematic and practical in its arrangement, and presents its subject matter clearly and forcibly to the reader or student.—*Maryland Medical Journal*, Nov. 15, 1880.

The only complete work on its subject in the English tongue, and, indeed, may now be said to be the only work of its kind in any tongue. It would require an exceedingly critical examination to detect in it any particulars in which it might be improved. The work is a monument to American surgery, and will long serve to keep green the memory of its venerable author.—*Michigan Med News*, Nov. 10, 1881.

ASHHURST (JOHN, Jr.), M.D.,

Prof. of Clinical Surgery, Univ. of Pa., Surgeon to the Episcopal Hospital, Philadelphia.

THE PRINCIPLES AND PRACTICE OF SURGERY.

Second Edition, enlarged and revised. In one very large and handsome octavo volume of over 1000 pages, with 542 illustrations. Cloth, $6; leather, $7; half Russia, $7 50. (*Just Issued.*)

Conscientiousness and thoroughness are two very marked traits of character in the author of this book. Out of these traits largely has grown the success of his mental fruit in the past, and the present offer seems in no wise an exception to what has gone before. The general arrangement of the volume is the same as in the first edition, but every part has been carefully revised, and much new matter added.—*Phila. Med. Times*, Feb. 1, 1879.

The favorable reception of the first edition is a guarantee of the popularity of this edition, which is fresh from the editor's hands with many enlargements and improvements. The author of this work is deservedly popular as an editor and writer, and his contributions to the literature of surgery have gained for him wide reputation. The volume now offered the profession will add new laurels to those already won by previous contributions. We can only add that the work is well arranged, filled with practical matter, and contains in brief and clear language all that is necessary to be learned by the student of surgery whilst in attendance upon lectures, or the general practitioner in his daily routine practice.—*Md. Med. Journal*, Jan. 1879.

The fact that this work has reached a second edition so very soon after the publication of the first one, speaks more highly of its merits than anything we might say in the way of commendation. It seems to have immediately gained the favor of students and physicians.—*Cincin. Med. News*, Jan. '79.

We have previously spoken of Dr. Ashhurst's work in terms of praise. We wish to reiterate those terms here, and to add that no more satisfactory representation of modern surgery has yet fallen from the press. In point of judicial fairness, of power of condensation, of accuracy and conciseness of expression and thoroughly good English, Prof. Ashhurst has no superior among the surgical writers in America.—*Am. Practitioner*, Jan. 1879.

STIMSON (LEWIS A.), A.M., M.D.,

Surgeon to the Presbyterian Hospital.

A MANUAL OF OPERATIVE SURGERY.

In one very handsome royal 12mo. volume of about 500 pages, with 332 illustrations; cloth, $2 50.

The work before us is a well printed, profusely illustrated manual of over four hundred and seventy pages. The novice, by a perusal of the work, will gain a good idea of the general domain of operative surgery, while the practical surgeon has presented to him within a very concise and intelligible form the latest and most approved selections of operative procedure. The precision and conciseness with which the different operations are described enable the author to compress an immense amount of practical information in a very small compass.—*N. Y. Medical Record*, Aug. 3, 1878.

This volume is devoted entirely to operative surgery, and is intended to familiarize the student with the details of operations and the different modes of performing them. The work is handsomely illustrated, and the descriptions are clear and well drawn. It is a clever and useful volume; every student should possess one. The preparation of this work does away with the necessity of poudering over larger works on surgery for descriptions of operations, as it presents in a nut-shell just what is wanted by the surgeon without an elaborate search to find it.—*Md. Med Journal*, Aug. 1878.

The author's conciseness and the repleteness of the work with valuable illustrations entitle it to be classed with the text-books for students of operative surgery, and as one of reference to the practitioner. —*Cincinnati Lancet and Clinic*, July 27, 1878.

SKEY'S OPERATIVE SURGERY. In 1 vol. 8vo. cl., of 650 pages; with about 100 wood-cuts. $3 25.

COOPER'S LECTURES ON THE PRINCIPLES AND PRACTICE OF SURGERY. In 1 vol. 8vo. cl'h, 750 p. $2.

GIBSON'S INSTITUTES AND PRACTICE OF SURGERY. Eighth edit'n, improved and altered. With thirty-four plates. In two handsome octavo volumes, about 1000 pp., leather, raised bands. $6 50.

THE PRINCIPLES AND PRACTICE OF SURGERY. By WILLIAM PIRRIE, F.R.S.E., Professor of Surgery in the University of Aberdeen. Edited by JOHN NEILL, M.D., Professor of Surgery in the Penna. Medical College, Surg'n to the Pennsylvania Hospital, &c. In one very handsome octavo vol. of 780 pages, with 316 illustrations, cloth, $3 75.

MILLER'S PRINCIPLES OF SURGERY Fourth American, from the Third Edinburgh Edition. In one large 8vo. vol. of 700 pages, with 340 illustrations, cloth, $3 75.

MILLER'S PRACTICE OF SURGERY. Fourth American, from the last Edinburgh Edition Revised by the American editor. In one large 8vo. vol. of nearly 700 pages, with 364 illustrations: cloth, $3 75.

GROSS (SAMUEL D.), M.D.,

Professor of Surgery in the Jefferson Medical College of Philadelphia.

A SYSTEM OF SURGERY: Pathological, Diagnostic, Therapeutic and Operative.

Illustrated by upwards of Fourteen Hundred Engravings. Fifth edition, carefully revised and improved. In two large and beautifully printed imperial octavo volumes of about 2300 pp., strongly bound in leather, with raised bands, $15; half Russia, raised bands, $16.

We have seldom read a work with the practical value of which we have been more impressed. Every chapter is so concisely put together, that the busy practitioner, when in difficulty, can at once find the information he requires. His work is cosmopolitan, the surgery of the world being fully represented in it. The work, in fact, is so historically unprejudiced, and so eminently practical, that it is almost a false compliment to say that we believe it to be destined to occupy a foremost place as a work of reference, while a system of surgery like the present system of surgery is the practice of surgeons. The printing and binding of the work is unexceptionable; indeed, it contrasts, in the latter respect, remarkably with English medical and surgical cloth-bound publications, which are generally so wretchedly stitched as to require re-binding before they are any time in use.—*Dub. Journ. of Med. Sci.*, March, 1874.

Dr. Gross's Surgery, a great work, has become still greater, both in size and merit, in its most recent form. The difference in actual number of pages is not more than 130, but, the size of the page having been increased to what we believe is technically termed "elephant," there has been room for considerable additions, which, together with the alterations, are improvements.—*Lond. Lancet*, Nov. 16, 1872.

It combines, as perfectly as possible, the qualities of a text-book and work of reference. We think this last edition of Gross's "Surgery," will confirm his title of "*Primus inter Pares.*" It is learned, scholar-like, methodical, precise, and exhaustive. We scarcely think any living man could write so complete and faultless a treatise, or comprehend more solid, instructive matter in the given number of pages. The labor must have been immense, and the work gives evidence of great powers of mind, and the highest order of intellectual discipline and methodical disposition and arrangement of acquired knowledge and personal experience.—*N.Y. Med. Journ.*, Feb 1873.

As a whole, we regard the work as the representative "System of Surgery" in the English language.—*St. Louis Medical and Surg. Journ.*, Oct. 1872.

The two magnificent volumes before us afford a very complete view of the surgical knowledge of the day. Some years ago we had the pleasure of presenting the first edition of Gross's Surgery to the profession as a work of unrivalled excellence; and now we have the result of years of experience, labor, and study, all condensed upon the great work before us. And to students or practitioners desirous of enriching their library with a treasure of reference, we can simply commend the purchase of these two volumes of immense research.—*Cincinnati Lancet and Observer*, Sept. 1872.

A complete system of surgery—not a mere text-book of operations, but a scientific account of surgical theory and practice in all its departments.—*Brit. and For. Med. Chir. Rev.*, Jan. 1873.

BY THE SAME AUTHOR.

A PRACTICAL TREATISE ON THE DISEASES, INJURIES and Malformations of the Urinary Bladder, the Prostate Gland and the Urethra.

Third Edition, thoroughly Revised and Condensed, by SAMUEL W. GROSS, M.D., Surgeon to the Philadelphia Hospital. In one handsome octavo volume of 574 pages, with 170 illustrations: cloth, $4 50.

For reference and general information, the physician or surgeon can find no work that meets their necessities more thoroughly than this, a revised edition of an excellent treatise, and no medical library should be without it. Replete with handsome illustrations and good ideas, it has the unusual advantage of being easily comprehended, by the reasonable and practical manner in which the various subjects are systematized and arranged. We heartily recommend it to the profession as a valuable addition to the important literature of diseases of the urinary organs.—*Atlanta Med. Journ.*, Oct. 1876.

It is with pleasure we now again take up this old work in a decidedly new dress. Indeed, it must be regarded as a new book in very many of its parts. The chapters on "Diseases of the Bladder," "Prostate Body," and "Lithotomy," are splendid specimens of descriptive writing; while the chapter on "Stricture" is one of the most concise and clear that we have ever read.—*New York Med. Journ.*, Nov. 1876.

BY THE SAME AUTHOR.

A PRACTICAL TREATISE ON FOREIGN BODIES IN THE AIR-PASSAGES.

In 1 vol. 8vo., with illustrations, pp. 468, cloth, $2 75.

COLEMAN (ALFRED), L.R.C.P., F.R.C.S., L.D.S., etc.

Senior Dental Surgeon and Lecturer on Dental Surgery to St. Bartholomew's Hospital and the Dental College of London.

A MANUAL OF DENTAL SURGERY AND PATHOLOGY.

Thoroughly revised and adapted to the use of American students, by Thomas C. Stellwagen, M.A., D.D.S., Professor of Physiology at the Philadelphia Dental College. In one handsome volume with about 400 illustrations. (*In Press.*)

DRUITT (ROBERT), M.R.C.S., &c.

THE PRINCIPLES AND PRACTICE OF MODERN SURGERY.

A new and revised American, from the Eighth enlarged and improved London edition. Illustrated with four hundred and thirty-two wood engravings. In one very handsome octavo volume, of nearly 700 large and closely printed pages, cloth, $4 00; leather, $5 00.

In Mr. Druitt's book, though containing only some seven hundred pages, both the principles and the practice of surgery are treated, and so clearly and perspicuously, as to elucidate every important topic. We have examined the book most thoroughly, and can say that this success is well merited. His book, moreover, possesses the inestimable advantages of having the subjects perfectly well arranged and classified and of being written in a style at once clear and succinct.—*Am. Journal of Med. Sciences.*

ASHTON ON THE DISEASES, INJURIES, AND MALFORMATIONS OF THE RECTUM AND ANUS: with remarks on Habitual Constipation. Second American, from the Fourth and enlarged London Edition. With illustrations. In one 8vo. vol. of 287 pages, cloth, $3 25.

SARGENT ON BANDAGING AND OTHER OPERATIONS OF MINOR SURGERY. New edition, with an additional chapter on Military Surgery. One 12mo. vol. of 383 pages with 184 wood-cuts. Cloth, $1 75.

HOLMES (TIMOTHY), M.A.,

Surgeon and Lecturer on Surgery at St. George's Hospital, London.

A SYSTEM OF SURGERY; THEORETICAL AND PRACTICAL.

IN TREATISES BY VARIOUS AUTHORS. AMERICAN EDITION, THOROUGHLY REVISED AND REWRITTEN by JOHN H PACKARD, M.D., Surgeon to the Episcopal and St. Joseph's Hospitals, Philadelphia, assisted by a large corps of the most eminent American surgeons. In three large and very handsome imperial octavo volumes of about 1000 pages each, with over 1000 illustrations on wood and thirteen lithographic plates, beautifully colored. (*Sold only by subscription.*) Price per volume, in cloth, $6 00; in leather, $7 00; in half Russia, $7 50. Per set, in cloth, $18 00; in leather, $21 00; in half Russia, $22 50.

VOLUME I. (*now ready*) contains GENERAL PATHOLOGY, MORBID PROCESSES, INJURIES IN GENERAL, COMPLICATIONS OF INJURIES AND INJURIES OF REGIONS.

VOLUME II. (*nearly ready*) contains DISEASES OF ORGANS OF SPECIAL SENSE, CIRCULATORY SYSTEM, DIGESTIVE TRACT AND GENITO-URINARY ORGANS.

VOLUME III. (*shortly*) contains DISEASES OF THE RESPIRATORY ORGANS, JOINTS, BONES, AND MUSCLES, OPERATIVE AND MINOR SURGERY, GUNSHOT WOUNDS, HOSPITALS AND MISCELLANEOUS SUBJECTS.

This great work, issued some years since in England, has won such universal confidence wherever the language is spoken, that its republication here, in a form more thoroughly adapted to the wants of the American practitioner, has seemed to be a duty owing to the profession.

To accomplish this, the aid has been invited of thirty-three of the most distinguished gentlemen, in every part of the country, and for more than a year they have been assiduously engaged upon the task. Though the original work presents the combined labor of the most eminent members of all the most prominent schools of England, yet the lapse of time since the appearance of the last edition, the progress of science, and the peculiarities of American practice, have rendered necessary a most careful, thorough, and searching revision. Each article has been placed in the hands of a gentleman specially competent to treat its subject, and no labor has been spared to bring each one up to the foremost level of the times, and to adapt it thoroughly to the practice of the country. In certain cases, this has rendered necessary the substitution of an entirely new essay for the original, as in the case of the articles on Skin Diseases, and on Diseases of the Absorbent System, where the views of the authors have been superseded by the advance of medical science, and new articles have therefore been prepared by Drs. ARTHUR VAN HARLINGEN and S. C. BUSEY, respectively. So also in the case of Anæsthetics, in the use of which American practice differs from that of England, the original has been supplemented with a new essay by J. C. REEVE, M.D., treating not only of the employment of ether and chloroform, but of the other anæsthetic agents of more recent discovery. The same careful and conscientious revision has been pursued throughout, leading to an increase of nearly one-fourth in matter, while the series of illustrations has been more than doubled, and the whole is presented as a complete exponent of British and American Surgery, adapted to the daily needs of the working practitioner

In order to bring it within the reach of every member of the profession, the five volumes of the original have been compressed into three, by employing a double-columned imperial octavo page, and in this improved form it is offered at less than one-half the price of the original. It is beautifully printed on handsome laid paper and forms a worthy companion to REYNOLDS'S "SYSTEM OF MEDICINE," which has met with so much favor in every section of the country.

The work will be sold by subscription only, and in due time every member of the profession will be called upon and offered an opportunity to subscribe.

The few notices appended will serve to indicate the hearty approval accorded to the unrevised edition on its appearance some years since:—

There is so much that is instructive, even to the experienced practitioner, in their practical and discriminating manner of dealing with mooted questions, none of which seem to be neglected; their abundant illustrations, drawn at once from an unlimited field of hospital experience, and their candid and sensible mode of handling the whole subject, that these particular portions of the work possess a value which places them far above any publication on the same topics yet issued in the language.—*Am. Journ. Med. Sciences.*

The enumeration of the treatises, and the names of the surgical writers from whose pens they proceed, suffice to show that this is no ordinary book, and that in the thousand pages of this goodly volume lies a store of information such as no other surgical work in the language can pretend to offer. Those who are acquainted with the special researches and publications of the respective authors will not fail to notice that by a judicious exercise of editorial discretion, each subject has been entrusted, as far as possible, to a surgeon of the hospitals who is known to have given especial attention to it, and to possess facilities for summing up with authority the accepted opinions of the day, and adding original matter to the stock.—*London Lancet.*

The work must be considered a very complete account of everything connected with the science and practice of surgery. In conclusion we can cordially recommend this work as a valuable addition to the library of the surgeon.—*Edinburgh Medical Journal.*

It is a cyclopædia of surgery of the most complete and extensive character; and we may justly state that its design and execution do great honor to those concerned, and that the large number and high standing of the authors selected for the various monographs render this "System" what it no doubt was intended to be, representative of the actual state of surgical science and art in the country.—*London Lancet.*

In conclusion, we will add that we can most conscientiously recommend the book to every medical practitioner. In recommending the "*System of Surgery*" to our friends who have to deal in surgical cases, we by no means wish to confine our recommendation to them alone. Every practitioner of medicine may cull something worthy of note from a perusal of this volume.—*The British Med. Journal.*

The four volumes remain a monument to the surgical genius of our day. The great majority of metropolitan surgeons of eminence and proved ability are represented in them; and for many years to come, whoever wishes to know the most authoritative words of English Surgical science on most subjects in the domain of surgery must turn to these pages to read what there is set forth. But taken as a whole it is the most important surgical work which has ever issued from the English press.—*London Lancet.*

BRYANT (*THOMAS*), *F.R.C.S.*,

Surgeon to Guy's Hospital.

THE PRACTICE OF SURGERY.

Third American, from the Second and Revised English Edition. Thoroughly revised and much improved, by John B. Roberts, M.D. In one large and very handsome imperial octavo volume of over 1000 pages, with 672 illustrations. Cloth, $6 50; leather, $7 50; very handsome half Russia, raised bands, $8 00. (*Just Ready.*)

Mr. Bryant's work has long been a favorite one with surgeons. As its name indicates, it is of a thoroughly practical character. It is distinctly individual in that it gives the results of the author's large and varied experience as an operator and clinical teacher, and is on that account prized deservedly high as an original work. The style is necessarily condensed, the descriptions of surgical diseases brief and to the point. The illustrations are well chosen, and the typical cases of the author's experience are full of interest, and are of more than ordinary value to the working surgeon.—*N. Y. Medical Record*, March 5, 1881.

It is a work especially adapted to the wants of students and practitioners. While not prolix, it affords instruction in sufficient detail for a full understanding of surgical principles and the treatment of surgical diseases. It embraces in its scope all the diseases that are recognized as belonging to surgery, and all traumatic injuries. In discussing these it has seemed to be the aim of the author rather to present the student with practical information, and that alone, than to burden his memory with the views of different writers, however distinguished they might have been. In this edition the whole work has been carefully revised, much of it has been rewritten, important additions have been made to almost every chapter.—*Cincinnati Med. News*, Jan. 1881.

The English edition, from which this is printed, has been carefully revised and rewritten; almost every chapter has received additions, and nearly one hundred new cuts introduced. The labors of the American editor, Dr. John B Roberts, have very much increased the value of the book. He has introduced many new illustrations and much new material not found in the English edition. He has written too with great conciseness, which is a rare virtue in an American editor of an English work. If one could procure or wished only one surgery, this volume would certainly be selected. If he desired two, Erichsen's Surgery would be added, and if he wished a third, Gross's Surgery would justly be the work selected. As the great work of Gross is amply sufficient for the wants of any surgeon, the priority given to Erichsen, and above all others, to this work of Bryant, is no labored eulogy of the last volume, but a simple and just statement of its demonstrable and pre-eminent merits.—*Am. Med. Bi-Weekly*, Feb. 26, 1881.

ERICHSEN (*JOHN E.*),

Professor of Surgery in University College, London, etc.

THE SCIENCE AND ART OF SURGERY;

being a Treatise on Surgical Injuries, Diseases and Operations. Carefully revised by the Author from the Seventh and enlarged English Edition. Illustrated by eight hundred and sixty-two engravings on wood. In two large and beautiful octavo volumes of nearly 2000 pages: cloth, $8 50; leather, $10 50; half Russia, $11 50. (*Now Ready.*)

Of the many treatises on Surgery which it has been our task to study, or our pleasure to read, there is none which in all points has satisfied us so well as the classic treatise of Erichsen. His polished, clear style, his freedom from prejudice and hobbies, his unsurpassed grasp of his subject, and vast clinical experience, qualify him admirably to write a model text-book. When we wish, at the least cost of time, to learn the most of a topic in surgery, we turn, by preference, to his work. It is a pleasure, therefore, to see that the appreciation of it is general, and has led to the appearance of another edition.—*Med. and Surg. Reporter*, Feb. 2, 1878.

Notwithstanding the increase in size, we observe that much old matter has been omitted. The entire work has been thoroughly written up, and not merely amended by a few extra chapters. A great improvement has been made in the illustrations. One hundred and fifty new ones have been added, and many of the old ones have been redrawn. The author highly appreciates the favor with which his work has been received by American surgeons, and has endeavored to render his latest edition more than ever worthy of their approval. That he has succeeded admirably, must, we think, be the general opinion. We heartily recommend the book to both student and practitioner.—*N. Y. Med. Journal*, Feb. 1878.

The seventh edition is before the world as the last word of surgical science. There may be monographs which excel it upon certain points, but as a conspectus upon surgical principles and practice it is unrivalled. It will well reward practitioners to read it, for it has been a peculiar province of Mr. Erichsen to demonstrate the absolute interdependence of medical and surgical science We need scarcely add, in conclusion, that we heartily commend the work to students that they may be grounded in a sound faith, and to practitioners as an invaluable guide at the bedside.—*Am. Practitioner*, April, 1878.

For the past twenty years Erichsen's Surgery has maintained its place as the leading text-book, not only in this country, but in Great Britain. That it is able to hold its ground, is abundantly proven by the thoroughness with which the present edition has been revised, and by the large amount of valuable material that has been added. Aside from this, one hundred and fifty new illustrations have been inserted, including quite a number of microscopical appearances of pathological processes. So marked is this change for the better, that the work almost appears as an entirely new one.—*Med. Record*, Feb. 23, 1878.

HOLMES (*TIMOTHY*), *M.D.*,

Surgeon to St. George's Hospital, London.

SURGERY, ITS PRINCIPLES AND PRACTICE.

In one handsome octavo volume of nearly 1000 pages, with 411 illustrations. Cloth, $6; leather, $7; half Russia, $7 50.

This is a work which has been looked for on both sides of the Atlantic with much interest. Mr. Holmes is a surgeon of large and varied experience, and one of the best known, and perhaps the most brilliant writer upon surgical subjects in England. It is a book for students—and an admirable one—and for the busy general practitioner. It will give a student all the knowledge needed to pass a rigid examination. The book fairly justifies the high expectations that were formed of it. Its style is clear and forcible, even brilliant at times, and the conciseness needed to bring it within its proper limits has not impaired its force and distinctness.—*N. Y. Med. Record*, April 14, 1876.

It will be found a most excellent epitome of surgery by the general practitioner who has not the time to give attention to more minute and extended works, and to the medical student. In fact, we know of no one we can more cordially recommend. The author has succeeded well in giving a plain and practical account of each surgical injury and disease, and of the treatment which is most commonly advisable. It will no doubt become a popular work in the profession, and especially as a text-book.—*Cincinnati Med. News*, April, 1876.

WELLS (*J. SOELBERG*),

Professor of Ophthalmology in King's College Hospital, &c.

A TREATISE ON DISEASES OF THE EYE. Third American,

from the Third London Edition. Thoroughly revised, with copious additions, by Chas. S. Bull, M D., Surgeon and Pathologist to the New York Eye and Ear Infirmary. Illustrated with about 250 engravings on wood, and six colored plates Together with selections from the Test-types of Jaeger and Snellen. In one large and very handsome octavo volume of 900 pages. Cloth, $5; leather, $6; half Russia, raised bands, $6 50. (*Just Ready.*)

The long-continued illness of the author, with its fatal termination, has kept this work for some time out of print, and has deprived it of the advantage of the revision which he sought to give it during the last years of his life. This edition has therefore been placed under the editorial supervision of Dr. Bull, who has labored earnestly to introduce in it all the advances which observation and experience have acquired for the theory and practice of ophthalmology since the appearance of the last revision. To accomplish this, considerable additions have been required, and the work is now presented in the confidence that it will fully deserve a continuance of the very marked favor with which it has hitherto been greeted as a complete, but concise, exposition of the principles and facts of its important department of medical science.

The additions made in the previous American editions by Dr. Hays have been retained, including the very full series of illustrations and the test-types of Jaeger and Snellen.

This new edition of Dr. Wells's great work on the eye will be welcomed by the profession at large as well as by the oculist It contains much new matter relating to treatment and pathology, and is brought thoroughly up with the present status of ophthalmology. Its chapter on refraction and accommodation—a subject much discussed of late years, and of great importance—is exceedingly complete.—*Louisville Med. News*, Nov. 13, 1880.

The merits of Wells's treatise on diseases of the eye have been so universally acknowledged, and are so familiar to all who profess to have given any attention to ophthalmic surgery, that any discussion of them at this late day will be a work of supererogation. Very little that is practically useful in recent ophthalmic literature has escaped the editor, and the third American edition is well up to the times. As a text-book on ophthalmic surgery for the English-speaking practitioner, it is without a rival.—*Am. Journ. of Med. Sci.*, Jan. 1881.

The work has justly held a high place in English ophthalmic literature, and at the time of its first appearance was the best treatise of its kind in the language. In the second edition, the author showed industrious research in adding new material from every quarter, and his spirit was eminently candid. A work thus built up by honest effort should not be suffered to die, and we are pleased to receive this third edition from the hands of Dr. Bull. His labor has been arduous, as the very great number of additions bracketed with his initial testify. Under the editorship which the third edition has enjoyed, the work is sure to sustain its good reputation, and to maintain its usefulness.—*N. Y. Med. Journ.*, Jan. 1881.

There is really no work which approaches it in adaptation to the wants of the general practitioner, while the most advanced specialist cannot rise from a perusal of its ample pages without having added to his knowledge. The American editor, Dr. Bull, won his spurs in ophthalmology some time back. His additions to the work of the lamented Wells are many, judicious, and timely, and in just so much have added to its value.—*Am. Practitioner*, Jan. 1881.

NETTLESHIP (*EDWARD*), *F.R.C.S.*,

Ophthalmic Surg. and Lect. on Ophth. Surg. at St. Thomas' Hospital, London.

MANUAL OF OPHTHALMIC MEDICINE. In one royal 12mo.

volume of over 350 pages, with 89 illustrations. Cloth, $2. (*Just Ready.*)

The author is to be congratulated upon the very successful manner in which he has accomplished his task; he has succeeded in being concise without sacrificing clearness, and, including the whole ground covered by more voluminous text-books, has given an excellent *résumé* of all the practical information they contain. We do not hesitate to pronounce Mr. Nettleship's book the best manual on ophthalmic surgery for the use of students and "busy practitioners" with which we are acquainted.—*Am. Jour. Med. Sciences*, April, 1880.

CARTER (*R. BRUDENELL*), *F.R.C.S.*,

Ophthalmic Surgeon to St. George's Hospital, etc.

A PRACTICAL TREATISE ON DISEASES OF THE EYE. Edited,

with test-types and Additions, by JOHN GREEN, M.D. (of St. Louis, Mo.). In one handsome octavo volume of about 500 pages, and 124 illustrations. Cloth, $3 75.

It is with great pleasure that we can endorse the work as a most valuable contribution to practical ophthalmology. Mr. Carter never deviates from the end he has in view, and presents the subject in a clear and concise manner, easy of comprehension, and hence the more valuable. We would especially commend, however, as worthy of high praise, the manner in which the therapeutics of disease of the eye is elaborated, for here the author is particularly clear and practical, where other writers are unfortunately too often deficient. The final chapter is devoted to a discussion of the uses and selection of spectacles, and is admirably compact, plain, and useful, especially the paragraphs on the treatment of presbyopia and myopia. In conclusion, our thanks are due the author for many useful hints in the great subject of ophthalmic surgery and therapeutics, a field where of late years we glean but a few grains of sound wheat from a mass of chaff.—*New York Medical Record*, Oct. 23, 1875.

BROWNE (*EDGAR A.*),

Surgeon to the Liverpool Eye and Ear Infirmary, and to the Dispensary for Skin Diseases.

HOW TO USE THE OPHTHALMOSCOPE. Being Elementary Instructions in Ophthalmoscopy, arranged for the Use of Students. With thirty-five illustrations.

In one small volume royal 12mo. of 120 pages: cloth, $1.

LAURENCE'S HANDY-BOOK OF OPHTHALMIC SURGERY, for the use of Practitioners. Second edition, revised and enlarged With numerous illustrations. In one very handsome octavo volume, cloth, $2 75.

LAWSON'S INJURIES TO THE EYE, ORBIT AND EYELIDS: their Immediate and Remote Effects. With about one hundred illustrations. In one very handsome octavo volume, cloth, $3 50.

BURNETT (CHARLES H.), M.A., M.D.,

Aural Surg. to the Presb. Hosp., Surgeon-in-charge of the Infir. for Dis. of the Ear, Phila.

THE EAR, ITS ANATOMY, PHYSIOLOGY AND DISEASES.

A Practical Treatise for the Use of Medical Students and Practitioners. In one handsome octavo volume of 615 pages, with eighty-seven illustrations: cloth, $4 50; leather, $5 50; half Russia, $6 00. (*Lately Issued.*)

Foremost among the numerous recent contributions to aural literature will be ranked this work of Dr. Burnett. It is impossible to do justice to this volume of over 600 pages in a necessarily brief notice. It must suffice to add that the book is profusely and accurately illustrated, the references are conscientiously acknowledged, while the result has been to produce a treatise which will henceforth rank with the classic writings of Wilde and Von Tröltsch.—*The Lond. Practitioner*, May, 1879.

On account of the great advances which have been made of late years in otology, and of the increased interest manifested in it, the medical profession will welcome this new work, which presents clearly and concisely its present aspect, whilst clearly indicating the direction in which further researches can be most profitably carried on. Dr. Burnett from his own matured experience, and availing himself of the observations and discoveries of others, has produced a work which, as a text-book, stands *facile princeps* in our language. We had marked several passages as well worthy of quotation and the attention of the general practitioner, but their number and the space at our command forbid. Perhaps it is better, as the book ought to be in the hands of every medical student, and its study will well repay the busy practitioner in the pleasure he will derive from the agreeable style in which many otherwise dry and mostly unknown subjects are treated. To the specialist the work is of the highest value, and his sense of gratitude to Dr. Burnett will, we hope, be proportionate to the amount of benefit he can obtain from the careful study of the book, and a constant reference to its trustworthy pages.—*Edinburgh Med. Jour.*, Aug. 1878.

TAYLOR (ALFRED S.), M.D.,

Lecturer on Med. Jurisp. and Chemistry in Guy's Hospital.

A MANUAL OF MEDICAL JURISPRUDENCE. Eighth American edition.

Thoroughly revised and rewritten. Edited by JOHN J. REESE, M.D., Prof. of Med. Jurisp. and Toxicology in the Univ. of Penn. In one large octavo volume of 933 pages, with 70 illustrations. Cloth, $5; leather, $6; half Russia, raised bands, $6 50. (*Just Ready.*)

The American editions of this standard manual have for a long time laid claim to the attention of the profession in this country; and that the profession has recognized this claim with favor is proven by the call for frequent new editions of the work. This one, the eighth, comes before us as embodying the latest thoughts and emendations of Dr. Taylor, upon the subject to which he devoted his life, with an assiduity and success which made him *facile princeps* among English writers on medical jurisprudence. Both the author and the book have made a mark too deep to be affected by criticism, whether it be censure or praise. In this case, however, we should only have to seek for laudatory terms.—*Am. Journ. of Med. Sci.*, Jan. 1881.

It is not very often that a medical book reaches its tenth edition, or that the last earthly labor is performed by the author in retouching the work that first came from his hand thirty-five years before. All this, however, has happened in the case of Dr. Taylor and his classical treatise. The pen dropped from the grasp only when the shadows of old age were rapidly deepening into the darkness of death. Under the circumstances, all the journalist has to do is to announce, not criticize the completed task. The value of the gem is too well known to require more than the telling that the master-hand has rebrightened its facets and polished its angles before leaving it as his legacy to his brethren in the profession.—*Phila Med. Times*, Dec. 4, 1880.

It will suffice to remark that this new edition shows the signs of judicious revision. A great number of illustrative medico-legal cases which have occurred since the last edition was published are cited in their proper connection, and add much to the interest and value of the work; they comprise the bulk of the additions to the text. As an indication of the freshness of the work, we notice numerous references to medico-legal experience that has transpired during the year just ended; among these is a comment by the American editor upon that midsummer madness, the Tanner fasting exploit of last August. In these features and in others there is ample evidence that this admirable book will maintain its high place as a standard authority concerning the matters of which it treats.—*Boston Med. and Surg. Journal*, Jan. 13, 1881.

BY THE SAME AUTHOR.

THE PRINCIPLES AND PRACTICE OF MEDICAL JURISPRUDENCE.

Second Edition, Revised, with numerous Illustrations. In two large octavo volumes, cloth, $10 00; leather, $12 00

This great work is now recognized in England as the fullest and most authoritative treatise on every department of its important subject. In laying it, in its improved form, before the American profession, the publishers trust that it will assume the same position in this country.

BY THE SAME AUTHOR.

POISONS IN RELATION TO MEDICAL JURISPRUDENCE AND MEDICINE.

Third American, from the Third and Revised English Edition. In one large octavo volume of 850 pages; cloth, $5 50; leather, $6 50.

The present is based upon the two previous editions; "but the complete revision rendered necessary by time has converted it into a new work." This statement from the preface contains all that it is desired to know in reference to the new edition. The works of this author are already in the library of every physician who is liable to be called upon for medico-legal testimony (and what one is not?), so that all that is required to be known about the present book is that the author has kept it abreast with the times. What makes it now, as always, especially valuable to the practitioner is its conciseness and practical character, only those poisonous substances being described which give rise to legal investigations.—*The Clinic*, Nov. 6, 1875.

Dr. Taylor has brought to bear on the compilation of this volume, stores of learning, experience, and practical acquaintance with his subject, probably far beyond what any other living authority on toxicology could have amassed or utilized. He has fully sustained his reputation by the consummate skill and legal acumen he has displayed in the arrangement of the subject-matter, and the result is a work on Poisons which will be indispensable to every student or practitioner in law and medicine.—*The Dublin Journ. of Med Sci.*, Oct. 1875.

ROBERTS (WILLIAM), M.D.,
Lecturer on Medicine in the Manchester School of Medicine, etc.

A PRACTICAL TREATISE ON URINARY AND RENAL DISEASES, including Urinary Deposits. Illustrated by numerous cases and engravings. Third American, from the Third Revised and Enlarged London Edition. In one large and handsome octavo volume of over 600 pages. Cloth, $4. (*Just Ready.*)

THOMPSON (SIR HENRY),
Surgeon and Professor of Clinical Surgery to University College Hospital.

LECTURES ON DISEASES OF THE URINARY ORGANS. With illustrations on wood. Second American from the Third English Edition. In one neat octavo volume. Cloth, $2 25.

BY THE SAME AUTHOR.

ON THE PATHOLOGY AND TREATMENT OF STRICTURE OF THE URETHRA AND URINARY FISTULÆ. With plates and wood-cuts. From the third and revised English edition. In one very handsome octavo volume, cloth, $3 50.

TUKE (DANIEL HACK), M.D.,
Joint author of The Manual of Psychological Medicine, &c.

ILLUSTRATIONS OF THE INFLUENCE OF THE MIND UPON THE BODY IN HEALTH AND DISEASE. Designed to illustrate the Action of the Imagination. In one handsome octavo volume of 416 pages, cloth, $3 25.

BLANDFORD (G. FIELDING), M.D., F.R.C.P.,
Lecturer on Psychological Medicine at the School of St. George's Hospital, &c.

INSANITY AND ITS TREATMENT: Lectures on the Treatment, Medical and Legal, of Insane Patients. With a Summary of the Laws in force in the United States on the Confinement of the Insane. By ISAAC RAY, M. D. In one very handsome octavo volume of 471 pages; cloth, $3 25.

It satisfies a want which must have been sorely felt by the busy general practitioners of this country. It takes the form of a manual of clinical description of the various forms of insanity, with a description of the mode of examining persons suspected of insanity. We call particular attention to this feature of the book, as giving it a unique value to the general practitioner. If we pass from theoretical considerations to descriptions of the varieties of insanity as actually seen in practice and the appropriate treatment for them, we find in Dr. Blandford's work a considerable advance over previous writings on the subject. His pictures of the various forms of mental disease are so clear and good that no reader can fail to be struck with their superiority to those given in ordinary manuals in the English language or (so far as our own reading extends) in any other.—*London Practitioner*, Feb. 1871.

LEA (HENRY C.).

SUPERSTITION AND FORCE: ESSAYS ON THE WAGER OF LAW, THE WAGER OF BATTLE, THE ORDEAL AND TORTURE. Third Revised and Enlarged Edition. In one handsome royal 12mo. volume of 552 pages. Cloth, $2 50. (*Just Ready.*)

This valuable work is in reality a history of civilization as interpreted by the progress of jurisprudence. . . . In "Superstition and Force" we have a philosophic survey of the long period intervening between primitive barbarity and civilized enlightenment. There is not a chapter in the work that should not be most carefully studied, and however well versed the reader may be in the science of jurisprudence, he will find much in Mr. Lea's volume of which he was previously ignorant. The book is a valuable addition to the literature of social science.—*Westminster Review*, Jan. 1880.

The appearance of a new edition of Mr. Henry C. Lea's "Superstition and Force" is a sign that our highest scholarship is not without honor in its native country. Mr. Lea has met every fresh demand for his work with a careful revision of it, and the present edition is not only fuller and, if possible, more accurate than either of the preceding, but, from the thorough elaboration, is more like a harmonious concert and less like a batch of studies.—*The Nation*, Aug. 1, 1878.

Many will be tempted to say that this, like the "Decline and Fall," is one of the uncriticizable books. Its facts are innumerable, its deductions simple and inevitable, and its *chevaux-de-frise* of references bristling and dense enough to make the keenest, stoutest, and best equipped assailant think twice before advancing. Nor is there anything controversial in it to provoke assault. The author is no polemic. Though he obviously feels and thinks strongly, he succeeds in attaining impartiality. Whether looked on as a picture or a mirror, a work such as this has a lasting value.—*Lippincott's Magazine*, Oct. 1878.

BY THE SAME AUTHOR.

STUDIES IN CHURCH HISTORY. THE RISE OF THE TEMPORAL POWER—BENEFIT OF CLERGY—EXCOMMUNICATION. In one large royal 12mo, volume of 516 pp.; cloth, $2 75. (*Lately Published.*)

The story was never told more calmly or with greater learning or wiser thought. We doubt, indeed, if any other study of this field can be compared with this for clearness, accuracy, and power.—*Chicago Examiner*, Dec. 1870.

Mr. Lea's latest work, "Studies in Church History," fully sustains the promise of the first. It deals with three subjects—the Temporal Power, Benefit of Clergy, and Excommunication, the record of which has a peculiar importance for the English student, and is a chapter on Ancient Law likely to be regarded as final. We can hardly pass from our mention of such works as these—with which that on "Sacerdotal Celibacy" should be included—without noting the literary phenomenon that the head of one of the first American houses is also the writer of some of its most original books.—*London Athenæum*, Jan. 7, 1871.
